Alcoholic Paralysis.—The earliest account of alcoholic paralysis is that of James Jackson,¹ who designated the disease, from its most prominent symptom, arthrodynia. He attributes it to ardent spirits, and chiefly observed it among women. "This arthrodynia comes on gradually. It commences with pain in the lower limbs, and especially in the feet, and afterward extends to the hands and arms. The hands may be affected first in some instances, but in all cases in the advanced stage of the disease the pain is more severe in the feet and hands than in the upper limbs. The pain is excruciating, and varies in degree at different times. It is accompanied by a distressing feeling of numbness. After the disease has continued a short time there take place some contraction of the fingers and toes and inability to use these parts freely. At length the hands and feet become nearly useless. The flexor muscles manifest, as in other diseases, greater power than the extensors, and the whole body diminishes in size, unless it be the abdomen; but the face does not exhibit the appearance of emaciation common to many visceral diseases. The diminution is especially observable in the feet and hands. At some time the skin of these parts acquires a peculiar appearance. The same appearance is noticed in a slighter degree in the skin of other parts. This appearance consists in great smoothness and shining, with a sort of fineness of the skin. The integument looks as if tight and stretched, without rugæ or wrinkles—somewhat as when adjacent parts are swollen. The skin is not discolored. In this disease there is not any effusion under the skin, and the character which it assumes arises from some change in the organ itself."

Since Jackson's day, Huss, Lancereaux, Leudet, and others have described various forms of paralysis due to alcohol. Wilks² under the term alcoholic paraplegia described a form of alcoholic paralysis of which he had seen numerous cases, especially in women addicted to alcoholic excesses. The symptoms are severe pain in the limbs, especially the lower ones, with wasting, numbness, anæsthesia, only slight power of movement or total inability to stand. The symptoms are not unlike those of ataxia. Wilks regarded the disease as due to degeneration of the cord and thickening of the membranes. Several of the cases terminated in recovery in a comparatively short time after the abrupt and complete withdrawal of alcohol. Since that time a number of cases have been reported by various observers.³

Hun concludes that alcoholic paralysis may be regarded as a special form of disease with the following symptoms: "Neuralgic pains and paræsthesiæ of the legs, gradually extending to the upper extremities, and accompanied at first by hyperæsthesia, later by anæsthesia, and

¹ *New England Journal of Medicine and Surgery*, vol. xi., 1822, "On a Peculiar Disease resulting from the Use of Ardent Spirits."

² *Lancet*, 1872, vol. i. p. 320.

³ See, in particular, Hun, *American Journal of the Medical Sciences*, April, 1885, "Alcoholic Paralysis." This paper contains a valuable résumé of the reported cases up to that time. Consult also Dreschfeld, *Brain*, July, 1884, and January, 1886.

in severe cases by retardation of the conduction of pain. Along with these symptoms appears muscular weakness, which steadily increases to an extreme degree of paralysis, and is accompanied by rapid atrophy and great sensibility of the muscles to pressure and to passive motion. Both the sensory and motor disturbances are symmetrically distributed. The paralysis attacks especially the extensor muscles. In addition to these motor and sensory symptoms, there is also a decided degree of ataxia. The tendon reflexes are abolished, and vaso-motor symptoms, as oedema, congestion, etc., are usually present. Symptoms of mental disturbance are always present in the form of loss of memory or transient delirium."

Lesions of the cord are absent, but degenerative processes in the peripheral nerves have been discovered in a number of cases. The symptoms are those of multiple neuritis, and the essential lesions consist in degenerative changes in the peripheral nerve-fibres. The associated mental derangement, tremor, and ataxia have been ascribed to changes in the cerebral cortex.

Dreschfeld has divided the cases, according to the more prominent symptoms, into two clinical groups—alcoholic ataxia and alcoholic paralysis.

The ataxic form represents a milder type. The symptoms are lancinating and shooting pains in the lower extremities, sometimes in the upper, with areas of anæsthesia and retarded sensibility. The muscles are painful upon pressure, and atrophy may be moderate or absent altogether. Inco-ordination is marked. The tendon reflexes are absent. Shooting pains down the legs to the toes of a paroxysmal character, and followed by a sense of numbness, also occur. Eye symptoms are wanting.

The paralytic form is usually associated with atrophy, affecting chiefly the extensors of the fingers and toes. The paralysis and atrophy in some cases come on acutely, in others more slowly. When the patients come under observation they are usually unable to stand or walk, and it is therefore not easy to make out whether or not the paralytic stage has been preceded by a stage of ataxia. As the sensory phenomena in these cases are the same as in the first group, it is probable that pseudo-ataxic symptoms have preceded the slowly oncoming paralysis. Paralysis and atrophy of the extensors of the fingers and toes, with paresis of the other muscles, are associated with the sensory phenomena above described. Tendon reflexes are absent; the superficial reflexes are much diminished. Recovery takes place in a considerable proportion of the cases upon the withdrawal of alcohol. The atrophy and paralysis pass away altogether, the tendon reflexes are restored, and the disturbances of sensation disappear. In the greater number of these cases persistent delusions are present.

Lancereaux¹ describes alcoholic paralysis as symmetrical, affecting either the upper or lower extremities and gradually extending toward the trunk. The lower extremities are invariably more affected than the upper, and the extensor than the flexor muscles. There is diminished reaction to electricity, and anæsthesia is present. The brain and spinal cord are normal, but the peripheral nerves show extensive degenerative changes.

4. *Disorders of the Special Senses.*—a. The Sight.—Disorders of vision

¹ *Gazette des Hôpitaux*, No. 46, 1883.

are among the most frequent and the earliest symptoms of chronic alcoholism. Phosphenes, scintillations, sensations of dazzling, *muscæ volitantes*, and streams of light are often complained of. These phenomena may be constant or transient. Diplopia and other visual disturbances of the most irregular and annoying character also occur. Sometimes there is dyschromatopsia; the colors are confounded: red appears brown or black, and green appears gray, etc. In the more advanced stages amblyopia may occur. The acuity of vision rapidly diminishes, sometimes to the point that the patient with difficulty distinguishes the largest print. Objects appear as seen through a fog, and their outlines are distinguished only after repeated and close effort. Again, blindness almost absolute occurs for the course of some minutes—passes away rapidly, only to return again at intervals. Not infrequently the sight is better in the morning and evening than during the day. Achromatopsia, characterized by enfeeblement, and not infrequently by the momentary loss of the power to recognize colors, and particularly the secondary tints, also occurs. Cases of Daltonism occasionally seem to depend, to some extent at least, upon alcoholic disturbances of vision. Impairment of the power to distinguish colors must not, however, be confounded with the difficulty experienced by many alcoholic subjects in recognizing different colors successively presented to the eye with some degree of rapidity. Such individuals are able to distinguish colors when sufficient time is permitted them. Their difficulty depends upon tardiness of perception, such as is often experienced by neurosthenic subjects in recognizing faces in a crowd, rather than upon any failure in the power of recognizing colors. As a rule, the disorders of vision are not permanent, at least in the beginning. Later, they are of longer duration, and alcoholic amblyopia occasionally degenerates into irremediable amaurosis. Ophthalmoscopic examination reveals at first no appreciable lesion, and the disturbance of circulation, venous stasis, and peripapillary infiltration thus observed appear to be inadequate to explain the visual disturbance. Atrophy of the optic nerve occasionally occurs as a direct result of alcoholism. Nystagmus has been frequently observed. The state of the pupils is variable and without constant relation to the acuity of vision. The pupils are not infrequently uniformly dilated, contracting slowly under the influence of light. More rarely they are permanently contracted; occasionally they are unequal. These modifications are often without demonstrable relation to anatomical lesions.¹

b. The Hearing.—The disturbances of hearing encountered in chronic alcoholism are in many respects analogous to those of sight. Patients complain of curious subjective sensations, which are described as humming or whistling sounds, the ringing of bells, music, or the murmur of a crowd. At times the sense of hearing is so exquisite that the least noise causes pain. On the other hand, hearing may be greatly impaired, diminishing by degrees until it becomes in some cases, without recognizable lesion, almost or completely lost.

c. The Taste.—As a rule, the sense of taste is impaired in chronic alcoholism; occasionally it is wholly lost.

d. The Smell.—The sense of smell is in most cases to some extent, and in many cases greatly, impaired, the most powerful odors being scarcely perceived by old toppers.

¹ Vide this *System of Medicine*, Vol. IV. p. 803.

Alcoholic Epilepsy.—Alcohol, and especially that combination of alcohol with oil of wormwood and aromatics known as absinthe, is capable of producing convulsive seizures resembling epilepsy. Certain forms of alcoholic convulsions can scarcely be distinguished from ordinary epilepsy. Acute alcoholism may be an exciting cause of the convulsive seizures in an epileptic. Alcoholic epilepsy is, however, peculiar to chronic alcoholism, and particularly in individuals in whom there is an hereditary tendency to nervous disorders. Once established, alcoholic epilepsy may continue even after the alcoholic habit has been discontinued. The attack is usually followed by marked mental disturbances. These vary from profound dulness to stupor or mania; they last from some hours to several days, and present the characters of similar conditions following non-alcoholic epileptic paroxysms.

C. PSYCHICAL DERANGEMENTS.—Yet more important than the visceral and nervous lesions of chronic alcoholism are the indications which it affords of a progressive debasing influence upon the mind. The moral sense, the will, and the intellect are involved successively in a process of deterioration, which, manifesting itself only in part and by little at first, becomes after a time general and plain to all the world, and ends at length in ruin more complete and more hopeless than that of the body. Indeed, it not infrequently happens that while the general health appears to be good and the nervous system, save in transient disturbances of function, presents no evidence of the toxic action of alcohol upon its tissues, serious psychical disorders are established. The alcoholic subject develops propensities, otherwise latent, that tend to refer him to the criminal or the insane classes of society. The psychical debasement, of which these propensities are the outcome, is, like the alcohol habit itself, progressive. This fact cannot be too strongly insisted upon. Like the loss of vascular tone, the sclerosis, the steatosis which alcohol induces in the body, this mental deterioration is cumulative and destructive. It is to its psychical manifestations that alcoholism owes its chief importance, not only as a study in pathology, but also as a problem of the gravest moment in social science.

1. *The Moral Sense.*—Deterioration of the sense of moral obligation is among the earlier of the mental phenomena of alcoholism. The moral sense is perverted and enfeebled. Sentiments of honor, of dignity, of reputation, and of decency are no longer cherished or regarded. The amenities of social life and the proprieties of personal conduct are disregarded or set at naught. He who was punctilious, considerate, and thoughtful becomes negligent, selfish, and indifferent to sentiments of honor and emulation; he gives himself up to indulgences formerly considered unworthy; his reputation and that of his family are no longer matters of concern to him; respect for public opinion is replaced by cynicism. Little by little the conception of duty, of justice, of honor are lost to him, or if he regards them at all it is rather as subjects for idle and purposeless discussion than as motives to regulate his life. These changes are gradual and progressive, their evolution being largely influenced by the hereditary traits and previous moral culture of the individual. The deterioration of the sense of right, and the coincident exaltation of those passions which are normally under its control, lead to the commission of the crimes peculiar to the early period of alcoholism. Indiffer-

ence is another characteristic of this period—indifference not incompatible with a selfishness of the most intense kind. The sense of obligation to the family is forgotten, and the responsibility of providing for and caring for others is unfelt. If the drunkard's own wants, and especially his craving for drink, are gratified, the necessities of those formerly dear fail to move him. The affections are not only enfeebled, but they are also perverted; not rarely they are replaced by aversion, disdain, and hatred. The individual who has been calm, reasonable, and patient becomes excitable, perverse, and intolerable of contradiction or opposition. Prone to acts of sudden violence, he becomes gloomy, taciturn, and preoccupied. He is disturbed by fixed tormenting ideas or by vague pursuing terrors. He thus becomes self-conscious, irritable, fault-finding, and easily provoked to passion. The character, after a time, undergoes still more decided change: alternations of indifference and irritability characterize his varying moods. After a time the joys and the sorrows of life alike fail to provoke real feeling. At length the confirmed sot manifests moral traits that are simply infantile; he laughs without motive, he weeps without cause.

2. *The Will*.—At the same time the will undergoes an enfeeblement even more marked. Except in paroxysms of transient excitement it is feeble and uncertain. The subject of chronic alcoholism scarcely knows his own mind under ordinary circumstances. Aware of his duties and his obligations, he is unable to discharge them. Especially does he lack the power to say No. Vacillation, indecision, and dependence upon others become characteristic traits. This loss of moral energy, combined with the loss of physical power brought about by continued and repeated excesses, begets at once a distaste for the ordinary occupations of life and an inability to perform them.

3. *The Intellect*.—Loss of intellectual power comes last. In some cases it shows itself only after the most prolonged excesses, when the body itself is becoming thoroughly broken down. Exceptionally, fitful intellectual power is curiously sustained to the last. The first evidence of intellectual failure consists in diminution of vivacity and readiness. The intellectual state is marked by apathy, obtuseness, and indifference; mental processes are performed slowly and with difficulty. This is perhaps one of the causes of the mental indolence characteristic of alcoholism. After a time the drunkard becomes timid, loses confidence in himself, and is unwilling to engage in enterprises demanding mental effort. Some tardiness of appreciation then shows itself; conversation becomes difficult; ideas are not spontaneous, but must be sought for; replies are not made with the usual promptness; it is difficult to arouse and fix the attention. The sense of self-respect is now lost, and it is almost impossible to make the subject comprehend his degradation. The intellectual deterioration becomes more and more marked. The memory fails little by little and becomes treacherous. Names and dates are recalled with difficulty. The conversation is interrupted by an inability to choose the proper words with precision, hence hesitancy, interruptions, and various forms of circumlocution. The power of argument and of reasoning is now much impaired, the judgment is uncertain, the association of ideas is inexact, and at length the intellectual degradation attains a degree that unfits the subject for the ordinary relations of life.

The above-described derangements of the viscera, of the nervous system, and of the mind are the morbid phenomena induced by long-continued excesses in alcohol. Whether merely functional or dependent upon recognizable anatomical lesions, they indicate pathological changes in the organism which are radical, and which under the influence of the continuously acting cause are progressive. Taken together, they constitute the condition known as chronic alcoholism. In view of the familiar experiences of every-day life, it is hardly necessary to repeat that these derangements are manifested in all degrees of intensity and in the most variable and complex combinations. The specific nature of chronic alcoholism is, in truth, due not to the derangements themselves, the greater number of which are such as we may encounter in morbid states not occasioned by alcoholic excesses, but to the combinations in which they occur in consequence of the action of the specific cause upon the organism as a whole. The prominence of particular symptoms or groups of symptoms in any given case is to be accounted for largely, if not wholly, by individual peculiarities.

Chronic alcoholism, however latent it may be, however sedulously concealed, warps the life of the individual in all its relations. In its advanced degrees it amounts to mental and physical dyscrasia. Between these extremes is every grade of incapacity and degradation. It is beyond the scope of this article to discuss the moral, social, or medico-legal bearings of this condition. Its purely medical relations are sufficiently obvious from what has gone before. It has been the writer's aim to make clear the existence and nature of the continuing condition.

It remains to describe certain other psychical disturbances which occur in chronic alcoholism, and which require separate consideration for the reason that they are accidental rather than essential, many cases running their course without their manifestation.

4. *Alcoholic Delirium in General.*—True alcoholic delirium, presenting the traits about to be described, is never the result of the direct primary action of alcohol upon the nervous system. Transient excesses produce acute alcoholism, drunkenness, which, varied as its manifestations are, differs essentially from that peculiar delirium which occurs only in individuals in whom the nervous system has undergone those nutritive changes that are brought about by prolonged alcoholic saturation.

The most striking peculiarity of this delirium relates to the hallucinations which attend it. These are almost invariably visual; occasionally they are also auditory. Their objects, whether men, animals, or things, are in constant and unceasing motion, appearing and disappearing, coming and going, and changing from place to place with extreme rapidity. In this respect they differ from the hallucinations of other forms of delirium, of which the objects are fixed and more or less permanent. As a result of this peculiarity, the objects of alcoholic delirium are almost invariably multitudinous, as swarms of vermin, herds of animals, multitudes of demons, and the like.

A second peculiarity is the restlessness of the delirium. The patient is invariably uneasy, apprehensive, always on the alert, declaring that some calamity threatens him or that some evil is about to befall him. In consequence of these apprehensions even momentary repose is wanting. If he lies down for a moment, it is only to rise again and peer under the bed

or into the corners, turning his head from side to side in search of some realization of the fears that torment him. This sense of apprehension impels the patient to hurry ever onward from place to place in search of the repose which he nowhere finds. It is increased to positive terror by the ever-varying and constantly-renewed hallucinations which torment him, and from which he seeks to escape, no matter how great the obstacles to be overcome.

A third peculiarity of alcoholic delirium is insomnia. This condition is of the most marked and stubborn character, even continuing for several days in succession.

5. *Delirium Tremens*.—This is the characteristic form of alcoholic delirium, and, as is indicated by the name, is invariably accompanied by tremor. It must be looked upon as an episode or epiphenomenon of chronic alcoholism. It is rare that even prolonged temporary excesses in persons ordinarily sober are followed by delirium tremens. Such excesses in the subjects of chronic alcoholism are, however, perhaps the most common cause of this condition. Orgies, especially when associated with venereal excesses, very frequently terminate in delirium tremens. Occasionally also, but much less frequently than was formerly supposed, the abrupt discontinuance of alcohol is followed by the outbreak. Other exciting causes are violent emotions, as anger or fright; hardships, such as prolonged hunger, over-exertion, or watching; acute maladies, as pneumonia, dysentery, erysipelas, the exanthemata, or rheumatism; finally, serious traumatism, with or without great loss of blood. Delirium tremens usually occurs in those addicted to the abuse of spirits, less frequently in beer-drinkers, and comparatively rarely in those whose excesses have been restricted to wine. The attack does not, as a rule, begin abruptly; its prodromes usually consist in an exaggeration of the previously existing symptoms of chronic alcoholism. The patient complains of malaise, restlessness; he becomes depressed, morose, anxious without cause, apprehensive of some calamity, or he is more impatient and choleric than before. The ability to apply himself to his ordinary occupations is lost. He complains of vertigo, ringing in the ears; sleep is disturbed, or there is already insomnia. At the same time the stomach is deranged, appetite is lost, the tongue is covered with a thick yellowish-white fur, and there is constipation or diarrhœa. The period of prodromes may last from a few days to a week.

The outbreak is characterized by delirium, without, at least in the greater number of cases, absolute loss of consciousness. That is to say, it is possible by addressing the patient with energy or by strongly arousing his attention to interrupt the delirium and for a moment recall the patient to himself. In the graver cases, however, loss of consciousness appears to be complete. The subjective impression of the delirium, as recollected at the termination of the attack, is that of a sense of overwhelming confusion and inability to recollect or co-ordinate the ideas that were crowding upon the brain. The hallucinations, as has already been indicated, relate almost exclusively to the organ of sight, more rarely to the hearing; also, and exceptionally, to the other organs of sense. They are almost always either terrifying or repugnant. The objects of the hallucinations of the sight have already been described. They consist of animals, serpents, and monsters, which crowd into the apartment, coming

usually toward the patient, disappearing in the walls, in the floor, under the bed, or among the bed-clothing. These visions are usually aggressive, threatening the patient, throwing themselves upon him, striking him, or tearing at his vitals. They are sometimes replaced by phantoms, spectres of the most horrible character, skeletons, death's-heads, or by flames which surround the patient and threaten to consume him. Sometimes the hallucinations relate to the daily occupation of the patient, and he pursues his tasks with a feverish and distressing anxiety. These hallucinations are almost invariably of the most fleeting, incoherent, and variable kind.

Auditory hallucinations occur usually in individuals of marked neurotic tendencies. They are apt to be more coherent than the hallucinations of vision, and are often of the nature of those which occur in the delirium of persecution. Sometimes they consist of cries, of chiding, of menacing voices, of the repetitions of obscene words and suggestions; sometimes they are cries of horror or the roars of animals, sometimes explosions or the discharge of firearms; or, again, they are terrifying threats. Hallucinations of taste and smell are much more rare, and occur in the subacute forms of delirium tremens. The patient complains of annoying odors or disagreeable tastes, either constantly present or upon the taking of food or drink. Disturbances of general sensibility show themselves in hallucinations in regard to sensations of pricking, burning, or tearing of the surface of the body, or of animals or vermin crawling over the patient. Hallucinations relating to the sexual instinct are far from rare. The hallucinations of every form are apt to be more frequent and more troublesome during the night than during the day.

Restlessness, fear, and anxiety are characteristic phenomena of delirium tremens. The patient is not only terrified by the imaginary objects which surround him, but often in their temporary absence he experiences an equal degree of fear for which he can assign no cause. It is to this condition of apprehension that is due the desire to escape from his present surroundings which is so characteristic of the delirium in question. Under its influence the patient occasionally commits acts of violence of the most serious kind. Sometimes the delirium is more quiet: the patient converses with individuals whom he supposes to surround him; he busies himself with his familiar occupations, giving orders, directing work, dictating letters, and arranging his affairs. At other times the delirium takes the form of apprehension of poisoning, and food and medicine are alike stubbornly refused.

The countenance, as a rule, is animated, the eyes brilliant and injected, the look fixed or peering, but always eager, or the expression may be haggard and agitated. The physiognomy, although largely influenced by the character of the delirium, may be said to be in most cases characteristic.

Sensation is usually impaired; especially is this true of sensibility to pain.

Tremor, although occasionally slight, may be said to be never wholly absent. Sometimes it affects the muscles of all parts of the body; more commonly it is limited to the hands, arms, tongue, and lips; less frequently it manifests itself in the lower extremities. Slight tremor may be increased by causing the patient to hold his hands extended with the

fingers separated. The movements of the hands consist of rapid rhythmical oscillations of nearly equal extent and duration. The tongue is protruded with a rapid jerking movement, and withdrawn with equal suddenness. It shows fibrillar trembling. The trembling is increased by voluntary movement, and is ordinarily associated with some loss of motor power. The gait is often hesitating and awkward; movements of the upper extremities are executed with difficulty, and speech is irregular and interrupted. The motor disturbances are occasionally associated with choreiform movements or actual epileptic convulsions.

Insomnia is a constant condition. It usually persists throughout the attack, and occasionally proves troublesome for several weeks after convalescence is in other respects complete.

In the absence of pulmonary complications the respiration is not disturbed, save as a result of the restlessness and physical effort which sometimes quicken it. The same statement is true of the pulse. The action of the heart is usually enfeebled, and the first sound weak. The temperature is normal. The skin is frequently bathed in copious perspiration. There is complete loss of appetite, and in most cases inability to retain food. Thirst is constant, often tormenting. The tongue is sometimes moist, and coated with thick white or yellow fur; sometimes hard and dry, sometimes red. The urine is scanty, dark-colored, and sedimentary. It occasionally shows traces of albumen. Constipation is the rule.

The duration of delirium tremens is from three to seven, or even ten or twelve, days. The course of the attack is paroxysmal or remittent. The symptoms usually undergo some improvement during the day, only to become more urgent at night. The periods of remission are occasionally marked by transient slumber; the recovery by prolonged and deep sleep. But this is by no means the rule. Several varieties of delirium tremens have been described by writers upon the subject. These are—the grave form, characterized by violence of the motor disturbances, aggravated delirium, and gravity of the general condition; the febrile form, in which after the third or fourth day the temperature, without pulmonary or other discernible complications, suddenly rises to 104° F. or beyond that point, with great aggravation of the general symptoms; the adynamic form, marked by failing heart-power, feeble or imperceptible pulse, profuse sweats, collapse, stupor, which deepens into coma and ends in death; and finally, the subacute form. Here the patient is quiet, but restless. The delirium scarcely passes beyond the limits of occasional wandering, and relates chiefly to matters connected with the daily interests and occupations of the patient. Tremor is more or less marked, and sleeplessness is stubborn.

The termination of delirium tremens is in—1, recovery; 2, in death; 3, in the chronic form; and 4, in other forms of insanity.

1. Recovery.—Except in the grave forms recovery may be said to be the rule. Occasionally ushered in by a prolonged, almost critical, sleep, more frequently it takes place by gradual improvement. In the latter case the remissions are more and more prolonged, and attended by increasing repose alike of body and of mind, and by tendency to sleep. The hallucinations become feebler and less tormenting, at length recurring only in the evening or at night, and especially as the patient is about

falling asleep. The anxiety and restlessness grow less urgent, consciousness becomes more secure, the trembling diminishes, and recovery is slowly established. The tremor is apt to persist some days into convalescence.

2. Death.—This mode of termination is not very common in the ordinary forms of delirium tremens. In the grave forms it is usual, sometimes occurring suddenly, sometimes gradually from intensification of the symptoms and failure of nervous power; or it may occur in consequence of pulmonary, cerebral, or renal complications; finally, the fatal termination is often due to the acute disease or the traumatism by which the delirium tremens has been excited, and of which it is, in fact, a complication.

3. Chronic Delirium Tremens.—This mode of termination, described by Lentz, is rare. The acute phenomena subside; the restlessness and the mental agitation diminish. Insomnia gives place to sleep, which is light and disturbed by dreams and nightmare; most of the hallucinations lose their activity and frequency, and finally disappear. The changing delirium settles into a fixed delirium of persecution; the tremor, while it becomes fainter, persists, and the condition is permanent.

4. Other Forms of Insanity.—This mode of termination has been studied especially by Magnan, who has classified the cases of delirium tremens into three different groups, according to their tendency to recover or to the development of mental alienation. The first group includes those cases which run a favorable course and terminate in complete convalescence; the second group, those cases in which the convalescence is prolonged and characterized by repeated relapses; the third group is composed of cases which likewise show a strong tendency to relapse, but in which the delirium continues after the other active symptoms have subsided. This form shows itself most frequently among the subjects of hereditary alcoholism. After repeated attacks the delirium becomes chronic. Morbid mental phenomena replace or accompany symptoms more directly referable to organic disturbances of the nervous system. Tremor gradually diminishes and disappears, the gastric symptoms subside, insomnia passes away, even hallucinations disappear, or at all events become infrequent; but the delirium which developed coincidentally with these symptoms continues, and finally becomes chronic, losing to a great extent its original characteristics and constituting a form of insanity. Finally, dementia constitutes an occasional mode of termination in delirium tremens. It does not often develop immediately, although cases of this kind have been recorded. More commonly, the alcoholic subject, losing little by little his mental activity after each attack of delirium tremens, subsides by degrees into absolute and irremediable dementia. Paretic dementia may also develop after prolonged alcoholic excesses characterized by repeated attacks of delirium tremens.

The anatomical lesions after death from delirium tremens shed no light on the pathogenesis of the condition. Meningeal congestion, cedema of the pia mater and of the cortical substance of the brain, scattered minute extravasations of blood, and some augmentation of the cerebro-spinal fluid have been observed. In the greater number of cases no lesions whatever beyond those characteristic of chronic alcoholism have been discovered.

6. *Alcoholic Insanity*.—Among the psychical derangements, it remains to notice briefly the more prominent forms of insanity which develop in the course of chronic alcoholism, in consequence either of hereditary or of acquired morbid mental tendencies. These are—*a*, melancholia; *b*, mania; *c*, chronic delirium; *d*, dementia; *e*, paretic dementia.

Alcohol is the most common of all the causes of insanity. Clouston¹ estimates that from 15 to 20 per cent. of the cases of mental disease may be put down to alcohol as a cause, wholly or in part. Those forms of insanity in the production of which alcohol is merely an occasional cause are not, however, properly included in the group of alcoholic insanities. Still less are we to include in this group cases of symptomatic dipsomania; that is to say, cases of insanity in which morbid impulse to drink constitutes a prominent symptom of the prodromic or fully-developed periods of various forms of mental disorder.

Alcoholic insanity manifests itself as an outcome of chronic alcoholism, just as epileptic and hysterical insanity show themselves as the outcomes of epilepsy and hysteria. This group properly includes various forms of mania-a-potu, especially the maniacal form of acute alcoholism, delirium tremens, and other transitory psychoses which occur in acute and chronic alcoholism.

In truth, the mental derangements of ordinary drunkenness constitute in many cases a form of transient insanity. These forms, have, however, already been considered at sufficient length. Dipsomania, for reasons already stated, cannot be regarded, either in its symptomatic form or in its essential form, as belonging to the group of alcoholic insanities.

a. Melancholia.—Melancholia is the most frequent form of true alcoholic insanity. It may begin abruptly or gradually, with changes of character, vague disquietude, great irritability, and disturbances of sleep amounting in many cases to insomnia. Hallucinations of hearing are characteristic. In this respect the morbid mental condition in question is in strong contrast with delirium tremens, in which the hallucinations are principally visual. The hallucinations of hearing usually consist of accusing or threatening voices. These voices inform the patient that he is to be poisoned, assassinated, murdered, or that outrages of all kinds are to be committed upon him; they accuse him of murder, of robbery, of rape, and of other shameful crimes. Præcordial distress is also apt to be present. In consequence of these hallucinations of hearing the patient falls into a profound melancholia, often characterized by suicidal impulses which are sometimes the direct outcome of hallucination, at other times blind and unreasoning. There is apt to be cephalalgia and insomnia. Trembling is not usually a marked symptom. Local anæsthesia and hyperæsthesia, if they occur, are transient. The ordinary duration of this form of alcoholic melancholia is much longer than that of delirium tremens, sometimes extending throughout several months. The termination usually is in recovery, less frequently in chronic delirium.

b. Mania.—This form of alcoholic insanity is characterized by various hallucinations which present peculiar characters. Thus, the hallucinations of vision commonly relate to supernatural apparitions, attended with luminous phenomena of various kinds. These visions may be occa-

¹ *Clinical Lectures on Mental Diseases*, Am. ed., 1884.

sional or they may be frequently repeated, or the hallucinations may consist of images of emperors, kings, princes, and potentates, or of military chieftains, in the midst of whom the patient passes his existence. Or, again, the hallucinations may be made up of historical scenes, pageants, the movements of armies, battles, and the coronations of kings, or they may be landscapes pleasant to the eye—snow-clad mountains, valleys filled with flowers, magnificent forests, and the like. These phantasmagoria are by no means fixed; on the contrary, they are of the most shifting character.

Auditory hallucinations are even more frequent, and quite as changeable. They bear a more or less well-defined relationship to the hallucinations of vision. They consist not rarely of promises of money, honors, titles, and the like. Sometimes they are voices from heaven, even the voice of God himself, commanding the patients to perform definite acts and promising in return equally definite blessings.

Hallucinations of general sensibility occur much less frequently. When present, they consist of various painful sensations, giving rise to the delusions of blows, stabs, bites of animals, electrical discharges, etc. In consequence of these hallucinations the delusions are often of a grandiose character. Patients believe themselves to be God, the pope, or some great potentate, or enormously rich, etc.

The somatic condition depends upon the degree of chronic alcoholism existing at the time of the manifestation of the mania. There are usually marked tremor, hesitation and uncertainty of speech, stubborn sleeplessness. Acute mania may show itself abruptly, attaining its full development in the course of a few days, or the development may be gradual. The prognosis in alcoholic mania is unfavorable; recoveries are rare. The fatal termination is sometimes the result of the maniacal condition itself, and sometimes the result of visceral complications. This form of insanity occasionally terminates in chronic delirium.

c. Chronic Delirium.—This form of alcoholic insanity is one of the terminations of acute alcoholic melancholia and of acute alcoholic mania. It is also one of the results of repeated attacks of delirium tremens. Finally, it may develop independently of these affections.

Developing independently, chronic delirium is usually of rapid invasion, and is characterized by the prodromes common to the various forms of alcoholic insanity—irritability, headache, vertigo, insomnia, etc. Hallucinations of hearing are very common, and relate principally to the sexual life of the patient. Voices taunt him with the fact that he is maimed or impotent; he hears persons whispering that he is about to be castrated or that he is the subject of loathsome venereal diseases, or they declare that he is known to be addicted to vile crimes and bestiality. Hallucinations of sight are much less common; those of the other special senses occasionally occur. The delirium takes the form of delusion of persecution. The patient believes himself the object of plots and conspiracies; his enemies are seeking to ruin his good name, to tarnish his reputation, to poison him. They put filth in his food or charge him with electricity; they steal away his vital force or his sexual power; they taunt him; they mock him; they beat him and rob him.

A delusion so frequent as to be almost characteristic of chronic alco-

holic delirium relates to marital infidelity.¹ The patients cherish unjust and often absurd suspicions of the virtue of their wives. These delusions arise independently of hallucinations either of sight or hearing, and are of the greatest importance, because they supply logical motives for the most appalling and brutal crimes.

Alcoholic delirium differs in the transitory and incoherent character of its delusions from ordinary chronic delirium, in which the delusions are much more apt to be fixed and permanent.

d. Dementia.—This is a common terminal condition of alcoholism. It may develop, without the intervention of other forms of mental disease, in the course of chronic alcoholism as a mere intensification of the intellectual and moral degradation of that condition. This is especially liable to occur in hereditary alcoholism. Dementia also closes the scene in a considerable proportion of cases characterized by repeated attacks of delirium tremens. It likewise constitutes the terminal condition in other forms of alcoholic insanity.

The symptoms are sometimes so slight as to escape ordinary observation. More commonly they are fully developed. As compared with ordinary dementia, they present but little that is characteristic. Alcoholic demented are perhaps more filthy and more difficult to manage, duller and more mischievous, than others. Their somatic disorders are more marked. In them hyperæsthesias are replaced by anæsthesias; sleep is apt to be irregular and disturbed; the hallucinations characteristic of the antecedent alcoholic psychosis now and then reappear. Slowly-developing failure of intellect, forgetfulness, stupor, end in more or less complete loss of mental power. Nevertheless, a small proportion of the milder cases are capable of arrest under treatment.

e. Paretic Dementia.—Alcoholism is an important etiological factor in the production of this condition. The intellectual disorders and motor disturbances which characterize it, varied as they are, are associated with cerebral lesions, and especially with lesions of the cortex equally varied—lesions which are common in chronic alcoholism. These lesions vary from meningeal congestion and inflammation to profound inflammatory and degenerative alterations in the cerebral substance.

Paretic dementia may develop after long-continued excesses without previous appreciable mental or cerebral symptoms. In such cases it presents no specific indications of its alcoholic origin. The difficulty of determining the influence of alcohol in its causation is increased by the fact that alcoholic excesses—symptomatic dipsomania—are frequent in the prodromic and early stages of this form of mental disease. Paretic dementia may also develop after repeated attacks of delirium tremens. Here the early attacks end in recovery apparently complete; later, the convalescence is unsatisfactory and prolonged, leaving some indications of intellectual enfeeblement, which, after renewed attacks, increases, and is accompanied by delusions of grandeur, embarrassment of speech, unequal dilatation of the pupils, and general paresis. The prognosis is practically hopeless.

¹ "The combination of a delusion of mutilation of the sexual organs with the delusion that the patient's food is poisoned, and that his wife is unfaithful to him, may be considered to as nearly demonstrate the existence of alcoholic insanity as any one group of symptoms in mental pathology can prove anything" (Spitzka, *Insanity*, N. Y., 1883).

III. Hereditary Alcoholism.

This term has been used in a somewhat vague manner to designate the morbid tendencies and pathological conditions directly transmitted by alcoholic subjects to their offspring. Chronic alcoholism on the part of one or both parents may be followed by morbid manifestations in the child. The hereditary transmission of the effects of alcoholism has been recognized from remote antiquity. Aristotle believed that a woman given to drunkenness would bear children with the same tendency. Plutarch affirms that the children of drunkards will abandon themselves to the same vice. Hippocrates speaks of the distressing effects of drunkenness upon the product of conception. Bacon states that many idiots and imbeciles are born of drunken parents. In more recent times the fact has been generally recognized that many maladies caused by the abuse of alcohol are liable to be transmitted to succeeding generations, and that alcoholism may in this way, in the course of two or three generations, lead to the complete extinction of families. Alcoholism on the part of the parents certainly exerts an unfavorable influence upon the health of their children, who are especially disposed to cerebral congestion, hypochondriasis, intellectual feebleness, and insanity. Two forms of hereditary alcoholism have been recognized: First, that in which the disease or defect of the parent is transmitted to the offspring; and second, that in which the disease or defect is not directly transmitted to the offspring, but a morbid tendency which manifests itself in diseases or defects of a different kind.¹

1. The appetite for strong drink is frequently transmitted from parents to the children, just as other traits of the mind or body. Sometimes it develops early, sometimes late in life; as a rule, however, this hereditary propensity shows itself at an early age, and is apt to be intensified at the time of puberty and the menopause. Objections have been urged against the theory of hereditary alcoholism. Among these the strongest is perhaps that the taste for drink in the offspring of alcoholic subjects is the result rather of opportunity and example than of heredity. The frequency with which alcoholic tendencies develop themselves in children reared and educated away from their parents, and the number of cases in which these tendencies show themselves only at an advanced period of life, long after the influence of example in childhood has ceased, sufficiently disprove this assumption. The hereditary influence does not, however, invariably manifest itself in the desire for drink. On the contrary, not rarely it consists in feebleness of nervous constitution, characterized by irritability, want of mental repose, or a restless or vicious disposition which demands constant excitement. Hence such individuals, although intellectually well developed, are often scarcely more than moral imbeciles, in whom the passion for drink may be replaced by the opium habit, addiction to gaming and to other vices, and whose career is shaped largely by an inordinate and insatiable craving for excitement of all kinds. Hereditary alcoholism follows the laws of heredity in general. The tendency may be transmitted directly from one generation to another,

¹ 1. *Heredite de similitude*, Alcoolisme héréditaire homotype; 2. *Heredite de transformation*, Alcoolisme héréditaire heterotype.

or may skip one or more generations, taking in the intermediate periods some different form.

2. The second variety is that in which the symptoms of chronic alcoholism are manifested in the offspring in the absence of the direct action of alcohol; that is to say, not the taste for alcohol, but the results of the gratification of that taste are transmitted, just as epileptic or hysterical patients may transmit to their offspring epilepsy or hysteria; thus it is not rare to encounter in the descendants of alcoholic parents perverted sensation, both general and special, hyperæsthesia, anæsthesia, flying neuralgias which do not always follow the course of particular nerves, but frequently affect in a general way the head or the members or manifest themselves as visceral neuralgias. These persons are much troubled with headache from slight causes and with migraine. Nor are disturbances of vision rare, nor vertigo. Insomnia is also frequent in such individuals, and augments the other symptoms. Digestive troubles also frequently occur, notwithstanding a regular and perfectly temperate life. Such persons are often subject to hallucinations of sight and hearing, and are liable to have delirium in trifling illnesses.

The second form of hereditary alcoholism manifests itself in a wholly different manner. The descendants, without a special appetite for strong drink, and in the absence of the special morbid manifestations above described, are singularly liable to mental and nervous diseases of various kinds. Among these convulsions and epilepsy are especially frequent; hysteria and various forms of insanity also occur. In this group of cases we find every degree of arrest of intellectual development, from mere feeble-mindedness to complete idiocy. As manifestations of the influence of alcoholism upon the offspring may be cited certain moral peculiarities otherwise inexplicable, such as are seen in children who at a very tender age show themselves vindictive, passionate, and cruel, to whom the sufferings of others afford pleasure, who torment their companions and torture their pets, and show precocious vicious tendencies of all kinds. Later in life these persons become lazy, intolerant of discipline, vagabonds, unstable of character, without the power of application and without moral sense. Given to drink, defiant of law, they constitute the great body of tramps, paupers, and criminals. The children of alcoholic subjects are often feeble and puny, pale, badly nourished, and curiously subject to morbid influences.

IV. Dipsomania.

Dipsomania, which has also been described under the term oinomania, is rather a form of insanity than of alcoholic disease. The characteristic symptoms are, however, in the greater number of instances, due to indulgence in alcohol. The subjects of this affection usually belong to families in which insanity, and especially this particular form of insanity, is hereditary.

There are two forms of dipsomania—the essential and the symptomatic. Of these, the latter is the more frequent. Its consideration requires in this connection very few words. It manifests itself by an irresistible desire on the part of many insane people for alcohol. It occurs both in

the prodromic and in the fully-established periods of insanity. It is especially common in various forms of mania and in the prodromic periods of general paralysis. The dominating influence in essential dipsomania is heredity. Occasional causes may bring on particular attacks, but their influence is secondary. Dipsomania cannot be looked upon as a distinct recurrent affection in an otherwise healthy person. At some period in their lives, and often long before the occurrence of characteristic paroxysms, dipsomaniacs show peculiarities indicating defects of mental organization. Certain symptoms of dipsomania are often mistaken for its cause. Thus, dyspepsia is more frequently an effect than a cause of the alcoholic excesses. The despondency, irritability, restlessness, hysterical manifestations, and insomnia which precede the attack are not the cause of it: they are its earliest symptoms.

The affection usually begins insidiously and is progressive. As a rule, although not always, it begins in early adult life. The manifestations of this disease are essentially intermittent and paroxysmal, but the impulse to drink must be regarded as a symptom which may be replaced by other irresistible desires of an impulsive kind, such as lead to the commission and repetition of various crimes, as the gratification of other depraved appetites, robbery, or even homicide. The paroxysms are at first of short duration, and are followed by return to the previous regular and decent manner of life. They become, however, by degrees, more violent and more prolonged. At first lasting for a few days or a week, by and by they extend to periods of a month or six weeks, the attack wearing itself out, and recurring with a periodicity sometimes variable and sometimes constant. In the intervals of these attacks for a considerable time the patients very often lead sober, chaste, and useful lives. At length, however, evidences of permanent mental trouble are manifested, and the case settles into confirmed insanity. The attack is usually preceded by evidences of mental derangement; the patient becomes restless and irritable; sleep is irregular and unrefreshing; he complains of general malaise, and is anxious, troubled by vague apprehensions. He presently abandons his usual occupations and gives himself up to disordered impulses, among which alcoholic excesses are the most frequent and the most easily gratified. Sometimes the patient passes his time at taverns drinking with all comers; at others he shuts himself up in a chamber and gratifies his desire for drink to the most extreme degree alone. Dipsomaniacs not rarely leave their homes and associates without warning or explanation, and pass the period of the paroxysm among associates of the most disreputable character. The desire for drink is gratified at all costs, and not infrequently they return to their friends without money and without sufficient clothing, most of it having been sold or pawned in order to purchase drink. The paroxysm is succeeded by a period of more or less marked mental depression, during which the patient not rarely voluntarily seeks admission to some asylum.

The true nature of dipsomania is frequently overlooked. As a symptom of hereditary insanity it is in striking contrast with the habitual propensity to drink which occurs in the ordinary alcoholic subject. The latter seeks occasions to drink. He renews his excesses not intermittently, but habitually. If in consequence of disgrace or misfortune or under strong moral suasion he is for a time abstemious, it is only to renew and to con-

tinue his indulgence upon the first favorable occasion. On the contrary, the true dipsomaniac recognizes his malady and struggles against it. Even more: for a time he shows much skill in concealing it. He avoids occasions to drink, and, reproaching himself for his mad and unreasonable desire, seeks by every means to overcome his impulse to it. The ordinary drunkard may become insane because he drinks; the dipsomaniac drinks because he is insane.¹

Dipsomaniacs are apt to manifest precocious or retarded intellectual development. They are from infancy or childhood especially prone to convulsive or other paroxysmal nervous phenomena. They are often choreic, often hysterical. This association with instability of the nervous system is related to the fact that dipsomania is more common in women than in men.

DIAGNOSIS.—1. Acute Alcoholism.—The diagnosis of the ordinary form of acute alcoholism, with the exception of alcoholic coma, requires no consideration. The diagnosis of alcoholic coma from profound coma due to other conditions is, in the absence of the previous history of the case, always attended with difficulty, and is in certain cases quite impossible. It is therefore of great practical importance to obtain the history where it is possible to do so. The odor of alcohol upon the breath is of less positive diagnostic value than would at first thought appear. In the first place, sympathetic bystanders may have poured alcoholic drinks down the throat of one found unconscious, or, in the second place, individuals who have taken a certain amount of drink may be, and not unfrequently are, seized with apoplexy in consequence of the excitement thereby induced. The more common conditions with which alcoholic coma is confounded are apoplexy from cerebral hemorrhage and narcotic poisoning, especially opium-poisoning. To these may also be added uræmic coma and, under exceptional circumstances, sunstroke. In all these cases the circumstances under which the individual has been found are of diagnostic importance.

In alcoholic coma the pupils are more commonly dilated than contracted, the heart's action feeble, the respiration shallow, the muscular relaxation symmetrical, and the temperature low. There is a strong odor of alcohol upon the breath.

In apoplexy from cerebral hemorrhage the condition of the pupils will depend upon the location of the clot. They may be moderately dilated, firmly contracted, or unequal. The enfeeblement of the heart's action is, as a rule, less marked than in profound alcoholic coma. The pulse may be small or full and slow or irregular. It is usually slow and full. The respiration is often, although not invariably, slow and stertorous. Not uncommonly, the eyes and also the head deviate from the paralyzed side. If the coma be not absolute, the muscular relaxation is unilateral. The temperature is at first slightly below the normal, but less, as a rule, than in alcoholic coma; after several hours it rises to or above the normal.

In complete opium narcosis the insensibility is profound; the heart's action is slow or rapid, but feeble; the respirations slow and shallow or quiet or stertorous; the face at first flushed, afterward pallid and cyanosed; the pupils minutely contracted or dilated as death approaches;

¹ Magnan, *Le Progrès médical*, 1884.

and the muscular relaxation complete, with abolition of reflex movements. In cases of doubt it is important to use the stomach-pump.

Uræmic coma is apt to be preceded by or alternate with convulsions. The pupils are more commonly slightly contracted than dilated, but are without diagnostic significance. The temperature is not elevated; it may even be low. The face may be pallid, pasty, and puffy, and there may be general anasarca if the nephritis be parenchymatous. On the other hand, in interstitial nephritis there is hypertrophy of the heart, without evidence of valvular disease, and some degree of puffiness of the lower extremities. In doubtful cases the urine should be drawn by a catheter and subjected to chemical and microscopical examination.¹ Diabetic coma occurs suddenly without convulsions. This condition may be suspected when the emaciation is extreme or upon the recognition of sugar in the urine.

Sunstroke is characterized by dyspnœa, gasping respiration, jactitation, and intense heat of the skin. The pulse varies. It may be full and labored or feeble and frequent. The face is usually flushed. The pupils, at first contracted, are afterward dilated. The coma is apt to be interrupted by transient local or general convulsions.

It is impossible to lay down any rules by which the maniacal form of acute alcoholism may be at once diagnosticated from acute mania from other causes. For the characteristics of the convulsive form of acute alcoholism and those forms which occur in persons of unsound mind the reader is referred to the descriptions of those conditions. The diagnosis of acute poisoning by alcohol in lethal doses can only be established during life by investigation of the history of the case.

II. Chronic Alcoholism.—The lesions of chronic alcoholism, as has already been pointed out, are not in themselves peculiar to that condition. Many of them occur with more or less frequency in morbid states not induced by alcohol. It is their association and progressive character which gives to chronic alcoholism its individuality. The occasional prominence of certain symptoms or groups of symptoms may thus in particular cases lead to some confusion of diagnosis, especially where the history is unknown or the habits of the individual are concealed. In the greater number of cases, however, the association of symptoms is such as to render the diagnosis, even in the absence of a direct history, a comparatively easy one.

Chronic alcoholism is a condition rather than a disease—a condition

¹ The following is the method recommended by Green (*Medical Chemistry*, Philadelphia, 1880) for the detection of alcohol in the urine: If its reaction be acid, the urine is exactly neutralized by potassium acid carbonate. It is then distilled on a water-bath in a flask or retort connected with a condensing apparatus. When about one-sixth of the liquid has passed over the distillate will, if alcohol be present, present the following characteristics: first, the peculiar alcoholic odor; second, a specific gravity lower than water; third, upon being mixed with dilute sulphuric acid and treated with a few drops of potassium bichromate solution the liquid becomes green, owing to the separation of chromic oxide; the odor of aldehyde may at the same time be observed. This reaction is not characteristic, but may serve to confirm other tests. Fourth, if dilute alcohol be shaken with an excess of solid and dry potassium carbonate in a test-tube, the greater part of the water will be appropriated by the potassium carbonate, and two layers of liquid will be formed. The alcohol constitutes the upper layer, and if sufficiently concentrated will burn upon the application of a flame. Finally, a small trace of alcohol may be separated from the urine without difficulty after the ingestion of alcoholic liquids by means of a good fractionating apparatus. Less than 1 per cent. of alcohol cannot be detected.

characterized by varying lesions of the viscera and nervous system, by profound disturbances of nutrition, and by grave mental and moral derangements. This fact being recognized, the cardinal error of diagnosis to be guarded against is that of overlooking the condition upon which the disease itself with which we have to do depends or is associated. Congestion, inflammation, sclerosis, and steatosis affect the various organs of the body and produce their characteristic symptoms. Profound and lasting disturbances of nutrition demand our attention. Psychological derangements of all grades, from mere moodiness to confirmed and hopeless insanity, take place. These affections must be diagnosticated for themselves here as elsewhere in clinical medicine. The recognition of the underlying condition can, however, alone supply the key to their true pathology.

Delirium tremens is occasionally diagnosticated with difficulty from some forms of insanity not caused by drink. Here transitory and fixed delusions, not mere terrors and hallucinations, are of importance, not less than the absence of the varied and complex associations of symptoms which are characteristic of alcoholism. The delirium of the acute infectious diseases may be mistaken for delirium tremens. Pneumonia, typhoid fever, and the exanthemata occasionally begin with delirium resembling in some respects delirium tremens. Here the history of the case, the pyrexia, and the general condition of the patient are sufficient to establish the diagnosis if the danger of error be borne in mind.

III. Hereditary Alcoholism.—The diagnosis of this condition can only be established by careful investigation of the family history and systematic study of the stages of progression by which the morbid condition presented by the patient has been reached.

IV. Dipsomania.—The diagnostic points are the hereditary transmission of this or other forms of insanity—the mental instability of the patient in early life and in the intervals of the paroxysms, the intermittent or cyclical recurrence of the attack, the morbid impulses of a different kind associated with the impulse to drink, and the struggle of the patient against his recurring impulses to uncontrollable excesses.

PROGNOSIS.—The prognosis in acute alcoholism of the ordinary form is favorable, so far as the immediate attack is in question. The prognosis in rapidly-developing, overwhelming coma from enormous doses of alcohol is in the highest degree unfavorable. Acute coma from moderate doses usually passes off in the course of some hours. It occasionally, however, terminates in fatal pneumonia.

The prognosis in delirium tremens of the ordinary form is favorable. It becomes, however, more and more grave with each recurring attack. Delirium tremens in patients suffering from advanced disease of the heart, lungs, liver, or kidneys, or complicated by acute diseases of these organs, is apt to prove fatal.

The prognosis of chronic alcoholism is gloomy. If the lesions be not advanced, permanent discontinuance of alcoholic habits may be followed by restoration of health, but, unfortunately, the discontinuance is too often merely temporary, the habit being too strong to be permanently broken off.

The prognosis in hereditary alcoholism is unfavorable, both as regards the alcoholic habit and as regards the development of serious diseases of

the nervous system under adverse circumstances, even in the absence of the direct action of alcohol.

The prognosis in dipsomania is unfavorable. The paroxysm may recur many times without apparent serious result; the patient in the course of some days or weeks recovers, abandons his evil courses, and resumes his usual occupations. After a time, however, the insanity of which the dipsomania is the recurring manifestation declares itself as a more or less permanent state. The outbreaks become more frequent and more prolonged, the mental condition in the intervals progressively more morbid, until the patient lapses by degrees into confirmed insanity.

The prognosis in all forms of alcoholism, both acute and chronic, is rendered in a high degree uncertain by the psychical disorders which characterize so many of its phases. In consequence of some of these conditions the patient loses at once his appreciation of bodily dangers and his power to avoid them; by reason of others, to escape imaginary evils he plunges into real ones; and finally some of them are of such a nature that they impel him to the blind and unreasoning commission of the most grievous crimes, including suicide and homicide.¹

TREATMENT.—The prophylaxis of alcoholism has regard to communities at large and to individuals. The prevention of the evils of excess by the control of the sale of drink constitutes one of the more important objects of state medicine. At the same time, the traffic in alcohol is curiously evasive of legal enactments. The difficulties attending the enforcement of sumptuary laws are well known. Restrictive laws concerning the making and sale of alcoholic drinks, while partaking of the nature of sumptuary laws are of more comprehensive character, being obnoxious to powerful commercial interests and to the sense of personal liberty of large numbers of persons of all classes. As a result of organized opposition and individual violation they are to a great extent inoperative as regards the prevention of alcoholism.

Aside from the question of revenue from taxation, the practical influence of law is in this matter somewhat limited, being confined chiefly to the prevention of the sale of liquors to minors and persons already intoxicated, and to ineffectual attempts in certain countries to regulate the quality of the drink sold. The penalties for personal drunkenness which does not lead to overt acts are, as a rule, wholly inadequate to restrain it. The best results upon anything like an extended scale have been obtained by the co-operative action of philanthropic individuals in endeavoring to influence the moral tone, especially among workingmen, to diminish temptations, and to provide for leisure hours, in the absence of drink, reasonable amusements and occupation to occupy the time ordinarily spent in taverns and similar places.

The decrease in the consumption of alcoholic drinks in the United States within recent years is doubtless due in part to increasing popular knowledge concerning the dangers of alcoholic excess and to the growth of a more wholesome public sentiment. It is, however, in part also due to poor wages among workingmen.

As regards the individual, prophylaxis against alcoholism consists

¹“I believe that more suicides and combined suicides and homicides result in this country from alcoholism in its early stages than from any other cause whatsoever” (T. S. Clouston, *Clinical Lectures on Mental Diseases*, Am. ed., 1884).

either in total abstinence from, or in the most guarded indulgence in, alcoholic beverages. It is unfortunate that individuals whose moral and physical organization is such as renders them most liable to suffer from the consequences of alcohol are by that very fact most prone to its temptations, and hence contribute largely to the subjects of alcoholism. These individuals are found among the ignorant, the very poor, and especially among neurotic subjects of all classes of society. Due consideration of this fact cannot fail to establish the responsibility of those fortunately not belonging to these classes, in two respects: first, that of example; and second, that of personal restraint from the standpoint of heredity. The influence of heredity among races addicted to alcohol has not yet attracted the attention it deserves. It is probable that much of the tolerance for alcohol exhibited by individuals, families, or even nations, is to be accounted for by heredity. Still more probable is it that most of the evils and crimes that befall alcohol-drinking communities and individuals are due directly or indirectly to the abuse of this agent. No argument against the indulgence in narcotics can be more potent than that derived from a consideration of the laws of heredity.

I. The Treatment of Acute Alcoholism.—The medical treatment of mere drunkenness requires no consideration. The rapid elimination of alcohol, and the transient nature of its pathological effects in excesses which are not repeated or prolonged, explain the spontaneous recovery, which is usually sufficiently prompt and permanent. The physical suffering and mental distress following unaccustomed excesses are of salutary influence. Under certain circumstances a powerful effort of the will is sufficient to control, at all events for a time, the more moderate effects of alcohol. A similar result follows the use of cold douches, the Turkish bath, and full doses of certain preparations of ammonium, particularly the officinal solution of the acetate of ammonium. In alcoholic stupor of an acute kind the patient may be left to himself, care being taken that the clothing is loosened and that the position is such as to prevent local paralysis from the nerve-pressure. Alcoholic coma, if of moderate intensity, may be managed in the same way. Profound alcoholic coma requires, however, more energetic measures. Frictions, artificial warmth, stimulating enemata, as of turpentine or of hot salt and water, an ounce to the pint, hypodermic injections of strychnia or atropia in minute doses and occasionally repeated, inhalations of ammonia, and occasional cold affusions, followed by brisk frictions with warm flannel and faradism of the respiratory muscles, may be needed to tide over the threatened fatal collapse. The stomach should be at once washed out with hot coffee.

In the convulsive form of acute alcoholism chloral in twenty-grain doses, repeated at intervals until sixty grains have been given, usually serves to arrest, or at all events to moderate, the paroxysm. It may be administered by the mouth or in double doses by the rectum. If chloral be inadmissible by reason of weakness of the circulation, paraldehyde may be substituted in doses of from half a drachm to one drachm, repeated at intervals of from one to two hours until quietude is produced. Where the convulsive paroxysms are of great violence it may be necessary to control them by the cautious administration of ether by inhalation.

The mania of acute alcoholism calls for energetic management. To

avert injury to the patient himself or to those about him he must be confined, if practicable, in a suitable apartment in a hospital; if not, in his own house and carefully watched. Here, as a rule, paraldehyde, chloral, or large doses of the bromides constitute our most efficient means of medication.

In all forms of acute alcoholism it is a rule admitting of no exception to at once withhold alcohol in every form and all doses. If, under exceptional circumstances, great nervous depression or flagging circulation seems to call for the use of alcohol in small amounts, it is far better to substitute other drugs. The frequently repeated administration of hot beef-tea or rich broths in small doses, with capsicum and the use of the various preparations of ammonia, or small doses of opium with or without quinia and digitalis, proves useful in proportion to the skill and discrimination with which they are selected and repeated. It is a good plan to commence the treatment with an active purge.

In the acute collapse following excessive doses—lethal doses—the stomach is to be immediately emptied by the tube or pump and washed out with warm coffee. In the absence of the stomach-tube emesis may be provoked by the use of mustard or sulphate of zinc or by hypodermic injection of apomorphia. The patient must be placed in the recumbent posture and surrounded with hot blankets. The cold douche may be occasionally applied to the head and face, and the muscles of respiration may be excited to action by faradism. Artificial respiration and friction of the extremities may also be required. Inhalations of ammonia may be used. The flagging heart may be stimulated by occasionally tapping the præcordia with a hot spoon—Corrigan's hammer. Hypodermic injections of digitalis may also be employed. Overwhelming doses of alcohol, leading promptly to collapse, usually prove fatal despite all treatment.

II. The Treatment of Chronic Alcoholism.—Whatever may be the prominence of particular symptoms or groups of symptoms, whether they indicate derangement of the viscera, of the nervous system, or of the mind, whatever their combination, the fundamental therapeutic indication in chronic alcoholism is the withdrawal of the poison. The condition is directly due to the continuous action of a single toxic principle: its relief when practicable, its cure when possible, are only to be obtained by the discontinuance of that poison. This is a matter of great, often of insurmountable, difficulty. The obstacles are always rather moral than physical. Occasional or constant temptation, the iron force of habit, the malaise, the faintness, the craving of the nervous system, and, worse than all, the enfeebled intellectual and moral tone of the confirmed drunkard, stand in the way. Even after success seems to have been attained, and the patient, rejoicing in improved physical health and in the regained companionship and consideration of his family and friends, feels that he is safe, it too often happens that in an unguarded moment he yields to temptation and relapses into his old habits. A patient of the writer, after seven years' abstinence from drink, again became its victim in consequence of the incautious suggestion of a young medical man, met at a summer hotel, to take brandy for some transient disorder, and died after eight months of uncontrollable excesses. It is necessary to guard the patient against the temptation to drink. To secure this he may be sent as a voluntary patient for a length of time to a suitable institution,

or, still better, he may place himself under the care of a conscientious, clear-headed country doctor in a sparsely-settled region, preferably in the mountains or at the seaside. The malaise, depression, insomnia, and other nervous symptoms when of moderate degree are best treated by abundance of nutritious and easily-assimilable food, taken often and in moderate amounts. To this end gastro-intestinal disturbances may be practically disregarded, except in so far as they regulate the selection of a highly nutritious diet. As a matter of fact, in the early periods of chronic alcoholism, while visceral lesions of a grave character are yet absent, appetite and digestion alike improve in the majority of cases upon the withdrawal of alcohol, provided a sufficiently abundant and easily assimilable dietary is insisted upon. Grave visceral lesions characterize a more advanced alcoholic cachexia and necessarily complicate the treatment. Nevertheless, even here the indication is the withdrawal of the poison. The nervous symptoms require special medication. The whole group of tonics, from simple bitters to quinia and strychnia, is here available. It is impossible to lay down rules for the treatment of particular cases except in the most general manner. In the absence of conditions calling for special treatment, such as gastritis, hepatic or pulmonary congestion, fatty heart, etc., good results follow the frequent administration of small doses of quinia and strychnia; thus, the patient may take one grain of quinia six or eight times a day, or a little gelatin-coated pill containing $\frac{1}{200}$ — $\frac{1}{100}$ of a grain of strychnia every hour during the waking day, amounting in all to one-twentieth, one-tenth, or one-fifth of a grain in the course of twenty-four hours. This treatment is often followed by the relief of tremor, the quieting of nervous irritability, and the production of good general results. The malaise, the general depression, and especially the sinking feeling at the pit of the stomach so often complained of by patients, are best relieved by food. Fluid extract of coca is also useful in these conditions. The value of cocaine in the management of the nervous symptoms of chronic alcoholism, and in particular as a temporary substitute for alcohol, is doubtful. The writer, having used it in a number of cases by the mouth and hypodermically in doses of $\frac{1}{4}$ —1 grain, has had variable results. In some cases it temporarily relieved the craving and concomitant symptoms; in others it failed wholly: in one instance one-fourth of a grain was followed by great nervous depression. It is desirable not to inform the patient of the nature of the remedy, especially if its use be followed by good results, lest the cocaine itself supplant alcohol as an habitual narcotic. Cold or tepid sponging, the occasional hot bath at bedtime, and the Turkish bath are useful adjuncts to the treatment. As a rule, opium is contraindicated. Sleep often follows the administration of a cupful of hot broth or milk at bedtime. Lupulin is here useful, and the writer has come to regard an ethereal extract of lupulin in doses of from one to three grains as a valuable and harmless hypnotic. If necessary, hypnotic doses of chloral or paraldehyde may be used, but care is required in their administration, and their early discontinuance is advisable. If anæmia be profound, chalybeate tonics do good, and among the preparations of iron pills of the dried sulphate with carbonate of potassium (Blaud's pills) are especially useful.

The obesity of drunkards, as a rule, diminishes on the withdrawal of alcohol. Under circumstances of partial or complete abstinence from

drink measures to reduce the weight of such patients are wholly inadmissible.

In conditions characterized by failure of mental power, in beginning dementia or threatened insanity, the syrup of the hypophosphites, the compound syrup of the phosphates, or cod-liver oil should be administered. These remedies are likewise useful in various forms of alcoholic paralysis, as are also faradism and galvanism employed *secundum artem*. The various forms of alcoholic insanity require special treatment, only to be had in institutions designed for the care of patients suffering from mental diseases in general.

Whilst it is desirable in the treatment of all forms of chronic alcoholism to secure the permanent discontinuance of the alcoholic habit, the skill, judgment, and experience of the physician must determine the degree of rapidity with which this, when practicable, is to be done. The number of cases in which alcohol can be discontinued at once and finally is limited; those in which it can be wholly given up in the course of a few days constitute the largest proportion of the cases; finally, in a small number of cases alcohol can only be withdrawn cautiously and by degrees.¹ Whilst it is in most cases essential to remove the patient from his customary surroundings and companionships, it is in the highest degree important to provide for him mental occupation and amusement. To this end a wholesome open-air life, with sufficient daily exercise to induce fatigue, is highly desirable, as indeed is the companionship of interested and judicious friends.

The Treatment of Delirium Tremens.—The patient should be confined in a large, well-aired apartment, without furniture except his bed, and when practicable he should have a constant attendant. The favorable influence of a skilful nurse in tranquilizing these patients is very great. The custom of strapping them to the bed by the wrists and ankles is to be deprecated. If the case be a mild one, and especially during convalescence, open-air exercise in the sunshine with an attendant is of benefit; care must, however, be taken to guard against the danger of escape.

Under no circumstances should visitors be permitted to see the patient. In young persons the treatment may be preceded by an active saline or mercurial purge. In elderly persons, those suffering from cachectic conditions, or in cases characterized by marked debility and feeble circulation—conditions frequent in persons who have had repeated attacks—it is not desirable to purge. Alcohol should be either wholly withdrawn or more or less rapidly diminished. It must be replaced by abundant food in the form of concentrated broths or meat-extracts. In cases of vomiting these must be given hot and in small doses frequently repeated. Bitter infusions may also be given, or milk or equal parts of milk and Vichy water. If there be thirst, the effervescent waters may be given freely. Patients often drink with satisfaction and apparent benefit hop tea, which may be made simply with water or with equal parts of water and porter.

¹It must be borne in mind that in chronic alcoholism acute maladies of all kinds, including traumatism, both accidental and surgical, act as exciting causes of delirium tremens. The part played by the abrupt diminution or withdrawal of alcohol under such circumstances is often an important one. It is the opinion of the writer that a certain amount of alcohol should be administered for a time at least in the accidental injuries and acute sicknesses of alcoholic subjects, and that the reduction should be gradually made.

The medicinal treatment will depend to a large extent upon the peculiarities of the case. In mild cases a combination of the watery extract of opium in small doses, not exceeding a quarter of a grain, with quinia and digitalis, repeated every four or six hours, is often useful. Although the view once entertained that the graver symptoms were the result of prolonged sleeplessness is no longer tenable, the induction of sleep, or at all events of mental and physical repose, is among the more important therapeutical indications. For this purpose hypnotic doses of opium are not only not desirable, but are even, in the majority of instances, attended with danger. The sleep which follows repeated and increasing doses of opium in delirium tremens has too often terminated in coma deepening into death. As calmatives, extract of cannabis indica, hyoscyamus, or the fluid extract of piscidia are useful. As hypnotics, the bromides, chloral, and paraldehyde yield, in the order here given, the best results. The bromides are better in large single doses than in small doses often repeated, better in combination than singly. Chloral, either by the mouth or by the rectum, in doses of from twenty to forty grains, is often followed by beneficial sleep. It is contraindicated where the heart's action is much enfeebled. Paraldehyde, in doses of half a drachm to one drachm, repeated at intervals of two or three hours until sleep is induced, is still more efficient. This drug may be administered without the fear of its exerting a depressing influence upon the heart. The depression characteristic of grave delirium tremens may be combated by repeated small doses of champagne or by carbonate of ammonium in five- or ten-grain doses; the vomiting, by withholding food and medication by the mouth, and giving them for some hours wholly by the rectum or hypodermically. Excessive restlessness is sometimes favorably influenced by cold affusion, followed by brisk friction and warm blankets with continuous artificial heat. The cold pack has proved useful.

Digitalis may be employed, *ex indicatione symptomatica*, but the enormous doses of tincture of digitalis used by the late Jones of Jersey and others are here mentioned only to be condemned.

To sum up, the chief indications for treatment are complete isolation, the withdrawal of alcohol, abundant, readily assimilable, nutritious food, and control of the reflex excitability of the nervous system.

III. Hereditary Alcoholism.—The treatment of the vicious propensities of the descendants of alcoholic parents does not fall directly within the province of the physician. It is among the most difficult problems of education. The recognition of the cause of evil traits manifested in childhood and youth may do something to avert dangers commonly unsuspected. All things considered, the outlook is not hopeful. The recognition, on the part of the physician, of the influence of hereditary alcoholism in cases of arrested development, feeble organization, or declared disease of the nervous system will perhaps do less to aid his treatment in many cases than to reconcile him to its want of full success. The cry of warning is to those who are eating sour grapes that the teeth of their children will be set on edge.

IV. Dipsomania.—The general indications for the treatment of dipsomania are two: first, the management of the paroxysm; second, the control of the general condition itself.

First, then, during the paroxysm the patient must be saved, in so far

as is possible, from the danger of injuring himself or others and from squandering his property. If the excesses are of such a degree as to render it practicable, the same treatment must be carried out as in cases of acute alcoholic mania and delirium tremens—namely, confinement in a suitable apartment under the care of an experienced nurse and the control of the doctor. Unfortunately, this plan is not always practicable in the early days of the outbreak. Here tonics, coca, and repeated small doses of quinia and strychnia are of advantage. Courses of arsenic at the conclusion of, and in the intervals between, the paroxysms are of use, on account of the excellent influence they exert on the general nutrition. These may be advantageously alternated with iron, cod-liver oil, and the compound syrup of the phosphates or of the hypophosphites. Hydrotherapy may also be used with advantage, and the influences of a well-regulated hydropathic establishment are much more favorable than those of institutions specially devoted to the treatment of alcoholic subjects. In the latter the moral atmosphere is apt to be bad; the patients support each other, and too often conspire to obtain in secret that which is denied them openly, or, if the discipline be too strict for this, they sympathize with each other in their restraint, react unfavorably upon each other in the matter of shame and loss of self-respect, and plot together to secure their liberty.

Few dipsomaniacs in the earlier periods are proper subjects for treatment in hospitals for the insane. If cerebral excitement or sleeplessness persist after the paroxysms, chloral, paraldehyde, or the bromides in large doses may be used to secure sleep. Various combinations of the bromides are often of use where the single salts fail. It must not be forgotten that during the paroxysm there is great danger lest the patient do himself or others harm. When there are indications of an impending attack, and during the period of depression following the attacks, benefit is derived from the daily use of bitter infusions. As a matter of fact, however, the management of these cases is among the most unsatisfactory of medical undertakings. The difficulty is increased by the latent character of the mental disorder in the intervals between the attacks. Even when such patients voluntarily enter hospitals for the insane, they cannot be retained there sufficiently long to derive any permanent benefit. What we want is, in the words of Clouston, "an island where whiskey is unknown; guardianship, combined with authority, firmness, attractiveness, and high, bracing moral tone; work in the open air, a simple natural life, a return to mother Earth and to Nature, a diet of fruits, vegetables, bread, milk, eggs, and fish, no opportunity for one case to corrupt another, and suitable punishments and deprivations for offences against the rules of life laid down. All these continued for several years in each case, and the legal power to send patients to this Utopia for as long a period as medical authority determines, with or without their consent."

THE OPIUM HABIT AND KINDRED AFFECTIONS.

BY JAMES C. WILSON, M. D.

NEXT in order to alcohol, opium and morphine are habitually abused to a greater extent than any other narcotic. Chloral is used in the same way by a large number of individuals. Paraldehyde, cannabis indica, ether, chloroform, and cocaine are also used to a less extent. The scope of this article does not include the consideration of acute poisoning by these drugs.

The habit of taking narcotics, whether medicinally or as a mere matter of indulgence, is apt speedily to become confirmed. The physiological dose more or less rapidly loses its power to affect the nervous system in the ordinary way. Tolerance increases with increasing doses, and in a comparatively short space of time poisonous doses are taken with impunity as far as immediate danger to life is concerned. The toxic effects of the poison are shown in characteristic perversion of the functions of the nervous system and of the mind. A condition is established in which the ordinary functions of life are properly performed only under the influence of the habitual narcotic, and in which its absence results in languor, depression, and derangement of bodily and mental processes. The habit, once established, thus makes for itself a constantly recurring plea for its continuance. Especially is this true of opium and morphia.

Opium and Morphine.

Opium-eating is chiefly practised in Asia Minor, Persia, and India. It is also prevalent in Turkey. It has been practised in India from very ancient times. The prevalence of this habit in the East is probably largely due to the restrictions placed upon the use of alcoholic beverages among the Mohammedans, and to some extent also to the long religious fasts observed by the Buddhists, Hindoos, and Moslems, during which opium is often used to allay the pangs of hunger. The prevalence of the opium habit in India is shown by the fact that the license fees for a single year amounted to nearly five hundred thousand pounds sterling. It is stated that in Samarang, a town of 1,254,000 inhabitants, the average quantity of opium consumed monthly is 7980 pounds. The town of Japava, with 671,000 inhabitants, consumed in fifteen days 5389 pounds

of opium. In 1850, 576,000 pounds of opium were imported into Java, besides an unknown quantity smuggled.¹

The habit is not confined to Oriental countries, but is also practised in various forms in the West. It is by no means rare on the continent of Europe. In certain districts of England, especially in Lincolnshire and Norfolk, more opium is consumed than in all the rest of the United Kingdom. Shearer² states that the increase in the practice of opium-eating among the workpeople of Manchester is such that on Saturday afternoons the druggists' counters are strewn with pills of opium of one, two, and three grains, in preparation for the known demand of the evening. The immediate occasion is said to be the lowness of wages, opium being used as a cheap substitute for alcohol or as a food substitute, or with the view of removing the effects of disease and depression. According to the same observer, laudanum is more or less in use as a narcotic stimulant in the cotton-spinning towns, where female labor is in requisition and is well paid. Children are accustomed to it from their earliest infancy. Their parents drug them with daily potions of Godfrey's cordial, Dalby's carminative, soothing syrup, and laudanum itself, during the long hours of their absence from home. While the habit of opium-eating cannot be said to be generally prevalent in any part of the United States, instances of it are frequently encountered in all classes of society, and particularly among people of means and refinement. The preparations employed in this country are crude opium, tincture of opium or laudanum, camphorated tincture of opium or paregoric, McMunn's elixir, Dover's powder, and the salts of morphia. All of these preparations are used by the mouth; opium is very frequently, especially among women of the better classes of society, habitually taken in the form of suppositories; finally, the acetate and sulphate of morphine are used by means of the hypodermic syringe. While it will be necessary to point out some differences in the effects of these drugs due to the preparation used or to the method in which it is employed, the distinction between the opium habit and the morphine habit, in itself an artificial one, will not be regarded in the course of the present article.

Opium-smoking is chiefly practised by the inhabitants of China and of the islands of the Indian Archipelago. It has been imported into those countries where Chinese labor is largely employed. The Chinese have transmitted it, to an extent which is fortunately very limited, to the inhabitants of certain of our cities. Opium-smoking is habitually practised in this country only among the more debased orders of society.

SYNONYMS.—Opiophagia, Morphiothy, Morphinism, Morphinomania, Morphomania, Morpheomania, are terms occasionally employed to designate the opium or morphia habit.³ Landowski, Levinstein, Jouet, and others use the term morphinism to denote the condition of the body; morphinomania, the condition of the mind in chronic morphine-poisoning. This distinction may be misleading. In effect, the pathological condition is complex, including derangements both somatic and psychical.

¹ *Archiv für Pharmazie*, 1873, cited by Von Beck, *Ziemssen's Cyclopædia*, vol. xvii.

² *Opium-smoking and Opium-eating, their Treatment and Cure*, by George Shearer, M. D., F. R. S.

³ The word morphinomania, used by writers, is contrary to all etymological rule (*Zambaco, De la Morphéomania*, Paris, 1883).

ETIOLOGY.—*A.* Predisposing Influences.—Pain holds the chief place among the influences which predispose to the formation of the opium habit. By far the greater number of cases have taken origin either in acute sickness, in which opium administered for the relief of pain has been prolonged into convalescence until the habit has become confirmed, or in chronic sicknesses, in which recurring pain has called for constantly repeated and steadily increasing doses of opiates. In view of the frequency and prominence of pain as a symptom of disease, and the ease and efficiency with which opium and its preparations control it, the remote dangers attending the guarded therapeutic use of these preparations are indeed slight. Were this not so, the number of the victims of the opium habit would be lamentably greater than it is. In a considerable proportion of cases of painful illness the relief afforded by opiates is attended by at least some degree of malaise, nausea, vomiting, and vertigo—symptoms which render the speedy discontinuance of the remedy scarcely less desirable than the control of the pain for which it was administered. Occasionally these symptoms are so distressing as to render opium wholly inadmissible. In other instances each successive dose is attended by an aggravation of the distress. More commonly, especially in acute illnesses, decreasing pain may be controlled by diminishing doses, thus rendering practicable entire discontinuance of the drug before those modifications of the nervous system, and especially before that tolerance for large doses, which constitutes the beginning of the opium habit, are established. For these reasons the use of opiates in acute sickness, if properly regulated, is attended with but little danger. Far different is it, however, in chronic painful illnesses. Here to procure relief by opium is too often to pave the way not only to an aggravation of the existing evils, but also to others which are often of a more serious kind. Opium is at once an anodyne and a stimulant. The temptations to its use are of a most seductive character. To the overworked and underfed mill-operator it is a snare more tempting than alcohol, and less expensive. It allays the pangs of hunger, it increases the power of endurance, it brings forgetfulness and sleep. If there be myalgia or rheumatism or neuralgia, and especially the dispiriting visceral neuralgias so common and so often unrecognized among the poorer classes of workpeople, opium affords temporary relief. The medical man suffering from some painful affection, the worst symptoms of which are relieved by the hypodermic injection of morphine, falls an easy prey to the temptation to continue it—a danger increased by the fact that he is too often obliged to resume his work before convalescence is complete. Indeed, the self-administered daily doses of physicians sometimes reach almost incredible amounts. To women of the higher classes, ennuyée and tormented with neuralgias or the vague pains of hysteria and hypochondriasis, opium brings tranquillity and self-forgetfulness.

Of 100 cases collected by Jouet,¹ the habit followed the therapeutic use of morphine in 32 cases of ataxia, 24 of sciatica and other neuralgias, 8 of asthma, 2 of dyspepsia, 4 of hypochondriasis, 2 of madness, 9 of painful tumors, 2 of prostatic inflammation, 7 of nervous conditions (not specified), 1 of peritonitis, 2 of periostitis, 1 of gastro-enteralgia, 4 of pleuritic pains, 1 of contracture, and 1 case of hæmoptysis.

The responsibility of the physician to his patient becomes apparent

¹ *Étude sur le Morphinisme chimique*, Thèse de Paris, 1883.

when we reflect that with very few exceptions the opium habit is the direct outcome of the use of the drug as a medicine.

The decade of life at which the opium habit is most common is between thirty and forty. But it may be developed at any age. Even infants are not rarely made the subjects of chronic opium narcotism by the use of soothing syrups and other poisonous nostrums.

Sex in itself exerts very little influence as a predisposing cause. Owing to collateral circumstances, the number of women addicted to opium is greater than the number of men. Kane¹ states that females more frequently fall victims to these drugs than males, in the proportion of three to one, and attributes this excess to the fact that women more often than men are afflicted with diseases of a nervous character in which narcotic remedies are used for long periods. This observer suggests as an additional explanation the occasional preference on the part of women for opium as a stimulant in place of alcohol, its effects being less noticeable and degrading. On the other hand, Levinstein observed in 110 cases 82 men and 28 women. He does not, however, regard the conclusion that the use is more common among men as warranted by these figures. The habit resulted in these 110 cases from the following causes: In 20 men and 6 women after acute affections; in 46 men and 17 women after chronic affections, these diseases being in each instance accompanied by great pain. One man began to use morphine as an antiaphrodisiac. Either to produce mental excitement simply or to cause forgetfulness of the ordinary cares of daily life, 15 men and 5 women indulged to an uncontrollable extent.

Occupation has in some respects much to do in favoring the development of the opium habit. Familiarity with the use of drugs exerts a powerful influence. Of Levinstein's 110 cases, 47 occurred in persons belonging to the medical profession or dependent upon it; thus, 32 physicians, 8 wives of physicians, 1 son of a physician, 4 nurses, 1 midwife, and 1 student of medicine.

A predisposing influence of more importance than would at first sight appear is found in sensational popular writings upon the subject. As Kane has well said, "At the time in which De Quincey, Coleridge, and Southey lived the people and the profession knew little of the opium habit save among foreign nations. The habitués were few in number, and consequently when De Quincey's article appeared it created a most decided impression upon the popular mind—an impression not yet effaced, and one which bore with it an incalculable amount of harm. Men and women who had never heard of such a thing, stimulated by curiosity, their minds filled with the vivid pictures of a state of dreamy bliss and feeling of full content with the world and all about, tried the experiment, and gradually wound themselves in the silken meshes of the fascinating net, which only too soon proved too strong to admit of breaking." There can be no question that a percentage of cases of the opium habit, small though it be, is even in our day to be attributed to this cause.

Somewhat analogous in its etiological importance is the influence of example upon persons of idle and luxurious habits. Nowhere in Western countries, with the exception of the opium-smoking dens of the Chi-

¹ *Drugs that Enslave*, Philadelphia, 1881. I refer with pleasure to the early labors of this observer. His later publications tell their own story.

nese and their depraved associates, are there public places of resort devoted to the practice of the opium and morphine habits, as there are in Turkey and the East. According to Jouet—whose statements are corroborated by occasional statements in French newspapers—the habitual injection of morphine is to-day, in France at least, almost a matter of fashion. Landowski states that friendship is occasionally pushed to the extent of the exchange of pretty syringes in silver cases as presents, and that a patient received upon his birthday a hypodermic syringe as a present from his sister. Zambaco, whose observations were made at Constantinople, states that among the Moslems the opium habitués prefer the crude drug, either alone or associated with certain aromatic substances, such as ambergris, canella, or saffron, which are used for their aphrodisiac effect. These mixtures are prepared openly in the family, and carried upon the person in the form of pills in rich boxes of gold and enamel among the better classes. This observer further says that the ladies of the better classes carry jewelled cases containing hypodermic syringes and artistic flacons for the seductive solution, and that they avail themselves of favorable opportunities to take an injection of morphine even when together.

In addition to the predisposing influences already mentioned, it has been customary to regard insanity as a cause of the opium habit. Laehr¹ and Fidler² have gone so far as to class the morphine habit among the psychoses. This view appears to be no longer tenable. The opium habit must be classed with the taste for alcohol, gambling, avarice, and lust as among human passions. That nervous subjects, invalids, and individuals wanting in moral and physical tone are specially prone to it is obvious. It constitutes in these cases, however, an expression of the morbid constitution rather than a substantive affection in itself. In the same manner, the opium habit in insane persons must be looked upon as an epiphenomenon of the morbid mental condition.

Levinstein has with reason insisted upon the essential difference between the disturbances resulting from chronic poisoning by alcohol, lead, arsenic, etc., and that produced by morphine. In the former group the mental conditions are expressions of physical and chemical alterations of the central nervous system, which, once established, persist for an indefinite period, whereas in morphinomania the troubles of the nervous system are chiefly functional and of a transitory character. He regards the nervous disorders developed from the prolonged use of morphine as the result simply of depression of the nervous system, and the extreme suffering experienced on the withdrawal of the regular dose to which the subject has been accustomed as a trouble of innervation rather than as a psychical derangement. This physical suffering and the mental depression which accompanies it have their analogues in the angina occasionally seen in paroxysmal affections of the heart, the blood-vessels, and the respiratory organs. Certain it is that individuals addicted to opium and morphine excesses in a high degree not only frequently retain full possession of their intellect, but occasionally achieve and maintain great distinction in professional and scientific life. Furthermore, subjects of the opium habit, notwithstanding the gravest mental disturbance manifested during the

¹ *Allgemeine Zeitschrift für Psychiatrie*, 1872.

² *Jahresb. der Gesellschaft für Natur und Heilkunde*, Dresden, 1876.

continuance or upon the cessation of the habit, usually exhibit when cured no further indication of mental disorder.

B. The Exciting Cause.—In addition to the usual constituents of vegetable substances, mucilage, albumen, proteids, fat, volatile substances, and salts of ammonium, calcium, and magnesium, opium contains a number of alkaloids, two neutral substances, and meconic acid. Some of the alkaloids are probably derivatives from morphia. The three most important alkaloids are morphine, codeine, and thebaine. The neutral substances are meconin and meconiasin. Morphine hydrochloras, acetas, and sulphas, codeina, and apomorphine hydrochloras are officinal in the United States Pharmacopœia. Opium and its alkaloids act principally on the central nervous system, and in mammals on the brain. The functions of the nervous system, as Brunton has pointed out, are abolished in the order of their development, the highest centres being the first affected. In man the action of opium is chiefly manifested upon the brain. With small doses a stage of excitement, attended by increased activity of the circulation, augmented nervous energy, and under favorable circumstances an agreeable languor, followed by quiet sleep, constitute the effects of the drug; with larger doses, of from one to two grains, the transient stage of excitement is followed by deep sleep, the awakening from which is marked by headache, nausea, and evidences of gastrointestinal catarrh; with still larger doses, of three grains or more, deep sleep is produced, which speedily passes into coma. The drug has an especial action on the vaso-motor system, which is manifested in its power to diminish congestion and relieve inflammation. With the exception of the urine and the sweat, the secretions of the body are diminished by opium. The action of the drug upon the intestines varies with the dose. In moderate doses it diminishes peristalsis and causes constipation; in very small doses it increases peristalsis; in large doses peristaltic action ceases. Morphine is eliminated unchanged by the kidneys. It is eliminated also by the gastro-intestinal mucous membrane, having been found in the stomach after hypodermic injection. The action of opium and its derivatives, as that of other narcotics, is much influenced by habit. In those accustomed to the drug large (and sometimes enormous) quantities are required to induce the characteristic manifestations. Not rarely these manifestations are much retarded. The enormous amount of two pints of tincture of opium has been taken in the course of a day; a female patient afterward successfully treated by the writer took habitually for a long period of time from ten to twelve grains of morphine per diem, hypodermically. Diedrich¹ assumes that a portion of the morphine introduced into the organism is converted into oxydimorphine or other analogous substances which have the property of counteracting to some extent the toxic effects of the morphine.

Levinstein concludes as a result of experiments upon animals that morphine, besides its influence upon the nervous system, exerts an especial action upon two sets of organs: first, upon the digestive tube; and second, upon the sudoriferous glands. Taken by the mouth, it irritates the gastric mucous membrane. Whether taken by the mouth or hypodermically, it diminishes the secretion of gastric juice and the peristaltic movements of the intestine. These disturbances serve to explain not

¹ *Ueber oxydimorphine*, Inaug. Diss., Göttingen, 1883.

only certain of the phenomena of the opium habit itself, but even more fully some of the symptoms manifested upon its discontinuance. The nausea, vomiting, and constipation occurring during the continuance of the habit must be looked upon as a result of the derangement of function of the gastro-intestinal glandular apparatus and the chronic catarrh which accompanies it. The abrupt discontinuance of the drug is followed by the sudden return of functional activity, hence salivation, persistent vomiting, anorexia, and diarrhœa.

The effects of habitual excesses in opium and morphine upon the nervous system are in essential particulars the same. Upon the functions of the digestive system and upon nutrition they differ to a considerable extent. Opium, as a rule, soon produces gastro-intestinal derangements of a marked kind. These derangements consist in loss of appetite, enfeebled digestion, nausea, vomiting, and constipation alternating with occasional diarrhœa. The anorexia is usually persistent and of a high degree, and has much to do with the development of the wasting which is so common and so marked. The occasional excessive appetite for food manifested by opium-eaters is of brief duration. Its gratification aggravates the functional disturbances, provokes gastro-intestinal catarrh, and thus tends to increase the general malnutrition. On the other hand, morphine is much better borne. At the present time almost all morphine habitués use the hypodermic syringe, and, notwithstanding the elimination of the drug in part by the gastric mucous membrane, thus escape in part its evil effects upon the organs of digestion, and remain for a long time, often despite enormous excesses, free from the nutritive disturbances which are almost characteristic of the habitual abuse of crude opium.

SYMPTOMATOLOGY.—The symptoms of the confirmed opium habit may be divided into two principal groups: first, the symptoms of chronic opium- or morphine-poisoning; and second, the symptoms due to the withdrawal of the drug.

I. Symptoms of Chronic Poisoning.—A considerable percentage of the individuals addicted to the opium habit preserve for a longer or shorter period of time the appearance of health; indeed, it is possible for very large doses of opium to be occasionally taken by certain individuals without appreciable impairment of the functions either of the body or the mind. These cases must, however, be looked upon as exceptional. It is estimated that from one-fourth to three-tenths of the entire population of China are addicted to the habit of opium-smoking. The statements of travellers concerning the effect of this habit are somewhat conflicting. When practised within bounds it appears to resemble in its effects the moderate use of alcoholic stimulants, increasing the ability to endure fatigue and diminishing for a time the necessity for food. In moderation it appears to have little injurious effect upon the general health. On the other hand, in the greater number of individuals the confirmed opium habit causes in a variable period of time symptoms of the most decided character; the appetite and general nutrition fail; emaciation is often rapid, commonly marked, and sometimes extreme. There are thirst and anorexia; a little later the patient begins to suffer from nausea with occasional vomiting. At this time a loathing for food alternates with *boulimia*. These occasional excesses in food are followed by *epigastric*

distress, heartburn, and great mental depression. The skin becomes relaxed, inelastic, and dull. Exceptionally, especially in women who use morphine hypodermically, embonpoint is preserved and the skin retains its normal tension and appearance. The countenance is pale, muddy, and sometimes slightly cyanotic. There is increased tendency to perspiration. Acne and urticaria are common. Herpes zoster is encountered with considerable frequency among opium subjects. In cases in which morphine is administered by means of the hypodermic syringe the resulting lesions of the skin are of importance. If the habit be concealed or denied, they are of diagnostic value. Not rarely they constitute serious affections in themselves. They are of all grades, from mere inflammatory points to coarse infiltration and ulceration. The wounds are frequently so thick set over the greater part of a limb as to present the appearance of a continuous eruption. In other cases scattered points of ulceration occur or extensive surfaces are occupied by a series of ulcerations varying in size from a split pea to an inch or more in diameter. Purulent inflammation of the subcutaneous tissues, with burrowing, also occurs. Numerous scars bear witness to the duration and extent of the habit. These lesions are usually due to unclean needles and impure solutions; in certain cases they are to be explained by the peculiarities of the individual as regards the tendency to inflammation of the integumentary structures; finally, instances are related in which immunity from skin lesions has existed in spite of rusty needles and carelessly kept solutions.

The expression of the countenance is sometimes dull, much more frequently furtive and timid. The repetition of the dose renders it eager and bright. The pupils are commonly contracted, sometimes enlarged, and occasionally unequal. Diminished power of accommodation is common, and diplopia has been occasionally observed.

The action of the heart is often irregular and weak. Disturbances of the vaso-motor system give rise to flushing of the face, irregular sensations of heat over the body, and sweating. It is probable that the albuminuria hereafter to be described is due to disturbance of the circulation in the kidneys. The pulse is variable; it is sometimes tense and full, sometimes small and thready, often irregular. The volume, tension, and rhythm of the pulse depend largely upon the state of the vaso-motor and general nervous systems. They vary according to the periods of stimulation, following doses or the periods of depression characterizing the intervals between the doses. Palpitations occasionally occur. Respiration is, as a rule, normal. Transient dyspnoea sometimes occurs after doses a little larger than usual. Subacute bronchitis is common. The urine is often diminished in quantity. Its specific gravity varies within extreme limits, being influenced rather by collateral circumstances than by the dose of opium or morphine consumed. In grave cases albuminuria occurs. Casts of various kinds are also encountered. As Levinstein¹ has pointed out, these changes in the urine are often transitory, disappearing upon the suppression of the opium habit.

In confirmed cases uric acid is increased and urea diminished. The chlorides are also diminished in amount. Vesical irritation is likewise common. It is apt to be accompanied by neuralgia of the urethra and

¹ *La Morphomanie*, 2d ed., Paris, 1880.

of the rectum. Strangury and retention of urine also occur in old cases. These complications are often followed by vesical catarrh.

Derangements of the central nervous system are constant and serious. The disorders which originally led to the use of opiates are in many instances intensified. The temper is capricious, fanciful, and discontented. There are giddiness, headache, and vertigo. Disturbed sleep, irregular flying neuralgic pains, and hyperæsthesia also occur. Spinal tenderness is occasionally encountered, with characteristic painful spots. Reflex excitability is augmented, but in aggravated cases the tendon reflexes are often impaired. Itching is common and troublesome. It may be local or general. Trembling of the hands and of the tongue also occurs. This tremor resembles in all particulars the tremor of chronic alcoholism, and, as many individuals addicted to the opium habit also abuse alcohol, it is not always easy to say to which of these poisons the symptom in question is to be referred: it may be due to their combined action. Disturbances of speech are not very uncommon. Sleeplessness is troublesome, but absolute insomnia is rare. The sleep which is obtained is late, irregular, and unrefreshing. In several cases that have occurred under the observation of the writer there has been habitual inability to sleep during the night, the patients wandering about, occupying themselves in attempts to read or write until toward morning, and then, under the influence of repeated doses, falling into a more or less profound slumber, which has often been prolonged till after midday. The effects of the dose upon the mind are in the early periods of the habit agreeable exhilaration, increased activity of imagination, and stimulation of the powers of conversation. These effects are sometimes manifested for a long period, and in many instances the most brilliant conversation, and among professional men and public speakers the ablest efforts, have followed the taking of large doses of opiates, and been followed in turn by periods of the most profound physical and mental depression. In the absence of the necessity for intellectual effort, and in individuals incapable of it, the mental condition produced by the dose is one of profound revery, largely influenced by the mental organization of the subject. This state is described, and in many particulars much exaggerated, in the writings of De Quincey, Coleridge, and others.

The voluptuous play of the imagination ascribed to the action of the drug by Orientals is for the most part absent among opium-takers in this country. If present at all, it occurs only to a limited degree. The corresponding fact is also worthy of note—namely, so long as the habit is continued the depression between the doses is less profound than that described as occurring in the East. One of the mental peculiarities of individuals addicted to the opium habit is secretiveness concerning their vice. Not infrequently, the real cause of the grave derangements of health thus produced is wholly unsuspected by the family or friends of the patient. When the habit is suspected or admitted, the amount and frequency of the dose are rarely fully known, patients almost invariably deceiving their friends in regard to the particulars of their indulgence. Individuals above reproach in other matters, and previously of unquestioned veracity, lie without any hesitation in this matter. A patient under my care who had secreted in her room a quantity of morphine when about to undergo treatment, denied either having taken or then having

in her possession any opium or morphine whatever, using the expression, "I call God to witness that I neither now have, nor have had since I began the treatment, any preparation of opium or morphine whatever." Within ten minutes sixty quarter-grain pills of morphine were discovered secreted under the bolster. This patient was a devout, refined, and, in regard to other matters, a trustworthy person.

The functions of the reproductive organs both in the male and in the female are seriously deranged. In the male sex enfeeblement of the sexual function is manifested in all degrees, even to complete loss of sexual desire and sexual power. In certain individuals opium and morphine in moderate doses produce some increase of sexual desire and power, which is, however, speedily lost on the continuance of the habit. Some doubt exists whether this is of psychical or physical origin—a question at once difficult to decide by reason of the reticence of opium-habitues upon this subject, and unimportant in itself. Levinstein makes the interesting statement that in no cases coming under his observation did the wives of morphomaniacs who had injected as high as fifteen grains of morphine a day reach the full term of pregnancy for two years prior to the treatment, notwithstanding the fact that they were still young, that they had borne children before their husbands had become addicted to morphine, and that they had not, up to the time of the formation of the habit by their husbands, suffered from premature accouchements.

Among women the morphine habit invariably produces derangement of the menstrual function. Menstrual irregularity, both as regards time and amount, is succeeded after a time by amenorrhœa. Vicarious hemorrhages do not occur. Complete amenorrhœa is sometimes established abruptly, and married women not infrequently suspect for this reason that they have conceived. In several cases of this kind under the observation of the writer the absence of enlargement of the breasts, of alteration of the areola, and of softening of the os after several months, indicated the improbability of these fears, notwithstanding the irregular appetite, the morning vomiting, the occasional palpitations and faintness, the hysterical condition, and the mental peculiarities of the individuals—phenomena unquestionably due to the action of the morphine itself. The amenorrhœa of the morphine habit is associated with sterility—a fact that renders probable the supposition that it is dependent upon absence of ovulation. Women addicted to the opium habit are capable of conceiving so long as menstruation persists, those only, however, going to full term who use very moderate quantities. In women using large doses abortion invariably occurs. The functional integrity of the reproductive system is re-established upon the permanent cessation of the habit. Women who are cured may again menstruate regularly and may again bear children. Morphine in women, as in men, is said to increase, when first habitually taken, the capacity for sexual pleasure.

Levinstein and others have described certain febrile conditions observed in individuals addicted to morphine. First, a form of intermittent fever closely resembling malarial fever. This fever of intermittent type occurs in individuals neither living in malarious regions nor previously exposed to malaria. In addition to periodicity, it presents other points of resemblance to malarial intermittent. The earlier paroxysms cease after the

administration of quinine. They are favorably influenced by change of residence, and recur with intensity after over-exertion, exposure, and upon the occurrence of acute maladies. The favorable influence of quinine is only transient; the febrile paroxysms recur after a time, notwithstanding the continued use of the medicament. This fever disappears without special treatment upon the discontinuance of the habit. It is more frequently of the tertian than of the quotidian type. Its paroxysms are marked by the symptoms of paludal intermittent. Neuralgias of various kinds, especially supraorbital, intercostal, and præcordial neuralgias, are apt to occur. The temperature during the paroxysm ranges from 102.5° to 104° . The area of splenic dulness is increased. More or less mental and physical depression follows the paroxysm, continuing in most cases through the period of apyrexia. These observations require further confirmation. Secondly, confirmed opium-habituated are peculiarly liable to transient febrile disturbances from slight causes. Finally, ephemeral fever, ushered in by chills or rigors and accompanied by headache, vertigo, thirst, malaise, restlessness, and even mild delirium, and terminating with profuse perspiration, occasionally occurs immediately after the injection of large doses of morphine.

The course of the opium habit, when once established, is, notwithstanding its occasional transient interruptions, gradual and progressive. Certain individuals endure enormous doses of opium or morphine for years without serious symptoms. In others moderate doses give rise in the course of a few months to anorexia, disturbances of nutrition, neuralgias, fitful and difficult sleep, and serious mental derangement. These symptoms are usually controlled by increasing doses and diminution of the intervals. Finally, however, the drug fails to produce either excitement or repose, and enormous doses are taken with but insignificant relief. This is the period of grave derangement of the mental and physical functions and of nutrition amounting to a true dyscrasia. The phenomena are analogous to those produced by the withdrawal of the dose. They are the symptoms of inanition, which in the absence of well-directed and energetic treatment speedily terminates in death.

II. Symptoms Due to the Withdrawal of the Drug.—Opium-habituated, differing as they do among themselves in the manifestations of the effects of the drug so long as it is freely taken, all alike develop characteristic symptoms upon its speedy or gradual withdrawal. The apparent immunity exceptionally observed now comes to an abrupt termination. The nervous system, whether it has been accustomed for months merely or for years to the influence of opiates, is upon their withdrawal forthwith thrown into derangement of the most serious and widespread kind. In the course of a few hours after the last dose the steady influence of the drug disappears. General malaise is associated with progressive restlessness; the ability to perform the ordinary duties of life gives way to profound depression and indifference; præcordial distress, accompanied by cough, is followed by insomnia, hallucinations, and sometimes by mania. The habitual pallor of the face is replaced by deep flushing or cyanosis. The heart's action becomes excited and irregular, then feeble; the pulse, at first tense, becomes slow, thready, and irregular. Colliquative sweats appear. Attacks of yawning and sneezing are followed by convulsive twitching and trembling of the hands. Speech becomes hesitating, drawling, and

stuttering. Troubles of the accommodation and even diplopia occur, often accompanied by excessive lachrymation. Transient and varying differences in the pupils are very frequent. Retinal hyperæsthesia may occur. In the amblyopia occasionally observed in subjects of the opium habit the ophthalmoscope reveals persistent anæmia of the retina. These phenomena are associated with a sense of perfect prostration which obliges the patient to take himself to his bed. Pain in the back and limbs, followed by neuralgias, now occurs. Complete anorexia, with easily-provoked or even causeless vomiting and persistent nausea and diarrhœa difficult to control, adds to the gravity of the condition. The abrupt discontinuance of the drug is followed in many individuals by mental phenomena of a marked character: hallucinations, illusions, and delirium continue for several days. The hallucinations relate to all of the senses, but especially to those of sight and hearing. The sense of smell is also occasionally affected, that of taste rarely. Syncopal attacks occur. These are usually transient; occasionally, however, profound syncope calls for the active interference of the physician. Epileptiform seizures also take place. Women who have previously suffered from hystero-epilepsy are prone to the recurrence of severe paroxysms. Trembling of the limbs, and especially of the lower extremities, rhythmical in time and often violent, must be ranked among the more characteristic phenomena produced by the abstinence from the drug. Sweating, although by no means constant, is among the earlier and more persistent phenomena. Urticaria occurs. Dyspnoea is common. Sometimes it is provoked by exertion; sometimes paroxysmal shortness of breath occurs spontaneously. Irritable cough is frequent. It is in many cases unattended by râles. Pre-existing bronchitis is of course accompanied by its characteristic signs and symptoms. Præcordial distress, with palpitation and a sense of oppression, is common. During the earlier days of abstinence the evidences of cardiac failure are marked. Enfeeblement of the first sound, irregularity of the heart's action, and intermission are common. The pulse phenomena correspond to the heart's action. Thirst is a very frequent symptom. It is often out of proportion to the loss of fluid by perspiration and diarrhœa. The urine does not contain sugar. Salivation is rare and of moderate degree. Nausea is persistent. Œsophageal spasm, provoked by every effort to swallow, occasionally occurs and constitutes a distressing symptom. Many patients also complain of spasmodic contraction of the anus. Neuralgia of the testicles also occurs. The cure of the opium habit is followed by rehabilitation of the sexual power in the male and by menstrual regularity and fecundity in the female. Levinstein has observed sexual hyperæsthesia during the first weeks of abstinence in both sexes. Albuminuria occurs in a large proportion of the cases. The albumen shows itself, as a rule, from the third to the sixth day after the discontinuance of the morphine, and disappears in the course of a very few days. It is usually of slight amount.

The behavior of patients undergoing the suffering attendant upon the abrupt, or even the gradual, withdrawal of the drug is variable. It depends upon the mental and physical organization of the different individuals and upon their ability to endure pain. Some rest quietly in bed, enduring with fortitude suffering from which there is no escape; others, silent, uncomplaining, and apathetic, present the appear-

ance of utter despair; a few, more fortunate than their fellows, lapse into a condition of almost continuous drowsiness. In the greater number of cases, however, these states of repose are but momentary or absent altogether. Restlessness is continuous, and very often intense; the patients are with difficulty kept in bed; if left to themselves they move frantically about the room, moaning, bewailing their condition, and begging the attendants for that which alone is capable of relieving their distress. This condition gradually subsides, giving way to a state of the most profound exhaustion. The exhaustion due to the reaction of the nervous system deprived of the stimulus of the drug is, on the one hand, favored by pre-existent derangement of the nutritive processes, and on the other increased by the pain, wakefulness, diarrhœa, and vomiting which accompany it. The appearance of the patient is now most pitiable; the countenance is blanched and pinched, the body occasionally drenched with sweat; the heart's action is feeble, and the pulse thready and irregular. This condition of collapse is usually of short duration, disappearing in favorable cases under the influence of appropriate nourishment administered in small quantities and with regularity. Where, however, the gastric irritability is unmanageable, an increasing tendency to collapse may threaten life. In rare cases suddenly-developed fatal collapse has occurred at a later period in the treatment, even after the patient has become able to take and retain food. The restlessness does not, however, always subside in this manner. In a considerable proportion of cases it increases. Hallucinations and delusions occur, and a condition of delirium tremens, scarcely differing from the delirium tremens of chronic alcoholism, is established. Tremor is a constant phenomenon of this condition. Sometimes the gravest symptoms of the suppression of the drug are developed with great rapidity. Jouet relates a case of a patient at the Salpêtrière who during a temporary absence from the hospital forgot her syringe and solution; her return being delayed from some cause, she, notwithstanding her struggles against the symptoms caused by the want of her habitual dose, suddenly fell in the street, her countenance haggard and anxious, her hands shrivelled, and her whole body bathed in drenching sweat. She immediately became maniacal, and demolished the glass and lamps of the coupé in which she was taken to the hospital. No sooner had she received her ordinary hypodermic dose than she recovered her usual quietude. This patient was neither hysterical nor had she previously suffered from nervous paroxysms. She was, however, accustomed to administer to herself at four o'clock every day a large hypodermic dose of morphine, and it was at a few minutes past four that the above-described seizure occurred.

DIAGNOSIS.—The diagnosis of the opium habit is in many cases attended with considerable difficulty. Many habitués, it is true, do not hesitate to admit the real cause of their symptoms; others, while seeking to conceal it, do so in such an indifferent manner that detection is not difficult; but the greater number for a long time sedulously conceal their passion, not only from their friends, but also from the physician whom they consult voluntarily or at the solicitation of those interested in them. If inquiries be made upon the subject, they deny the habit altogether, often with vehement protestations. If forced to admit it, they are very apt to misstate the amount employed or the frequency of the repetition of the dose. As a rule—to which there are, however, not infrequent exceptions—emacia-

tion is marked, appetite is diminished and variable, the pulse is small, the circulation feeble, the respiration shallow and occasionally interrupted by long-drawn sighs, the pupils are as a rule contracted, constipation is present, often alternating with diarrhœa. When to these conditions, for which no cause can be found upon careful examination, there are added marked change in disposition, periods of unaccountable dulness and apathy alternating with unusual vivacity and brightness, especially when insomnia alternates with periods of prolonged and heavy sleep, the abuse of morphia may be suspected. If the hypodermic syringe be used the wounds made by the needle confirm the diagnosis. These punctures are usually found in groups upon the thighs, legs, arms, and abdomen. Close inquiry into the habits of the patient, who either goes himself or sends at short intervals for unusual quantities of opium or morphia to some neighboring apothecary, is sometimes necessary to confirm the diagnosis. Finally, the presence of morphine in the urine¹ renders the diagnosis positive, notwithstanding the most vehement assertions of the patient as regards his innocence of the habit and the extreme cunning with which it is concealed.

PROGNOSIS.—The prognosis is favorable as regards the discontinuance of the habit for a time, doubtful as regards a permanent cure. Relapses are apt to occur. They are more common in men than in women, in the aged than in middle life, and in persons of feeble physical and mental organization than in those who are possessed of bodily and mental vigor. Relapses also occur more frequently in those individuals addicted to alcohol, and in those who are habitually subjected to temptation by reason of their avocation, such as doctors, nurses, and apothecaries, than in others. The danger of relapse is greater where the habit has been formed in consequence of chronic painful affections than where it has been rapidly developed in the course of acute illnesses. Of 82 men treated by Levinstein, relapses occurred in 61; of 28 women, in 10; of 38 physicians, in 26. The danger of relapse diminishes with the lapse of time; nevertheless, a single dose of morphine or a hypodermic injection may, after an abstinence of months, precipitate a relapse. Indeed, the return of the habit is in the majority of instances caused by the thoughtlessness of medical men in prescribing in these cases opiates for maladies which are often in themselves insignificant.

Chloral Hydrate.

The prediction made by B. W. Richardson, within two years of Liebreich's announcement of the medicinal properties of chloral, that its

¹ "According to Bouchardat, morphine, when taken in the free state or under the form of opium, speedily appears in the urine, and may be detected by the liquid yielding a reddish-brown precipitate with a solution of iodine in iodide of potassium. Since, however, as we have already seen, this reagent also produces similar precipitates with most of the other alkalies and with certain other organic substances, this reaction in itself could by no means be regarded as direct proof of the presence of the alkaloid. Moreover, we find that the reagent not unfrequently throws down a precipitate from what may be regarded as normal urine, while, on the other hand, it sometimes fails to produce a precipitate even when comparatively large quantities of the alkaloid have been purposely added to the liquid" (Wormley, *Micro-chemistry of Poisons*).

The presence of meconic acid or morphine in the urine can only be positively determined by elaborate chemical analysis. In cases of doubt the urine should be submitted to a competent analyst. To make sure that opium or its derivatives are not being taken, the feces must also be examined.

abuse would become widespread, has been abundantly fulfilled. The consumption of this substance as a narcotic has reached an extent in certain classes of society which raises it, after alcohol and opium, to the third place among such agents.

SYNONYMS.—The Chloral habit, Chloralism.

ETIOLOGY.—*A.* Predisposing Influences.—Age exerts but little predisposing influence. Cases occur almost exclusively in adults, and the greater proportion of these are in middle life. The abuse of chloral is relatively somewhat more common among males than among females. Individuals addicted to this habit usually belong to the refined and educated classes of society; the fascinations of chloral remain thus far unknown to the great mass of the people. Professional men and those engaged in literary work form a very considerable proportion of the cases. Chloral is occasionally used by hospital nurses, and very frequently by prostitutes. Chronic alcoholism is an important predisposing element in the formation of the chloral habit; in fact, morbid conditions attended by insomnia from whatever cause tend to the formation of this habit.

B. The Exciting Cause.—Chloral is a powerful hypnotic, usually without unpleasant after-effects. In full doses it is a depressant to the nerve-centres at the base of the brain and to the spinal cord. It enfeebles the action of the heart, depresses respiration, and lessens reflex activity. It has no action on the secretions except that of the kidneys, which it frequently augments.

The habit has in some few instances been developed in consequence of the indulgence in a morbid desire to experience the effects of the drug. In a majority of instances it is due to the continuance of the medicine indefinitely after the sickness in which it was originally prescribed has ceased. I have known apothecaries to renew prescriptions of chloral often enough to supply a daily dose of from forty to sixty grains for years—in one instance for more than four years.

The dose taken by victims of the chloral habit varies greatly. Thirty or forty grains daily is a moderate amount. Not rarely this quantity is repeated twice or oftener within the space of twenty-four hours. The tolerance after a time exhibited by the organism for enormous doses of alcohol and opium is not established, as a rule, in regard to chloral. The victim of the latter after a little time discovers the average dose required to produce narcotic effects, and, while he may vary it within limits, he is liable to acute toxic effects if it be greatly exceeded. Death from such excesses is not uncommon.

SYMPTOMATOLOGY.—*I.* Symptoms Due to Habitual Excesses.—The habitual use of chloral, notwithstanding its ruinous consequences in a certain proportion of the cases, is less dangerous than that of opium or morphine. Many individuals take chloral in considerable doses for years without obvious ill effect. The craving for it is much less intense than that for opium or morphine, and is readily satisfied by other drugs. In point of fact, persons addicted to chloral very frequently exchange it for other narcotics. For these reasons the chloral habit is more easily cured.

Derangements of the digestive system are common, but by no means constant. They are (1) primary, and due to the direct irritant action of the drug upon the mucous tissues of the mouth and stomach; and (2) secondary, due to its effects upon the nervous system and the circulation.

Irritation of the mucous membranes is very common. This not rarely amounts to gastro-duodenal catarrh with its characteristic symptoms. Jaundice is common, sometimes intense. A sense of fulness with pain and tenderness in the hepatic region is frequent. Constipation, with clay-colored stools, is the rule. It occasionally alternates with diarrhœa. The tongue is often coated and the breath foul. On the other hand, in a fair proportion of the cases the digestive organs are not affected. Chloral has been said to occasionally exert even a favorable influence upon appetite and digestion when taken before meals. The recent observations of Fiumi and Favrat¹ in a man suffering from a gastric fistula and insomnia have shown that chloral hydrate in twenty- or forty-grain doses, administered before or at the beginning of a meal, retarded digestion by increasing the secretion of mucus in the stomach. The acidity of the gastric juice is diminished temporarily. The secretion of pepsin is not changed. Taken two hours after meals, doses not exceeding forty grains caused no derangement of gastric digestion.

Persons not habituated to chloral usually experience a sense of constriction upon swallowing it, and a disagreeable after-taste.

The circulation is much affected. Chloral weakens, and finally paralyzes, the vaso-motor centre, and thus dilates the vessels; it at the same time weakens the action of the heart. Its habitual use is attended by flushing of the face, congestion of the eyes, and fulness of the head. The heart's action is weak, intermittent, irregular; palpitation occurs; the pulse is full and compressible or small and weak. It is usually slow.

The blood undergoes changes corresponding to the general disturbances of nutrition. What the special changes in its composition may be is not known. Many of the cases, even after the prolonged use of the drug in considerable doses, show few evidences of malnutrition or of anæmia. In the greater number, however, wasting is marked, and the physical signs and rational symptoms of profound anæmia are present. Deterioration in the composition of the blood is further indicated by petechiæ, hemorrhage from mucous surfaces, sponginess of the gums, and serous effusions.

The respiration is not permanently affected, save in grave cases. It is then slow, irregular, and shallow. Dyspnœa is common and easily provoked. It is usually accompanied by cough and abundant frothy expectoration. These symptoms vanish upon the discontinuance of the drug. In a fatal case of chloral-poisoning seen by the writer, in which the daily use of the narcotic in non-poisonous amounts had been for a long time varied at intervals of five or six weeks by doses sufficient to induce prolonged coma, death was preceded by Cheyne-Stokes respiration. This patient was a retired dentist, and kept the solution of chloral in a large unlabelled bottle. The actual doses taken were not ascertained.

The muscular system shares in the general malnutrition. The muscles become flabby and wasted. Persons addicted to chloral are very frequently of nervous organization and sedentary habits, and hence of poor muscular development prior to the use of the drug.

The kidneys show no constant derangement. In a certain proportion of the cases chloral acts as a diuretic, largely increasing the urinary excretion. Albumen is present in a certain proportion of the graver

¹ *Archives Ital. de Biologie*, vol. vi. No. 3.

cases, when it is apt to be associated with anæmia, serous effusions, and a tendency to hemorrhages from mucous tracts. The occurrence of casts and the persistence of albuminuria after the discontinuance of chloral suggest an antecedent or coincidently developed nephritis. The reducing substance present in the urine after small doses of chloral is uro-chloralic acid (Mering and Musulus). It gives the reaction of sugar with the copper and bismuth tests, but is levogyrate. Glycosuria is occasionally encountered.

Vesical and urethral irritation occurs in a small proportion of the cases. When these symptoms vanish upon the discontinuance of the drug and recur upon its resumption, it may be fairly assumed that they are due to its action. A great number of morbid phenomena relating to the genito-urinary tract and to the urine, that have been ascribed to the action of chloral in those addicted to its use, are due to associated conditions rather than to the drug itself.

It has been claimed upon evidence that does not appear to the writer adequate that chloral sometimes acts upon the sexual system as an aphrodisiac, sometimes as the reverse. More or less complete impairment of sexual power and appetite is the rule in individuals addicted to great excesses in narcotics of all kinds. Menstruation is not arrested by chloral as by morphine, nor does it necessarily cause sterility in the female.

The skin undergoes nutritive disturbances of a marked kind. As a result of individual peculiarity, single doses or medicinal doses continued for brief periods of time have occasionally caused erythematous, urticarious, papular, vesicular, and pustular eruptions. Of these, the first named is of most frequent occurrence. The habitual abuse of chloral causes in many individuals chronic congestion of the face, neck, and ears. This redness is often very striking. It is increased by the use of alcohol. Erythematous patches upon the chest, in the neighborhood of the larger articulations, and upon the backs of the hands and feet, also occasionally occur. They are often associated with urticaria. General eruptions resembling measles, scarlatina, and even mild variola, are said to have been observed after large doses of chloral. Purpura is by no means rare in old cases, and falling of the hair and atrophy and loss of the nails occur.

The nervous system bears the blunt of the disturbance, and the more significant symptoms relate directly to it.

The hypnotic effect is usually preserved. Hence the chloral habitué is dull, apathetic, somnolent, disposed to neglect his ordinary duties and affairs. He passes much of his time in a state of dreamy lethargy or in deep and prolonged sleep, from which he awakes unrefreshed and in pain. In one of my cases, however, even larger doses than usual at length failed to induce more than fitful slumber, and the insomnia which led to the formation of the habit finally reasserted itself, reinforced by the unutterable miseries of chloralism.

Headache is a frequent symptom. It is usually general, sometimes frontal, often referred to the top of the head. It is commonly severe, not rarely agonizing, and is described as a pressure, weight, or a constricting band. It is associated with injection of the eyes, flushing of the face, confusion of thought, inability to converse intelligently or to articulate distinctly, and other evidences of cerebral congestion. Vertigo is common.

Sensory disturbances are frequently present. They consist in local areas of hyperæsthesia, more frequently of anæsthesia, numbness of the hands and fingers or of the feet, formication of the surface of the body and limbs, and burning or neuralgic pains in the face, chest, and extremities. The pains in the limbs are almost characteristic. They are acute and persistent, neuralgic in character, but not localized to particular nerve-tracts. They are more common in the legs than in the arms, and occupy by preference the calves of the legs and the flexor muscles between the elbows and the wrists. They do not implicate the joints, are not aggravated to any grave extent by movement, and are often temporarily relieved by gentle frictions. The pains of chloralism have been described as like encircling bands above the wrists and ankles.

Sensations of chilliness alternating with flashes of heat are experienced. The temperature is, in the absence of complications, normal. Excessive doses are followed by a reduction of one or more degrees Fahrenheit, lasting several hours.

Among the motor disturbances are the following:

Tremor.—This symptom is not common. It is neither so pronounced nor so distinctly rhythmical as that of alcoholism or the opium habit. It is increased upon voluntary effort. It affects chiefly the hands and arms and the tongue.

Palsy.—Loss of power in the lower extremities has been observed in a number of instances. It varies in degree from paresis to complete paraplegia. Its occurrence may be gradual or sudden. It passes away upon the discontinuance of the habit. In many respects this condition resembles alcoholic paraplegia.

Impairment of Co-ordinating Power.—Ataxic phenomena are sometimes present. The patient has difficulty in walking in the dark, cannot stand with his eyes closed, has trouble in buttoning his clothes, and the like.

Impairment or Abolition of the Knee-jerk.—In a man aged fifty, who had taken thirty to sixty grains of chloral hydrate at night for eighteen months, the writer observed complete loss of the knee-jerk, which, however, reappeared in the course of a few weeks after the discontinuance of the drug.

In rare cases epileptiform seizures have occurred.

Chloral produces in certain individuals, even as the result of a single dose, congestion and irritation of the conjunctiva. Apart from this idiosyncrasy, its habitual use not infrequently causes conjunctivitis. This affection is occasionally of a severe grade and accompanied by œdema of the eyelids and great photophobia. Retinal congestion has been noted by several observers. Amblyopia, disappearing upon the cessation of the habit, has also been observed.

Psychical Derangements.—The mental and moral perversion caused by immoderate chloral-taking shows itself rapidly. The transient stimulating effects of the dose of opium or morphine in those accustomed to these drugs are seen not at all or to a very slight extent in chloralism. Hence the mental state is characterized by dulness, apathy, confusion, and uncertainty. These conditions alternate with periods of irritability and peevishness. The physical sufferings of the chloral-taker in the daily intervals of abstinence are greater than those of the morphine-

taker; his mental depression less. The one is tormented by the agony of pain, the other by the anguish of craving. To the former repetition of the dose brings stupor and sleep, to the latter exhilaration and activity. In certain respects, however, the effects of these drugs upon the mind are similar. They alike produce intellectual enfeeblement, inability to concentrate the mind, habitual timidity, and impairment of memory. In the worse cases of chloralism hallucinations, delusions, and delirium occur. Acute mania may occur, and dementia constitutes a terminal state.

II. Symptoms Due to Abstinence from Chloral.—The symptoms occasioned by the abrupt discontinuance of even large habitual doses of chloral are not, as a rule, severe. In this respect the difference between this drug and opium and its derivatives is very marked. The chloral-taker not infrequently substitutes some other narcotic, as alcohol or opium, for his usual doses without discomfort, and in many instances voluntarily abstains from the drug, without replacing it by others for periods of weeks or months.

The more important of the symptoms induced by sudden discontinuance relate to the nervous system. Insomnia is usual. It is not always readily controlled, and constitutes one of the principal difficulties in the management of these cases. Headache is rarely absent; it is in many cases accompanied by vertigo. Occipital neuralgia frequently occurs, and is often severe. Neuralgias of the fifth pair also occur. Darting pains in the limbs are usual, and the fixed aching pains already described as peculiar to habitual chloral excess are present, and often persist for a long time after the withdrawal of the drug.

Irregular flushes of heat, nervousness, restlessness, inability to fix the attention, formication, burning sensations in various regions of the surface of the body, are unimportant but annoying symptoms.

In a considerable proportion of the cases delirium occurs. It is commonly associated with tremor, great prostration, complete insomnia, sweating, inability to take food, and vomiting, and resembles in every particular the delirium tremens of alcoholic subjects. In the absence of this condition gastric derangements are not of a grave kind. The nausea, vomiting, epigastric pain, and diarrhœa which are induced by the discontinuance of opium are absent, or if present at all only to a slight degree. As a matter of fact, the functions of the digestive system are in a very short time much more perfectly performed than before. Hemorrhage from the stomach, bowel, or urinary tract may also occur.

The conjunctivitis and cutaneous eruptions usually disappear with promptness as soon as the influence of the habitual chloral excesses passes away.

DIAGNOSIS.—The diagnosis of the chloral habit is attended with much less difficulty than that of the morphine habit. In the first place, there is general and often serious derangement of health without adequate discoverable cause. The appetite is poor and capricious, the digestion imperfect and slowly performed; jaundice of variable intensity, often slight, sometimes severe, occurs in many cases; the bowels are not, as a rule, constipated. Dyspnœa upon slight exertion is, in the absence of pulmonary, cardiac, or renal cause, of diagnostic importance. The circulation is, as a rule, feeble. Disorders of the skin, persistent or easily provoked conjunctivitis, puffiness about the eyelids, and a tendency to hemorrhage

from mucous surfaces also occur. When with these symptoms, irregularly grouped as they are, we find a tendency to recurring attacks of cerebral congestion, persistent or frequently recurring headaches, and the characteristic pains in the legs, the abuse of chloral must be suspected. This suspicion becomes the more probable if there be a history of protracted painful illness or of prolonged insomnia in the past. The adroitness of these patients in concealing their vice, and the astonishing persistency with which they deny it, are remarkable. In the absence of the characteristic association of pains, conjunctivitis, and affections of the skin the diagnosis is attended with considerable difficulty. It becomes probable from the association of chronic ill-health, not otherwise explicable, with perversion of the moral nature, enfeeblement of the will and of the intellectual forces. It is rendered positive, notwithstanding the denials of the patient, by the discovery of the drug or the prescription by means of which it is procured.

PROGNOSIS.—If the confirmed chloral habitué be left to himself, the prognosis, after excessive doses or the stage of periodical debauches has been reached, is highly unfavorable. The condition of mind and body alike is abject. There is danger of sudden death from cerebral congestion or heart-failure—a mode of termination by no means rare.

On the other hand, the prognosis under treatment may be said to be favorable. The habit is much more readily broken up, and the danger of relapse is far less, than in cases of confirmed opium or morphine addiction. Nevertheless, the underlying vice of organization which impels so many individuals to the abuse of narcotics precludes a permanent cure in a certain proportion of the cases of chloralism. Sooner or later relapse occurs—if not relapse to chloral, relapse to opium, morphine, or alcohol, or into that wretched condition in which any narcotic capable of producing excitement and stupor is taken in excess as occasion permits.

Paraldehyde.

The use of this hypnotic is not unattended with danger. In a single case afterward under the observation of the writer paraldehyde was used in large and increasing doses for the sake of its narcotic properties. The patient, a young married woman whose family history was bad, her mother having died insane, contracted the chloral habit after an acute illness. After some months a cure was effected without great difficulty. She relapsed into chloralism after a second sickness which was attended with distressing insomnia. The habit was again broken up. In consequence of over-exertion in social life during a winter of unusual gayety insomnia recurred. For the relief of this condition paraldehyde was prescribed with success. Notwithstanding its disagreeable and persistent ethereal odor, and the precautions taken by the physician, this lady managed to secure paraldehyde at first in small quantities, afterward in half-pound bottles from a wholesale druggist, and took it in enormous amounts, with the result of producing aggravated nervous and psychical disturbances corresponding to those produced by chloral, but without the disturbances of nutrition attendant upon the abuse of the latter drug. The patient remained well nourished, retained her appetite and digestion, and was free

from disorders of the skin and the intense neuralgia which had been present during both periods of chloral abuse. She suffered, however, from a persistent binding headache, disturbances of accommodation, phosphenes, and brow-pains. Under the influence of moderate doses she was enabled to take part in social life with some of her old interest and vivacity. The brief intervals of abstinence which occasionally occurred were characterized by distressing indifference to her friends and surroundings and by apathy and depression. At frequently-recurring intervals the indulgence in excessive doses, constituting actual paraldehyde-debauches, was followed at first by maniacal excitement of some hours' duration, later by profound comatose sleep lasting from one to three days. Upon the complete withdrawal of the drug this patient manifested the symptoms produced by complete abstinence in the confirmed morphine habit—yawning, anorexia, epigastric pains, vomiting, diarrhoea, absolute sleeplessness, extending over several days, heart-failure, collapse, colliquative sweating, and finally well-characterized delirium tremens. At the end of a week, under the influence of repeated small doses of codeine, sleep was secured, and within a month convalescence was complete. This person now continues free from addiction to any narcotic, in good health, and able to sleep fairly well, after the lapse of several months since the complete discontinuance of paraldehyde.

Cannabis Indica, Ether, Chloroform, and Cocaine.

These drugs are habitually used as narcotic stimulants by a limited number of individuals. Cannabis indica, or Indian hemp, the hashhish of the Arabians, is said to be largely used in India and Egypt. It is occasionally taken by medical students and other youths of an experimental turn of mind, but no case of habitual hashhish addiction has come under the observation of the writer.

The use of ether as a narcotic stimulant is occasionally observed among druggists, nurses, and other hospital attendants, but does not give rise to clinical phenomena sufficiently marked or distinctive to demand extended consideration in this article. The same remark may be made of chloroform, which is also used in the same way to a considerable extent among women suffering from neuralgia and other painful or distressing affections of the nervous system. The fact that individuals are every now and then found dead in bed with an empty chloroform-bottle by their side serves to indicate the extreme danger attending the vicious use of this substance.

Cocaine, within the short time that has elapsed since its introduction into therapeutics, has unquestionably been largely abused, both within the ranks of the profession and among the people. Highly sensational accounts of the disastrous effects resulting from its habitual use in excessive doses have appeared in the newspapers and in certain of the medical journals. No case of this kind has fallen under the observation of the writer, and it would appear premature to formulate definite conclusions concerning the effects of cocaine upon the data thus far available.

Treatment.

The treatment of the opium habit and kindred affections is a subject which derives its importance from the following facts: First, the gravity of the disease, as regards the functions both of the body and of the mind; second, the enormous suffering and misfortune, alike on the part of the patient himself and on the part of those interested in him, which these affections entail; third, the fact that they are not self-limited, and therefore cannot be treated with indifference or upon the expectant plan, but are, on the other hand, progressive and gradually destructive of all that makes life worth living, and at last of life itself; and finally, because they are capable at the hands of skilful and experienced physicians of a cure which in a considerable proportion of the cases may be made permanent.

The treatment of these affections naturally arranges itself under two headings: (*a*) the prophylactic, (*b*) the curative treatment.

a. Prophylaxis.—It is impossible to overrate the importance of a true conception of the duty of practitioners of medicine in regard to the prophylaxis of the opium habit and associated affections. In communities constituted as are those in which the physicians practise into whose hands this volume is likely to fall, a large—I may say an enormous—proportion of the cases of habitual vicious narcotism is due to the amiable weakness or thoughtlessness of medical men. A majority of the cases occur either in chronic painful affections attended or not by insomnia, or as a result of acute illness in which narcotics have been employed to relieve pain or induce sleep. The chronic affections constitute two classes: First, those manifestly incurable, as visceral and external cancer, certain cases of advanced phthisis, confirmed saccharine diabetes, and tabes dorsalis. In such cases the use of morphine in large and often-repeated doses, although attended with evils and likely to shorten life, amounts to a positive boon. It is neither practicable, nor would it be desirable, to interfere with it. To this class may be added those cases of grave valvular or degenerative disease of the heart where the patient has become addicted to the habitual use of narcotics. Here, notwithstanding the evils resulting from these habits, among which the likelihood of shortening the period of life must unquestionably be counted, the dangers of the withdrawal of the drug are so great that it must be looked upon as neither desirable nor feasible. Attention must, at this point, be called to the fact that great caution is required in the management of pregnant women addicted to narcotics. Incautious attempts to withdraw the habitual drug are almost certain to be followed by speedy loss of the foetus; and it is to my mind questionable whether anything more than the most guarded reduction of the daily dose should be attempted while the pregnancy continues.

The second class of chronic cases includes individuals suffering from diseases which are remediable or capable of decided or prolonged amelioration. Among these affections are painful diseases curable by surgical procedures, such as certain obstinate and intractable localized neuralgias, painful neuromas, irritable cicatrices, pelvic and abdominal tumors, and surgical affections of the joints and extremities. Here, either before or after radical surgical treatment, an effort to relieve the patient from the bondage of habitual narcotism should be made. For reasons that are

obvious, measures having this end in view should be instituted by preference subsequently to surgical treatment. To this class also belong certain painful affections occupying the border-region between surgery and medicine. These are floating kidney, renal and hepatic abscess, calculous pyelitis, cystitis, impacted gall-stones, and thoracic and abdominal aneurism. In these cases the possibility of a cure renders it in the highest degree desirable that the opium habit should be stopped. Whether this attempt should be made while the patient is under treatment for the original affection, or deferred until relief has been obtained, is a question to be decided by the circumstances of the particular case under consideration. Finally, we encounter a large group of chronic painful affections coming properly under the care of the physician in which the opium habit is frequently developed. This group includes curable neuralgias of superficial nerves, as the trigeminal, occipital, brachial, intercostal, crural, and sciatic, and visceral neuralgias, as the pain of angina, gastralgia, enteralgia, and the pelvic and reflex neuralgias of women. Here also are to be mentioned the pains of neurasthenia, hypochondriasis, and hysteria. In this group of affections the original disease constitutes no obstacle to the attempt to break up the habit to which it has given rise.

The practice of using narcotics, especially the preparations of opium, in large and increasing doses for the relief of frequently-recurring pains, especially in neurotic individuals, is a dangerous one. When necessary at all, the use of these drugs should be guarded with every possible precaution. In the first place, in so far as is practicable, the patient should be kept in ignorance of the character of the anodyne used and of the dose. In the second place, the physician should personally supervise and control, in so far as is possible, the use of such drugs and the frequency of their administration, taking care that the minimum amount capable of producing the desired effect is employed. In the third place, the occasional alternation of anodyne medicaments is desirable. Fourthly, an effort—which, unfortunately, is too often likely to be unsuccessful—should be made to prevent repeated renewals of the prescription without the direct sanction, or indeed without the written order, of the physician himself. Finally, the danger of yielding to the temptation to allow a merely palliative treatment to assume too great importance in the management of painful affections must be sedulously shunned. Too often these precautions are neglected, and the patient, betrayed by a dangerous knowledge of the drug and the dose by which he may relieve not only physical pain, but also mental depression, and tempted by the facility with which the coveted narcotic may be obtained, falls an easy victim to habitual excesses. The lowered moral tone of convalescence from severe illness and of habitual invalidism increases these dangers. Yet more reprehensible than the neglect of many physicians in these matters is the folly of the few who do not hesitate to fully inform the patient in regard to the medicines given to relieve pain or induce sleep, and to place in his hands designedly the means of procuring them without restriction for an indefinite period of time. Almost criminal is the course of those who entrust to the patient himself or to those in attendance upon him the hypodermic syringe. No trouble or inconvenience on the part of the physician, no reasonable expense in procuring continuous medical attendance on the part of the patient for the sake of relief from pain, can ever offset, save in cases of the final stages

of hopelessly incurable painful affections, the dangers which attend self-administered hypodermic injections.

The uniform and efficient regulation of the sale of narcotic drugs by law would constitute an important prophylaxis against habitual narcotism. Unfortunately, the existing laws relating to this subject are a dead letter. They are neither adequate to control the evil nor is their enforcement practicable. Nostrums containing narcotics, and particularly opium and morphine, in proportions that occasionally produce fatal results are freely dispensed at the shops to all comers. Prescriptions calling for large amounts of opium, morphine, codeia, chloral, cannabis indica, etc. are dispensed to the same individuals at short intervals over the counters of apothecaries for months or years after the illness in which they were originally prescribed is over. Yet more, occasional cases come to light which serve to indicate the appalling frequency with which opium, its tincture, morphine, and solutions of chloral are directly sold to unauthorized individuals. If the evil thus accomplished were better understood, the paltry profit realized from such nefarious trading would rarely tempt men to the commission of the crime which these practices constitute.

Finally, the dissemination of a wholesome knowledge of the methods by which the opium habit and kindred affections are induced, of the serious character of these affections, and of the dangers attendant upon an ignorant and careless employment of narcotics, would constitute an important measure of prophylaxis. I am fully aware of the evils resulting from the publication of sensational writings relating to this subject. Notwithstanding these dangers, I am convinced that a reasonable and temperate presentation of the facts in the popular works upon hygiene used in schools and in the family would exercise a wholesome influence in restraining or curing the tendency to the practice of these vices.

Where these habits have resulted in consequence of the medicinal abuse of narcotics in acute cases from which the patient has long recovered, a determined effort to break them up should at once be instituted.

b. The Curative Treatment.—The responsibility assumed by the physician in attempting to cure patients suffering from the confirmed abuse of narcotics is often a serious one. Much judgment must be exercised in the selection of cases. The responsibility of the physician, beginning as it does with the judicious selection of the cases, does not cease with the active management of the patient until the habit has been completely broken up, but involves for a considerable period of time such continued personal influence and supervision as is needed to avert relapse. It is needless to say that such supervision and influence must, after a more or less extended period, in nearly every case come to an end, but the important fact is to be borne in mind that the danger of relapse becomes less and less with the progress of time; therefore, the more extended the period during which the personal control of the physician may act as a safeguard to his patient the better.

The question as to whether the cure should be attempted in the patient's own home or away from it does not appear to the writer to admit of discussion. Some trustworthy observers¹ have reported successful cases not only

¹ See, for example, Waugh, "A Confirmed Case of Opium-addiction treated Successfully at the Patient's Home, with Remarks upon the Treatment, etc., *Philadelphia Medical Times*, vol. xvi., March 20, 1886.

of the home-treatment of opium-addiction, but even under circumstances in which the patients have been permitted to go at large. Many physicians do not hesitate to undertake the treatment with certain precautions at the home of the patient. On the other hand, those whose experience in the management of these cases is most extended look upon attempts of this kind as likely to be unsuccessful in the great majority of the cases of the opium or morphine habit. In cases of chloralism and the abuse of less formidable narcotics, as cannabis indica, paraldehyde, etc., the home-treatment, if judiciously carried out, usually succeeds, but the cases in which the home-treatment proves successful in curing the confirmed addiction to opium or morphine must be looked upon as exceptional. The reasons for this are obvious. They relate to a variety of circumstances which tend to weaken the mutual relations of control and dependence between the physician and his patient. The doubts, criticisms, remonstrances, even the active interference, of the patient's friends tend to weaken the authority of the physician and to hamper him in the management of the case; the discipline of the sick-room is maintained with greater difficulty; the absolute seclusion of the attendant with his patient is a practical impossibility. Affectionate but foolish friends come with sympathy at once disturbing and dangerous. Some devoted and trusty servant cunningly conveys from time to time new supplies of the coveted drug, or, if these accidents be averted, the very consciousness of the separation which amounts to a few feet of hall-way only is in itself a source of distress to the patient and his friends alike. Furthermore, the period of convalescence following the treatment is attended with the greatest danger of relapse—a danger which is much increased by the facility of procuring narcotics enjoyed by the patient in his own home as contrasted with the difficulties attending it away from home under the care of a watchful attendant. The desirability of undertaking the treatment away from the patient's home can therefore scarcely be questioned. That this plan is more expensive, and that it involves a radical derangement of the ordinary relations of the patient's life, are apparent rather than real objections to it. The very expense of the cure within the limits of the patient's ability to pay, and the mortification and annoyance of temporary absence from usual occupations and seclusion from friends, are in themselves hardships that enhance the value of the cure when achieved, and constitute, to a certain extent, safeguards against relapse. Whether the treatment can be more advantageously carried out in a private asylum designed for the reception of several such cases, or in a private boarding-house, or at the home of the physician himself, is a question to be determined by circumstances. The writer is of the opinion that with well-trained and experienced attendants, well-lighted, airy rooms in the upper part of a private house are to be preferred on account of the seclusion thus secured.

In general, two methods are recognized: (*a*) that of the abrupt suppression of the drug, and (*b*) that of the gradual diminution of the dose. Both of these methods demand the isolation of the patient, and to some extent at least the substitution of other narcotics. The isolation of the patient under the care of skilled and experienced attendants may be secured in a suitable private boarding-house, in the home of a physician, or in a private room of a well-appointed general or special hospital. Favorable opportunities are also afforded in private institutions devoted

to this purpose. The apartment occupied by the patient should be so arranged as to guard against attempts at suicide, and the furniture should be of the simplest character. The heating and lighting arrangements must be such as to render any accidental injury to the patient during paroxysms of sudden maniacal excitement quite impossible. From the beginning of the treatment the patient must under no circumstances be left alone. Two attendants are required, one for the day and one for the night. They should be not only skilful and experienced, but also patient and firm; and, as a considerable proportion of the patients are persons of education and refinement, intelligence and good manners are desirable on the part of those who must be for a length of time not only the nurses, but also the companions, of the sufferer. It is desirable that the separation of the patient from his family and friends should be made as complete as possible. During the continuance of the active treatment no one should be admitted to the patient except his physician and regular attendants. Communication with his friends by letter should be interdicted. The enforcement of this rule must be insisted upon. So soon as the acute symptoms caused by the withdrawal of the drug subside and convalescence is fairly established, brief visits from judicious members of the family in the presence of the nurse may be permitted. At the earliest possible moment open-air exercise by walking or driving must be insisted upon, and change of scene, such as may be secured by short journeys or by visits to the seashore, is useful. These outings require the constant presence of a conscientious attendant.

The Treatment of the Opium and Morphine Habit.—*a.* The Abrupt Discontinuance of the Drug: the Method of Levinstein.—This method is thus described by the observer whose name it bears: Directly upon admission the patient is given a warm bath, during which time careful examination of his effects is made by a responsible person for the purpose of securing the morphine which the patients, notwithstanding their assertions to the contrary, frequently bring with them. These measures of precaution are by no means unnecessary. An officer had saturated his cigarettes and cigars with a solution containing opium, and smoked for twenty-four hours almost without interruption. Another officer had slipped morphine between the soles of new slippers. Other individuals concealed immediately after their arrival morphine in powder in the upholstery of the sofa, upon the canopy and in the ventilators of the windows. Other patients enclosed morphine in envelopes of thin paper, which were placed between the leaves of their books, stitched it in the folds and lining of their garments, etc.

The first symptoms of the withdrawal of the drug show themselves in delicate individuals at the end of three or four hours, and in robust persons about fifteen hours, after the last dose. These symptoms consist of malaise, restlessness, a sense of muscular tension, chilly sensations, and the like, but do not demand treatment. As soon as shivering commences the patient must be put to bed—a measure to which, as a rule, he readily assents on account of the sense of muscular fatigue now experienced. For the relief of the headache, which is rarely absent, applications of cold water or of ice or ether-douches to the forehead may be employed. For the distressing gastralgia compresses moistened with chloroform may be applied to the epigastrium. The colic, which is often distressing,

may be treated by sinapisms or hot compresses. The nausea and vomiting and epigastric distress, which are apt to continue for several days, may be treated by a solution of bicarbonate of sodium with tincture of nux vomica and essence of mint. If the vomiting be excessive, recurring twenty or thirty times in the course of twenty-four hours, small doses of morphine by the mouth must be given. If by reason of the continued vomiting and inability to retain nourishment dangerous exhaustion develops, nutritive enemata must be administered. The diarrhœa requires little treatment during the early days. If, however, it be excessive and persists beyond the third or fourth day, large enemata of warm water of a temperature of 98° F., repeated two or three times during the day, are attended by excellent results. The insomnia, which constitutes a most distressing symptom, defies every kind of treatment during the first three or four days. During this time prolonged baths are not well borne, and even when they are employed they scarcely produce more than half an hour or an hour of sleep. Chloral is also, under these circumstances, inadmissible, whether administered by the stomach or by the rectum. It does not induce sleep, and its employment is very often followed by a high degree of excitement. After the fourth day it is well borne by many persons, and manifests its usual hypnotic property. Warm baths of five minutes, followed by cold affusions, exert an excellent influence upon the general debility and mental depression of the first days. The objections of patients to these baths cease after they have experienced the excellent results which follow their use. During the bath stimulants, such as champagne, port, and hot bouillon, may be given. Care must be paid to the alimentation from the very beginning of the treatment. During the first days liquid nourishment should be given, and abundance of wine and other alcoholic beverages according to the previous habits of the patient. Some nourishment is to be given every hour or every two hours. Many patients experience an intense craving for alcoholic drinks; others, on the other hand, are unable to take them. To the former wine, beer, etc. may be given freely during the first three or four days; to the latter a restricted milk diet may be given, one to two quarts in the course of twenty-four hours. Such is the method of Levinstein, to which he adds, however, important modifications for those—and their number is large—who are unable to bear the abrupt withdrawal of the drug.

This method is attended in all cases by indescribable sufferings, and in many by serious dangers. Among the last, collapse and delirium tremens demand special consideration. The collapse which occurs in a certain proportion of the cases requires prompt and energetic treatment. The pulse becomes feeble, small, gradually or suddenly diminishes in frequency; the countenance is pale; the previous agitation gives place to an ominous calm; there is a tendency to syncope, accompanied by persistent somnolence and slowing of the respiration. Inhalations of ammonia and the administration of aromatic spirits of ammonia, champagne, brandy, or hot coffee, with frictions of the surface and cold applications to the head, may occasionally produce reaction. As a rule, however, it is necessary to administer a hypodermic injection of morphine. This condition of collapse, once having shown itself, is apt to recur upon the same or the following day. The treatment of the delirium tremens

consists in isolation, the administration of abundant nourishment, the use of the bromides, chloral, or paraldehyde, with alcoholic stimulants. As this complication is unattended by danger to life, and usually disappears in the course of a few days, the administration of morphine is not required.

The modifications of this method suggested by Levinstein for those who are unable to bear the abrupt suppression of the drug are as follows: The patient is isolated and guarded; for two or three days his habitual dose is administered, this duty being performed by the physician himself. The drug is then abruptly discontinued. At the end of twenty-four hours the phenomena of abstinence are manifested; the pulse loses its regularity, distressing diarrhoea and vomiting occur, etc. These symptoms are controlled by the injection of morphine, the dose being much smaller than that to which the patient has been accustomed. By this means the sufferings of the patient are ameliorated, and the dangers attendant upon the rapid suppression of the drug are averted. At the end of twenty-four hours it becomes necessary to again administer the drug, but in diminished dose. After a time it is discontinued altogether.

b. The Gradual Diminution of the Dose.—This method is now generally employed. It consists in isolation of the patient with proper attendants and the progressive diminution of the dose. The drug should always be administered by the physician himself. The rapidity with which it is suppressed will be determined by the circumstances of the individual case. The time occupied should not exceed ten days. In the majority of cases it will be much shorter than this. If the administration of morphine to correct urgent symptoms be at all required after this time, it will be at most on one or two occasions at intervals of twenty-four or forty-eight hours. When the process of reducing the dose is too greatly prolonged, the sufferings of the patient are unnecessarily aggravated. As the diminution progresses the relief produced by each dose is followed by distressing reaction. The anticipation of smaller doses from time to time or from day to day is a matter of great distress to patients. After a while their courage and endurance fail them, and they seek by every possible means to secure at least one good dose of the coveted drug.

The symptoms produced by the suppression of the drug speedily show themselves, increasing in intensity as the dose diminishes. Temporary amelioration is, however, produced by each of the successively diminishing doses of the drug. Whatever may have been the method followed by the patient, the hypodermic injection of morphine is to be preferred in the treatment. The disturbances of the digestive system which speedily appear require but little special medication. The danger of inanition which attends the complete loss of appetite, the inability to take ordinary food, and the frequent often uncontrollable vomiting, are best met by the systematic administration of easily assimilable liquid diet, consisting of lime-water and milk, milk and Vichy water, pancreatized milk, koumiss, concentrated broths, the expressed juice of fresh partly-cooked beef, and the various commercial foods used in the artificial feeding of infants. Vomiting rarely occurs immediately after the ingestion of articles of this kind. If it takes place in the course of an hour, some degree of digestion and absorption will have taken place. Should, however, all food be rejected by the stomach, efforts at rectal

aliméntation must be attempted. Efforts to control the vomiting by medicines other than the administration of opium or morphine in some way are not usually attended by success. The diarrhœa is usually frequent, the stools being liquid, sometimes small, often copious, and amounting in number from eight or ten to thirty or more in the course of twenty-four hours. They are not usually attended by pain. Some relief to this symptom follows the administration for a time of large doses of bismuth subnitrate (grs. xx to xxx) every second, third, or fourth hour. The sinking feeling at the pit of the stomach and the epigastric pain are to some extent alleviated by external applications. Hot fomentations or compresses containing a few drops of chloroform or turpentine are also useful.

The derangement of the respiratory system, which consists usually in a certain amount of bronchitis with more or less cough and some dyspnoea aggravated by exertion and movement, does not usually require special treatment.

Disturbances of the circulation constitute a very important group of symptoms, and require close watching always, active interference frequently. For the relief of the phenomena due to flagging action of the heart the recumbent posture, external warmth, friction of the extremities, the application of turpentine stupes or mustard to the præcordial and epigastric regions, the inhalation of ammonia or the administration of preparations of ammonia, and sometimes digitalis, which may be given either by the mouth or hypodermically, will be required. Alcohol, however, will prove in the greater number of cases a most useful remedy—in many an indispensable one. It may be given in the form of milk-punch, hot toddy, or of port, champagne, etc., according to the requirements of the case. Failure of the circulation may, notwithstanding every effort to control it, reach such a degree as to jeopardize the patient's life. Under such circumstances the treatment must be interrupted by the immediate administration of small but efficient doses of morphine, which, if necessary, must be repeated. As diarrhœa increases the quantity of urine excreted rapidly diminishes. It may not exceed eight or ten fluidounces in the course of twenty-four hours. After the third or fourth day of the treatment the urine in a considerable proportion of cases contains albumen and occasionally casts. The oliguresia is largely due to the excessive loss of fluid by the bowel, and does not require treatment. Nor, indeed, is active treatment demanded by the albuminuria, which usually spontaneously subsides in the course of a few days, although it sometimes persists for some weeks or months. Persistent albuminuria requires appropriate treatment.

The nervous symptoms, which constitute a most important group, are favorably influenced by methodical aliméntation and the free use of alcoholics. Care must be taken to reduce the amount of alcohol administered as convalescence progresses. With the re-establishment of the normal functions of the body, the disappearance of insomnia, and improved nutrition, alcohol may in the majority of cases be rapidly diminished or wholly withdrawn. This course, favored by the regular life which the patient should be obliged to lead on becoming convalescent, and the feeling of general bienaise which is gradually developed as the cure progresses, is rendered especially important by the fact that a considerable proportion of opium-habitues are individuals of unstable nervous organization, which in itself constitutes a powerful predisposing influence to alcoholism.

It seems hardly necessary to describe in detail the treatment demanded for the relief of the varied disturbances of the nervous system. The use of coca in the form of a good preparation of the wine or fluid extract in appropriate doses, to which may be added tincture of cannabis indica, exerts a favorable influence. The administration of cocaine by the mouth and hypodermically has in some instances seemed to me to be followed by favorable results. It is not, however, to be adopted as a routine practice, by reason of its occasional depressing effect and the possible danger of replacing the opium habit by a craving for cocaine. Lupulin, and in particular an ethereal extract of lupulin, exerts a favorable but not very powerful influence in tranquillizing the nervous system. With the view of controlling to some extent the insomnia, the hypodermic injections should, during the early part of the treatment, be so timed that the period of sleep or drowsiness which they produce should occur during the night. As soon as the number of injections is reduced to one daily, that one should be administered at the latest convenient hour before midnight. For twenty-four or forty-eight hours after the final discontinuance of morphine but little effect may be expected from ordinary doses of other sleep-inducing drugs. Chloral in single large doses (grs. xx to xxx), either alone or associated with a corresponding large dose (grs. xl to lx) of one of the bromides, administered on the second or third night after total suppression, is very often followed by prolonged, tranquil, and refreshing sleep. Caution must be observed, however, in administering chloral so long as the indications of feeble circulation persist. Paraldehyde, although less certain, is a less dangerous hypnotic under such circumstances. Massage, hot baths, and the cold pack are all useful adjuvants to the treatment. The sweating when copious and distressing is favorably influenced by sponging with hot alcohol.

The abject mental state of the patient calls for much firmness, gentleness, and tact on the part of the physician and attendants. Every effort should be made to inspire courage and hope. Neither the importance of the symptoms nor the intensity of the sufferings of the patient should be underrated; nevertheless, the ordeal is a limited one. In the majority of instances, to get rid of the opium means to get well, because opium, unlike alcohol, does not leave permanent structural lesions of any organ. The expectation of a radical cure must therefore be confidently presented to the patient as a consolation in his sufferings.

With the return of convalescence sexual power is restored and menstruation is re-established. Insomnia and muscular weakness usually persist into the convalescence for some weeks, and only gradually yield to careful regulation of the daily life of the patient, with abundant nutritious food, open-air exercise, and change of scene. The insomnia of this period constitutes a serious symptom, for the reason that it constantly subjects the patient to the temptation to return to the use of hypnotics. In the course of time, however, the normal physical and mental condition is regained, and the patient may be permitted to return to his former pursuits and associations.

The Treatment of the Chloral Habit.—That which has been said in the foregoing pages concerning the prophylaxis against the opium habit applies with equal force to chloral and other narcotics. The curative treatment of habitual addiction to chloral is attended neither by the dif-

faculties nor the dangers which are encountered in the management of the opium habit. The symptoms attending the discontinuance of chloral are less severe and less persistent; in fact, individuals accustomed to the taking of large doses of chloral not infrequently voluntarily discontinue its use for considerable periods of time. As a rule, the treatment may be carried out at home, the patient, however, being isolated and cared for by a watchful attendant. The drug should be stopped at once. For the first few days alcoholic stimulants should be freely given. Systematic feeding, pepsin, full doses of quinine, followed after a time by strychnia, and, as soon as the condition of the digestive system will permit of it, by iron, fulfil the general indications. Cod-liver oil and malt extracts may be given with advantage. Cardiac failure, collapse, and delirium tremens are to be treated in the same manner as similar complications occurring in the treatment of the opium habit. Vomiting is much less likely to occur, and when present is less persistent and less difficult of management. Diarrhœa does not usually prove troublesome, the bowels, on the contrary, being constipated. The latter condition yields to mild laxatives or to simple enemata. Hemorrhages from the various mucous tracts may be controlled by fluid extract of ergot, the hypodermic injection of solution of ergotin, minute doses of wine of ipecac, or fluid extract of hamamelis. The conjunctivitis which is occasionally present usually subsides spontaneously upon the discontinuance of chloral. It may be treated by instillations of a 2 per cent. solution of cocaine and mild borax lotions (grs. v to fʒj). The after-treatment must be carefully carried out. Relapses are less frequent than after the opium habit.

The Treatment of Habitual Addiction to Paraldehyde, Cannabis indica, Ether, Chloroform, etc. must be based upon the general principles indicated in the foregoing pages. Cases of the habitual abuse of these drugs are comparatively infrequent on the one hand, and on the other do not often present the serious and progressive symptoms produced by excesses in opium and chloral; hence they come but rarely under the care of the physician, except in those unhappy individuals in whom the propensity to vicious narcotism is such that any drug capable of producing excitement and oblivion is made the means of gratification, and all are used by turns as the opportunity occurs.

CHRONIC LEAD-POISONING.

By JAMES C. WILSON, M. D.

DEFINITION.—The term chronic lead-poisoning is used to designate the morbid phenomena induced by the gradual accumulation of lead in the organism.

SYNONYMS.—Plumbism, Saturnism, Morbus plumbeus, Molybdosis, Molybdonosus, Intoxication saturnine, Bleivergiftung.

CLASSIFICATION.—Chronic lead-poisoning manifests itself in serious disorders of nutrition which are widespread and implicate all the tissues of the body; but for the reason that its more striking and characteristic symptoms relate to the nervous system, it has been classed among disorders of that system as a toxic neurosis.

Acute poisoning by lead is an entirely different affection. It depends upon the power of the salts of lead to coagulate albumen. Its symptoms are those of acute corrosive gastritis; derangements of the nervous system are secondary. It does not fall within the scope of the present article.

HISTORY.—Chronic lead-poisoning must have existed from the infancy of the arts in which the metal is employed. It does not, however, appear to have been recognized until after the time of Hippocrates. Celsus was aware of the danger attending the administration of lead. Nicander, Dioscorides, Aretæus, and Paul of Ægina recognized lead colic and the paralysis resulting from its long-continued introduction into the stomach. Among Arabian physicians, Rhazes and Avicenna accurately describe the effects of the preparations of lead. No considerable addition to the knowledge of the subject was made until the seventeenth century. In 1616 was printed at Poitou the famous work of Citois, *De novo et populari apud Pictones dolore Colico bilioso Diatriba*. The epidemic colic described by this author was caused, although he little suspected it, by the common use of wine which had been treated by lead to remove its acidity. This practice, which is of very ancient date, and is described in the writings of Cato, Pliny, and Columella, was at one period very general in Europe, and had been forbidden by imperial ordinances as early as 1437.¹ It remained for Stockhausen, in a treatise published at Goslar in 1656, and entitled *De Lythargyri Fumo, noxiō, morbifico ejusque metallico frequentiori morbo vulgo dicto Hutten-Katze*, to demonstrate that Poitou colic was produced by lead in particles in

¹ Vide Tanquerel des Planches, *Lead Diseases*, translation by S. L. Dana, M. D., LL.D., Lowell, 1848.

emanations, and for Wepfer in 1671 to first clearly point out the fact that the epidemic colic so often described was usually caused by lead in wine. During the eighteenth century the epidemic colic attracted much attention among medical men, and its etiology was made clear. Henkel called the affection founder's colic, and showed how it was produced in those engaged in casting lead; Huxham, in his work on *Fevers* (1745), described the disease as it prevailed in Devonshire, and several English observers conclusively proved that the epidemics of colic frequently appearing in certain districts were caused by the presence of lead in cider, and that it was due to the action of the apple-juice upon lead used in the construction of the presses and implements employed in the manufacture of that popular beverage.

During the current century the closer study of the etiological relations of disease has revealed many unsuspected sources of lead-poisoning in the arts, and of lead contamination, both accidental and intentional, in articles of food, drink, and luxury. Hence the literature of the subject has assumed very extensive proportions. The French physicians have devoted much attention to this subject. The great work of Tanquerel des Planches, to which reference has already been made, remains to this day the most complete and comprehensive authority. Quite recently valuable additions to existing knowledge have appeared in some of the Paris theses.¹

ETIOLOGY.—A. Predisposing Influences.—Individuals exposed to lead and its compounds are not all equally prone to its effects. The degree of liability is to some extent dependent upon individual susceptibility, and to a much greater extent upon circumstances which are determined by the season, climate, age, sex, diet, and mode of life of different persons. It will be convenient to consider the predispositions which arise from occupation under the head of the Exciting Cause.

Variations in the degree of susceptibility to chronic lead-poisoning appear to be explicable in a majority of the cases solely upon the theory of idiosyncrasy. While a large proportion of the cases are in well-developed, strong, and previously healthy adults, individuals of feeble constitutions do not escape. Those occupations which involve the greatest exposure to the danger of contracting this affection at the same time demand the powers of a robust frame. Habitual recognition of these dangers, such as begets the habitual exercise of reasonable precautions against them, diminishes to some degree the liability of a few workmen.

Season.—Due allowance being made for the difference in the number of workmen employed in manufactures which involve exposure to lead, and especially in the making of white lead, at different seasons of the year, it has been found that attacks of lead colic and of lead palsy are more common in warm than in cold weather. Heat predisposes to the attack, either by favoring the dissemination of the lead compounds or by facilitating their absorption by various channels, especially by the skin, which is more freely exposed in summer, and at the same time more or less bathed in sweat in which the dust of lead salts may be dissolved.

¹ Vide Capelle, *De l'Intoxication saturnine*, Paris, 1883; Séguin, Ch., *De l'Albuminurie transitoire des Saturniens*, Paris, 1883; Goudot, *Étude sur la Goutte saturnine*, Paris, 1883; Verdugo, *Contribution à l'Étude de la Goutte saturnine*, Paris, 1883; and Coutard, *La Colique du Poitou considérée comme Intoxication saturnine*, Paris, 1884.

Climate.—In the absence of definite statistics upon the subject, it appears probable that the dangers of chronic lead-poisoning would be greater in warm than in cold climates. The clinical features of the affection are alike in all parts of the globe.

Age.—The majority of individuals attacked are adults. Nevertheless, children employed in occupations involving exposure to lead are attacked with great frequency—so much so that it may be concluded that their liability is in fact greater than that of adults.

Sex exerts a decided influence, women being, under nearly similar circumstances, less frequently attacked than the men employed in the same factories—a fact to be explained only by their greater willingness to exercise the recognized precautions.

Diet does not constitute a predisposing influence. It is nevertheless probable that a deficient diet favors the development of the affection. Excesses in food, and especially excesses in drink, predispose to lead colic.

The mode of life is important. Those who lead sober, regular, and, above all, cleanly lives are less liable to the affection than the intemperate, irregular, and careless. Particularly are the dangers in factories increased by neglect of ventilation. Persons suffering from affections of the digestive tract are not, among lead-workers, more prone to lead colic than their comrades who are free from such diseases.

B. The Exciting Cause.—Metallic lead is probably inert, but, owing to the ease and rapidity with which it oxidizes and forms salts, lead in any form, if introduced into the body continuously for a length of time, produces characteristic toxic effects. The oxides, acetates, and carbonate of lead, being soluble in the gastric juice, act more surely.¹ But the sulphate, the least soluble of the lead compounds, may also have this effect (Gasserow).

The channels by which lead is introduced into the body are the alimentary canal, the respiratory tract, and the cutaneous surface. Hence the modes of introduction are of almost endless variety. The conveyance of lead into the stomach constitutes the most common as well as the most important means of access to the organism. This may be in the form of medicine, as the acetate, the unduly prolonged use of which, even in moderate doses, sometimes produces chronic poisoning. Articles of diet are not infrequently contaminated by lead derived from different sources, of which the most common is the lead glaze of earthenware vessels, which is soluble in acid fluids. According to Naunyn, beer drawn through lead pipes may cause chronic lead-poisoning, which has also been frequently ascribed to the use of shot in cleaning bottles used for wine and malt liquors. Drinking-water is occasionally contaminated with lead derived from pipes made of this metal and cisterns painted with lead colors. Pure water, freed from gases, does not act upon lead when the air is excluded. In the presence of air, however, an oxide of lead is formed which is partially soluble in water. If nitrates, nitrites, and chlorides, such as constitute ingredients of sewage, are also present, they form soluble compounds with lead and increase the proportion of lead salts soluble in the water. For this reason water contaminated by sewage is rendered decidedly more dangerous if carried in leaden pipes. On the

¹ Naunyn, *Ziemssen's Encyclopædia*, vol. xvii.

other hand, the purer the water the greater the danger. Hence rain-water and pure spring-water cannot safely be stored in cisterns painted with lead colors nor conveyed in leaden pipes, nor can lead covers be used for cisterns, because of the condensation of the vapor of water, which drops back, holding lead salts in solution. The sulphates, phosphates, and carbonates usually found in river-waters form insoluble lead compounds, which, being deposited upon the interior of the pipes, act as protectives and prevent further chemical changes.

Still more common is the accidental conveyance of lead dust and lead compounds to the mouth in consequence of their adhering to the hands or settling from the atmosphere upon articles of food and drink, in the case of workmen engaged in the various arts in which lead is freely used. As a rule, to which the exceptions are rare, the more severe cases of chronic lead-poisoning occur only among workers in lead, as miners, those employed in white-lead factories, painters, typesetters, plumbers, and lapidaries.

Potters engaged in the glazing of common pottery and tiles, workmen in file-factories, workers on colored papers and in enamels, especially in glass enamels, brushmakers for the reason that the bristles are sometimes colored by lead preparations, and those engaged in sewing coarse goods because the thread is sometimes treated with a preparation of lead in order to add to its weight, are likewise liable to chronic lead-poisoning. The introduction of lead into the body through the respiratory tract is a subject of the greatest importance in the trades. Inadequate ventilation of working-rooms, living or sleeping in apartments connected with or contiguous to factories in which lead is largely used, and particularly in lead-factories, is attended with serious dangers, as is also the habit of eating food in such apartments or drinking water that has been standing in them. The possibility of lead-poisoning by way of the respiratory tract has been questioned. In view of existing knowledge as to the readiness with which carbon in minute states of subdivision finds its way into the connective lymph-channels of the lung, there can be no doubt that the habitual respiration of an atmosphere loaded with the dust of lead or its preparations in a minute state of subdivision may give rise to chronic lead-poisoning. At the same time, the experiments of Hassel¹ render it probable that less absorption takes place directly by means of the pulmonary mucous membrane than by way of the mucous membrane of the mouth and throat. It must be borne in mind that none of the preparations of lead are volatile. This affection is also occasionally observed in clowns and others upon the stage or elsewhere, who habitually use cosmetics containing lead. The use of cheap tinfoil, into the composition of which lead enters largely, as a wrapper for tobacco and snuff is said to occasionally produce chronic lead-poisoning. It is stated by Naunyn that mattresses filled with horse-hair died black by lead compounds have occasioned this affection. The same authority states that a proof-reader was poisoned by reading printed proof for many years. Chronic lead-poisoning is pre-eminently a disease of the industrial arts. The means of obviating or diminishing the dangers of those exposed by their occupation to the preparations of lead will be considered under the head of Prophylaxis.

¹ *The Inhalation Treatment of the Diseases of the Organs of Respiration, including Consumption*, London, 1885.

The quantity of lead absorbed is of less importance than is its continuous introduction. As stated in the definition, the phenomena of chronic lead-poisoning are those brought about by the gradual accumulation of lead in the system, the amount absorbed into the blood in any given cases being comparatively small, even where large quantities are ingested. Hence prolonged exposure to small amounts of lead is attended with greater danger than a comparatively brief exposure to larger quantities. It is stated that the members of the household of Louis Philippe at Claremont manifested the symptoms of chronic lead-poisoning after the lapse of seven months in consequence of drinking water which contained a mere trace of lead. On the other hand, several grains of acetate of lead may often be administered medicinally to patients for a week at a time without inducing the phenomena of this affection, although, in view of the idiosyncrasy of many individuals, the exhibition of lead preparations for prolonged periods is not advisable.

According to Heubel,¹ the blood and internal organs contain but very small amounts of lead—.02 per cent. in the maximum. It is probable, therefore, that the more insoluble of the lead compounds may yield a sufficient amount of absorbable lead to produce the characteristic constitutional effects.

So long as the urine remains free from albumen, it serves for the elimination of a mere trace of lead. In albuminous urine the amount is larger. Lead is found in the bile and feces in small quantities.

SYMPTOMATOLOGY.—The general description of chronic lead-poisoning must include a great number of symptoms that do not always occur in regular order or sequence. According to the prominence of certain of these symptoms in particular cases the specific effects of lead may be grouped under the following five heads: (1) disturbances of nutrition; (2) the colic; (3) the arthralgia; (4) the paralysis; and (5) lead encephalopathy.

1. Disturbances of Nutrition.—After the long-continued introduction of lead into the system the signs of impaired nutrition manifest themselves in almost all cases. The appearance of the patient is changed; he becomes thin, anæmic, and of a somewhat peculiar yellowish complexion. This hue of the skin, to which the term *icterus saturninus* has been applied, is not due to the deposition of bile-pigments. The wasting of the tissues of the body seems to implicate the muscular to a much greater extent than the adipose tissues. In the majority of cases a dark or bluish-black line is observed at the border of the gums. This line is more strongly marked in the upper than in the lower jaw. It is, as a rule, more plainly developed in persons of careless habits, whose teeth are the seat of deposits of tartar, but the teeth in such individuals are often discolored and appear to be elongated in consequence of the retraction of the edge of the gums. This bluish or violet-black gingival line is due to the deposit of particles of sulphide of lead in the substance of the gum, in consequence of the reaction between the sulphuretted hydrogen formed by the decomposition of particles of food and the lead particles present in the mouth. According to Tanquerel, this color may extend over the greater part of the gum or even to the mucous membrane of other portions of the mouth. If due care be exercised, there is little danger

¹ *Pathogenese und Symptome der Chronic Bleivergiftung*, Berlin, 1871.

of confounding the lead-line with the livid border of the gums frequently seen in people whose teeth are in bad condition. The occasional absence of this line in otherwise well-characterized cases of chronic lead-poisoning is to be noted. It does not occur when the teeth have been lost, and is slight if they are kept clean.

Patients complain of habitual dryness of the mouth and of an insipid, mildly astringent, sweetish, or faintly metallic taste; the tongue is coated, the breath fetid. There are nausea and occasional vomiting. Constipation is common. The patient is now liable to attacks of lead colic, joint trouble, and the specific palsy, or to cerebral disturbances of grave character. Of these affections, colic is the most frequent; the joint affection is next in order; the paralysis far less common, and the cerebral disturbances comparatively rare. Continued exposure results after a time in an intensification of the malnutrition, either with repeated attacks of colic or the other specific disturbances, or occasionally in their absence, although at length the positive lead dyscrasia is established, characterized by obstinate dyspepsia, constipation, and intensification of the curious earthy or yellowish color of the skin, which is succeeded by the pallor of profound anæmia. Loss of muscular power with transient œdema now shows itself. The patient becomes apathetic, irritable, and morose. As the condition of cachexia deepens muscular tremor occasionally shows itself. After a prolonged period of profound ill-health the patient succumbs to some complication, among the more frequent of which are tuberculosis, pneumonia, and chronic interstitial nephritis. Gout is a very common complication of chronic lead-poisoning.

2. Lead Colic; Colica saturnina; Colique de plomb; Bleikolik.—This affection is also known as painter's colic, Devonshire colic, colica pictonum, the last term being derived from Poitou. It occasionally develops abruptly without previous symptoms. In the majority of cases, however, the earlier disturbances of nutrition before pointed out precede the attacks, often by a period of weeks or months. An increased tendency to constipation with transient recurrent abdominal pains, occurring sometimes immediately after food, more frequently at irregular intervals, often characterizes the prodromic period. There is, moreover, an intensification of the other symptoms of chronic lead-poisoning. The appetite is decidedly impaired, so also are the powers of digestion; the foul condition of the mouth becomes more annoying, and the peculiar taste alluded to more persistent and more marked. Constipation occasionally alternates with diarrhœa. The colicky pains which constitute the attack are of variable intensity, but usually severe. They are of the nature of true colic. Pressure over the seat of pain almost invariably gives relief, particularly in severe attacks. During the remission pressure is grateful to the patient. The position of the pain varies. Its most common seat is in the region of the umbilicus. It may occupy the epigastric and hypochondriac regions or the lower part of the abdomen, extending from side to side above the level of the pubic bone. These colics are of some minutes' duration, recurring after short intervals, which are characterized by a certain amount of continuous cramp. Tenesmus is frequent. It may be accompanied by strangury or retention of urine, with pain in the course of the ureters, the spermatic cord, or in the penis. Shooting pains in the breast also occur. The abdomen

is retracted, and scaphoid to such an extent in some instances that the prominence caused by the bodies of the vertebræ is apparent in the median line of the abdomen. It occasionally happens, however, that retraction does not occur, the belly, on the other hand, remaining prominent. As a rule, to which there are few exceptions, the bowels are constipated. This condition is often stubborn. In rare cases, however, the colic is accompanied by diarrhœa. Nausea is of common occurrence. Vomiting is sometimes violent and distressing, being ushered in by repeated attacks of retching. The vomited matters are usually discolored by bile, and icterus of slight degree usually occurs. The pulse is invariably diminished in frequency, sometimes as low as 40 or even 30, per minute. It is at the same time full and tense. The pulse-frequency is occasionally variable within comparatively brief periods of time. Respiration is increased in frequency during the attack. The urine is small in quantity and of high specific gravity, and frequently contains small amounts of albumen. It is sometimes entirely suppressed. Fever is absent, and the slight increase of temperature occasionally observed is attributable to the restlessness of the patient. The intellectual condition usually remains clear, but in violent cases it is characterized by excitement. The paroxysms of pain are more severe in the latter part of the day and during the night. The course of the attack is irregular. Relapses, which may occur in the course of some days or even weeks, are frequent. The duration of the attack does not, as a rule, exceed a week, but the illness is often protracted by repeated relapses, and in continued exposure to the cause the tendency to colic may become chronic. The termination of the attack is in most instances as abrupt as its onset, and with the cessation of the colic the associated symptoms, such as retraction of the abdomen, constipation, vomiting, and diminished frequency of the pulse, rapidly subside. Lead colic is not unfrequently associated with the other affections of chronic lead-poisoning. The prognosis is favorable, the mortality being about 2 per cent.

3. The Arthralgia; *Arthralgia saturnina*.—The tissues entering into the formation of the joints and the muscular masses contiguous to them are frequently the seat of intense paroxysmal pains, which appear more or less suddenly, either with or without prodromes, and run a course similar to that of lead colic, exhibiting violent exacerbations and occasional more or less complete remissions. These pains are accompanied by painful contractions of the muscles. They are somewhat relieved by pressure and friction and aggravated by exercise and exposure to cold. Swelling and redness over the affected joints, ligaments, and tendons are absent. These pains do not follow the course and distribution of the nerve-trunks, and lack the tender pressure-points of true neuralgias. They are more common in the lower extremities, the knee being especially apt to be affected. When they affect the upper extremity the elbow and shoulder suffer more frequently than the other joints. The flexor muscles are much more frequently attacked than the extensors. The muscles of the back, especially the great masses of long muscles in the lumbar region, whose function is to sustain the equilibrium of the body, are frequently implicated. The intercostal muscles and the muscles of the neck are also frequently affected. The small joints and the muscles of the hands and feet as a rule escape. The pain is tearing and burning in

character, and very often severe. It is occasionally associated with tremor. The derangement of the alimentary canal, especially constipation, which is so characteristic of lead colic, is often absent. Fever does not occur.

A careful study of these cases establishes the fact that in a considerable proportion of them the morbid condition is myalgic. Whether it be due to simple muscular malnutrition or to some specific action of lead upon the muscle-substance is not determined. The analogy between these muscular pains and lead colic renders it probable that in a large majority of the cases the latter view is correct. These pains are frequently associated with the attack of lead colic; sometimes, however, they precede the colic, while at other times they follow it. After a series of remissions and exacerbations the pain often ceases as suddenly as it began. As in other lead affections, relapses are frequent. The prognosis is favorable.

The English physicians, and especially Garrod,¹ Todd,² and Bence Jones,³ have insisted upon the frequency of gout in chronic lead-poisoning. Murchison,⁴ Wilks,⁵ and others regard this association as causative. This view has not found general acceptance in France. Lance-reaux⁶ in particular, after a comparative study of the lesions of the kidney and of the joints in saturnine cachexia and the corresponding lesion of gout, concludes that the gouty kidney and the kidney of lead-poisoning have the same appearance, and are simply varieties of interstitial nephritis, and that the articular and arterial lesions in both affections are identical. So-called saturnine gout differs in no respect, either in its clinical or anatomical characters, from ordinary gout. It would therefore appear superfluous to describe saturnine gout. At the same time, it must be insisted upon that chronic lead-poisoning exercises an important influence in the production of gout—a causal relation due to the fact that lead diminishes the excretion of uric acid.

4. Lead Palsy; Lead Paralysis; Paralyse Saturnine; Bleilähmung.—This condition is fourth among the affections due to chronic lead-poisoning, both in frequency and in the order of succession. Nevertheless, like each of the others, it may be the first in the order of appearance after disturbances of nutrition which are in some rare cases of very slight degree. As a rule, however, the paralysis has been preceded by colic or by joint affection, or by both. Tanquerel⁷ found that in 88 cases of lead palsy 25 had been preceded by an attack of colic, 15 by two attacks, 3 by ten attacks, 1 by fifteen attacks, and that in single cases as many as twenty, and even thirty, attacks of lead colic had occurred before the appearance of paralysis.

The length of time over which habitual exposure to lead without the development of palsy may extend was found by the same observer to vary from eight days to ten, twenty, or even twenty-five years. One individual first suffered from paralysis after fifty-two years of exposure.

Without dwelling upon the sources of error in statistics of this kind,

¹ *Medico-Chirurg. Transactions*, 1854, vol. lvi.

⁶ "Nephritis et Arthrites saturnines: coincidence de ces Affections paralleles avec la Nephrite et l'Arthrite gouteuse," *Arch. gén. de méd.*, Decembre, 1881.

⁷ *Loc. cit.*

it must be conceded that they establish in a general way the extraordinary differences in the susceptibility of individuals. There are persons who every time they are attacked with colic, of whatever degree of severity, suffer also from paralysis. Others, on the contrary, suffer from repeated attacks of violent colic without the development of paralysis.

Lead palsy is an affection of adult life. Of 102 cases, 2 only occurred in individuals below twenty years of age.

Like the other specific lead affections except the encephalopathy, palsy is more common in the summer than at any other season.

Those who have once suffered are very liable to successive attacks. Tanquerel and Maréchal have observed many returns of paralysis, presenting the characters of the original attack, many years after the patient had withdrawn from exposure to lead.

Perverted sensations of the parts about to be affected, such as coldness, numbness, and hyperæsthenia, may precede the attack. Impairment of motor-power, manifested by feebleness, stiffness, or awkwardness and tremor, also appears in the prodromic period. This trembling consists in slight agitation of the muscles, rather than in well-marked rhythmical contractions. These precursors may indeed constitute the attack, which occasionally, and especially under treatment, terminates at this point. The prodromic symptoms are less severe during the day, while the patient is at work; at night they are aggravated. After some days they end in the characteristic paralysis. Colic is a common precursor. After the attack some stiffness of the muscles is experienced, which terminates by rapid loss of power or abruptly in actual palsy. Occasionally encephalopathy precedes the paralysis. It is rare that prodromes are wholly absent.

In the great majority of the cases the upper extremities and the extensor muscles are first attacked. If the paralysis be slight other muscles may escape. The characteristic form of lead paralysis consists in loss of power in the extensors of the hands and fingers, especially of the extensor communis, without implication of the supinator longus. The muscles affected are in the region of distribution of the musculo-spinal nerve. The deformity is known as wrist-drop. Next in order, the triceps and deltoid are most frequently attacked. The lower extremities commonly escape for a considerable time. When attacked, the extensor muscles of the feet and toes are the first to suffer.

Paralysis of the dorsal muscles occurs in rare instances. It gives rise to a peculiar stooping, uncertain, and tottering gait. Paralysis of the intercostal and laryngeal muscles was observed by Tanquerel. Paralysis of the muscles of the face or of those of the eye has never been observed in consequence of lead-poisoning. The loss of power never corresponds strictly to the distribution of the branches of a single nerve-track.

The paralysis, as a rule, affects both sides, and frequently the corresponding muscles of the two extremities. Sometimes, however, the affected muscles of the two sides are not the same, and it occasionally happens that the affection is limited to one side. In very rare cases, the arm and leg on the same side being paralyzed, the affection resembles hemiplegia.

Local paralysis may be limited to the extensor muscle of a single finger

or may involve all the muscles of a limb. There may be slight impairment of power in the flexor muscles. The enfeeblement of certain flexor muscles, especially of those of the fingers, may, Naunyn suggests, be only apparent, the position of the hands being in pure extensor paralysis unfavorable to the exercise of the flexors and limiting their function.

Sensation is not, as a rule, affected in lead paralysis. Pains in the paralyzed muscles, in neighboring muscular masses, and in the structures about the joints often precede the attack of paralysis. Anæsthesia of the skin is rare. When present, it is usually of slight degree, and corresponds to the region of the paralysis. Deep anæsthesia has also been observed.

Atrophy of the paralyzed muscles is constant and rapid. It frequently reaches a high degree, causing characteristic deformities, which are rendered more marked by the fact that the adjacent non-paralyzed muscles preserve to a great extent their original state of nutrition. As the neuromuscular lesion progresses other deformities arise, in consequence of derangements of the balance of force between opposing muscles and from other causes. Among these deformities are partial or complete dislocations of the more movable joints, as the shoulder and phalanges, with the formation of tumors, which, when they occupy the dorsum of the hand, might be carelessly mistaken for the nodosities of gout. It is to be noted that the latter are occasionally present as complications.

There is rapid diminution, and finally complete loss, of the reaction to the faradic current. With the galvanic current the reaction of degeneration is usually well marked. The reaction of degeneration may be demonstrated in the extensors of the limbs in lead-poisoning before wrist-drop has occurred.

The course of lead palsy is very variable. In a few cases it is progressive. When local emaciation or atrophy arrives at the last degree of marasmus, the skin seems glued to the bones, to such an extent are the paralyzed parts wasted; the muscles especially are so thinned that the contour of the bones is easily distinguished. If the paralysis attack the whole of the limb, then this organ, abandoned to its own weight, stretches the ligaments and permits the head of the bone to leave its cavity. In other rare instances the paralysis remains stationary for long periods of time, only to grow worse after each new attack of lead disease. Much more frequently lead paralysis disappears spontaneously or under treatment in the course of some days or weeks. The convalescence is gradual, and usually rapid, when the gravity of the lesion is considered; occasionally it is complete in the lapse of a few days.

The prognosis depends upon the degree of lead cachexia present, the possibility of withdrawing the patient from the exposure, and finally upon the degree and extent of the paralysis and of the atrophy. It is rendered unfavorable by the necessity of the prolonged exposure of the patient to lead, by a high degree of disturbance of the general nutrition of the patient; and by the fact of his having presented for a considerable period the evidences of lead disease, with occasional attacks of colic or arthralgia; by the complete loss of power and electrical reactions in the affected muscles; and, finally, by absolute wasting of the muscular masses. The prognosis is less favorable in relapses than in the primary attack.

Progressive muscular atrophy has been frequently observed in patients suffering from lead disease (Naunyn).

5. The Encephalopathy; Encephalopathia Saturnina.—This term was suggested by Tanquerel to designate collectively the various morbid cerebral phenomena produced by chronic lead-poisoning. It embraces, therefore, those affections due to the action of lead upon the central nervous system, and occasionally described as lead insanity, delirium, convulsions, epilepsy, coma, etc. It is, of all the disorders produced by lead, the most rare. Tanquerel met with seventy cases only. It occurs only in those individuals who are exposed to large quantities of lead, and in such a manner as to favor the absorption of the metal and its compounds by the digestive and respiratory tract. Hence house-painters and the workers in lead-factories supply the greater number of cases. The time of exposure elapsing before the manifestations of the special morbid action of the poison upon the nervous system show themselves varies from a few days to many years. In a large proportion of the cases the time has been less than one year.

Women are much less liable than men—a fact clearly due to the nature of their occupations even when involving exposure to lead.

The majority of the cases have occurred between the ages of twenty and fifty. Alcoholic habits, insufficient and unwholesome diet, privations, exposure, and an irregular life especially predispose those working in lead to the affection. Lead encephalopathy has developed with nearly equal frequency in warm and in cold weather. Relapses are frequent.

Among the prodromes are headache, vertigo, agitated and interrupted sleep marred by distressing dreams, and troublesome insomnia; derangements of the special senses, dimness of vision, alterations of the pupils, tinnitus aurium; dysphagia and a sense of constriction of the pharynx have also preceded the attack of cerebral disorder. It is usually preceded likewise, and often by a considerable lapse of time, by the other lead affections above described—namely, colic, arthralgia, and palsy. Psychical derangements—stupor, apathy, or excitement—also precede the attack. In a small number of cases lead encephalopathy has occurred abruptly without prodromes.

The symptomatology is exceedingly variable and irregular. Three forms, the delirious, the comatose, and the convulsive, have been described. These conditions may succeed each other in the same attack. The delirium is variable in kind. It is apt to be at first tranquil; after some time it becomes paroxysmal and furious. It is broken by intervals of somnolence. At length true sleep supervenes, and the patient awakes restored almost completely to his reason.

Coma may develop suddenly, even instantaneously. In a very few cases the comatose form has developed itself alone during the course of chronic lead-poisoning. As a rule, however, it is preceded by delirium or convulsions.

The convulsive form is the most common. The convulsions may be partial, involving the face or the one side of it, a single limb, or one side of the body. They may be general, without loss of consciousness. These incomplete attacks are apt to be followed, after a period of dulness or unconsciousness, by acute eclampsia. Epileptiform attacks may now follow each other in rapid succession, ending in more or

less profound coma. The attacks are sometimes separated by intervals of uneasiness, restlessness, or delirium. These attacks continue several days. If they are very violent and frequent death may rapidly supervene. In favorable cases consciousness is gradually restored, or the patient may awaken suddenly from his drowsiness after some hours or a day.

These attacks are not preceded by an aura.

Amaurosis is among the more important of the symptoms produced by the action of lead upon the nervous system. It is usually accompanied by dilatation of the pupils. The amaurosis gradually disappears as the other symptoms subside, and with the improvement in sight the pupils contract. Recovery is frequently complete. Occasionally vision does not return with the improved general condition. Norris¹ saw, in two cases of lead-poisoning due to the use of white lead as a cosmetic, marked choking of the discs in connection with severe cerebral symptoms. The terminal condition, when recovery does not take place, is that of nerve-atrophy.

Albuminuria is common in this as in other lead affections. It may be of moderate amount and due to the rapid breaking-down of the blood-corpuscles which marks the exacerbation of the general condition. Albuminuria may be a direct consequence of the eclampsia. Finally, it may be due to coexisting nephritis.

The prognosis is in a high degree unfavorable.

MORBID ANATOMY AND PATHOLOGY—There are no well-characterized anatomical lesions in chronic lead-poisoning. Lead has been found in almost every organ and tissue in the body. It exists in combination with the albumen of the tissues. The changes in the nervous system that have thus far been described are neither constant nor characteristic. The same is true of the lesions of the intestines. The paralyzed muscles are found to have undergone atrophy, with loss of the striæ and increase of connective tissue. The nerve-trunks are also the seat of atrophic degeneration.

The mode of action of lead is not yet determined. The view of Henle, that lead acts chiefly upon the unstriated muscular fibre, was at one time generally accepted, and served to explain many of the characteristic phenomena of the disease. On the other hand, there is much in the clinical history to support the opinion of Heubel, that its primary action is upon the nervous system. Whether the peripheral degeneration by which the paralysis is to be explained is primary or secondary to central degeneration in the anterior cornua of the gray matter of the spinal cord, is yet in dispute. Some of the forms of encephalopathy are doubtless due to the nephritis which is found in many cases of chronic lead disease, and are, in fact, symptoms of uræmia. In the great majority of the cases this is not the case. The morbid condition must be explained by the direct toxic action of lead upon the central nervous system. No theory adequate to account for all the cerebral manifestations has yet been suggested. Naunyn has pointed out the resemblance between the nervous and psychical derangements in lead encephalopathy and those which characterize chronic alcoholism, and suggests that lead, like alcohol, produces these effects not as a direct poison, but indirectly in consequence of abnormal nutrition of the whole system, brought about

¹ See this *System of Medicine*, Vol. IV.

by the continued circulation of a foreign poisonous material in the blood.

Chronic Lead-Poisoning in Animals.—Animals exposed to lead under conditions favorable to the development of the lead affections in man suffer in like manner. Instances of this kind are of frequent occurrence in and about large lead-factories. The drinking of water containing lead also gives rise to these affections in animals. Horses, dogs, cats, and fowls have frequently suffered from lead colic. Horses used in lead-factories suffer from a form of laryngeal obstruction due to lead paralysis of the muscles of the larynx. Relief has followed tracheotomy and the introduction of a canula, and removal to an atmosphere free from lead has resulted in recovery. Cats who spend some time in red-lead workshops frequently are paralyzed. Even the rats in lead-factories become paralytic (Tanquerel).

DIAGNOSIS.—The diagnosis of the affections due to chronic lead-poisoning is, as a rule, unattended with difficulty. The malnutrition, anæmia, poor digestion, foul mouth, stubborn constipation, and the gingival line, considered in connection with the history of prolonged or habitual exposure to lead, would warrant the assumption that the relation between this poison and the symptoms is a causal one. When there is added colic, arthropathies, and paralysis, or the cerebral states having the characters above described, the assumption becomes a certainty. The absence of any one of the ordinary phenomena, such as the blue line or constipation, would still leave the clinical picture sufficiently full to justify the diagnosis. The reaction of degeneration, which is usually marked in saturnine wrist-drop, with the escape of the supinators, distinguishes it from pressure paralysis of the musculo-spiral.

TREATMENT.—*A. Prophylaxis.*—Free ventilation and scrupulous cleanliness constitute, in general terms, the most efficient safeguards for those whose occupations involve prolonged exposure to lead. Workmen employed in lead-factories and those otherwise exposed to lead should be compelled to wash their hands and change their outer clothing before eating; they should also bathe regularly every day on leaving work; under no circumstances should they be suffered to eat or sleep in or near the workshops. As all kinds of work in the manufacturing of lead preparations are not attended with equal risk, the workers should from time to time be transferred from one department to another or from in-door to out-door work. In order to prevent the constant rising of dust, the floors are to be kept constantly sprinkled or covered with moist sawdust. It is unnecessary to go into further details in regard to the hygiene of the subject. It is probable that towels and sponges worn over the mouth, or other forms of respirators, because of the inconvenience which they occasion and the false sense of security which attends their use, are of less value than has been generally supposed.

It appears scarcely needful to here insist upon the avoidance of cosmetics and hair-dyes containing lead, or upon the exercise of reasonable prudence in the matter of the manufacture, sale, and use of articles of food or drink which are liable either by accident or design to become adulterated with lead compounds.

The use of sulphuric-acid lemonade is a measure of prophylaxis of less real value than was at one time supposed, seeing that the sulphate of lead

is in itself capable of producing the disease. Occasional doses of magnesia sulphate are of use where a tendency to constipation exists. Workmen who begins to show signs of chronic lead-poisoning should without delay abandon their work and seek some occupation free from its peculiar dangers.

The precautions against the use of water contaminated with lead have been pointed out under the heading Etiology.

B. Curative Treatment.—When the disease shows itself, no matter in what form, the primary indication is the discontinuance of exposure to lead. Chronic cases of malnutrition, constipation, functional nervous disorder, will occasionally be found upon careful search to depend upon long exposure to lead in some unsuspected way. The cause being removed, such cases often promptly recover.

Measures aimed first at the separation of the lead from the tissues, and then at its elimination from the body, constitute a rational treatment. Sulphur baths and the internal administration of sulphur may be employed with a view of converting the lead eliminated by the skin and mucous membranes into an insoluble sulphide, and thus preventing its resorption. Repeated laxative doses of castor oil will remove unabsorbed lead from the intestinal canal. The plan of treatment at present in general favor consists in the combined use of potassium iodide and magnesium sulphate. From five to twenty grains of the iodide are to be given in not less than six or eight fluidounces of water three times daily, the stomach being empty: two hours after each dose one or two drachms of the magnesium sulphate are to be taken; after this dose an ordinary meal.

This treatment is designed to dissolve the lead deposited in the tissues, and cause its elimination by the mucus of the alimentary canal in part, and to a slight extent also by the urine. The magnesium sulphate tends to remove such lead as finds its way into the alimentary canal thence with all possible rapidity. These measures, together with the removal of the patient from further exposure, exert of themselves a favorable influence upon the malnutrition and anæmia. Quinine, strychnine, iron, cod-liver oil may be advantageously administered as the toxic effects of the lead pass away.

The colic demands the administration of opium or its derivatives to relieve the pain, which is commonly excruciating. For this purpose the hypodermic injection of morphia is our most efficient remedy. Alum in doses of twenty to thirty grains every four or six hours is useful in lead colic.

For the relief of the local paralytic affections local as well as general treatment is necessary. Massage is of great use, especially when combined with passive movements. Galvanism, one large electrode being applied to the cervical vertebra, the other to the extensor surface of the affected limbs, is followed by excellent results. Labile currents of fifteen or twenty cells should be thus applied, the poles being changed several times at each sitting. As the nutrition of the muscles improves faradic currents may be occasionally substituted. Persevering treatment is necessary to obtain the best results.

For the present relief of the arthralgia gentle frictions with or without anodyne liniments must be employed. The hypodermic use of morphine

may become necessary in cases in which the pain is urgent. It is, however, here as elsewhere, to be if possible avoided. The tendency to recurrent joint-pains rapidly disappears as the poison is eliminated from the organism.

For the relief of the severe cerebral symptoms which are described under the term Encephalopathy special treatment is of little avail. All observers agree in recommending an expectant plan. The measures of treatment directed against the general condition, as above described, must be steadily continued. The influence of chronic lead-poisoning upon pregnancy is very deleterious. Constantine Paul¹ and others have shown that the early death of the fetus very constantly occurs. The prompt removal of women who have become pregnant, from all exposure to lead, and energetic medicinal treatment, are needed to obviate the danger of abortion.

PROGRESSIVE UNILATERAL FACIAL ATROPHY.

By CHARLES K. MILLS, A. M., M. D.

DEFINITION.—Progressive unilateral facial atrophy is a disease characterized by progressive wasting of the skin, connective tissue, fat, bone, and more rarely muscles of one side of the face.

SYNONYMS.—Progressive facial hemiatrophy, Neurotic atrophy of the face (Virchow), Facial trophoneurosis (Romberg), Prosopodismorphia (Bergson), Atrophy of the connective tissue of the face or Laminar aplasia (Lande).

HISTORY AND LITERATURE.—This disease has been known to the medical profession since 1825, when, according to Eulenburg, it was first described by Parry. The *Index Catalogue* contains references to thirty books and articles on the subject in various languages. Eulenburg gives a bibliography which contains thirteen references not given in the *Index Catalogue*. One personal case, which will be detailed later, has fallen under observation. In all, I have collected from fifty to sixty cases. The number of reported cases is slowly increasing; nevertheless, the disease must still be regarded as rare. Carswell,¹ according to Lasègue,² first arranged scientifically the various lesions which might arise in consequence of a retardation and arrest, or even inverted action, in nutrition, and at the same time that he assigned their causes pointed out the several forms of atrophy. Aran³ has written a contribution on the subject, furnishing valuable material for classifying atrophies. Romberg called general attention to the disease in his clinical researches, published in 1846. He described the disease under the name of a new form of atrophy of the face, and took the position that it was a primary trophoneurosis. Of contributions by American writers, a paper by Bannister⁴ is the most complete and valuable. This not only contains two fully and carefully reported cases, but also a thorough discussion of special symptoms and the pathology of the disease. The chapter of Eulenburg⁵ contains an excellent sketch of the disease, and is especially valuable for the discussion of the various theories as to its nature.

ETIOLOGY.—The disease is of much more frequent occurrence among females than males. Out of 25 cases which I have been able to classify,

9 were in men and 16 in women. It is an affection of comparatively early life. The following were the ages of 25 patients: under ten years, 7; from ten to twenty years, 11; from twenty to thirty years, 6; over thirty years, 1.

Graefe¹ reports a case due to syphilis, in which there was also paralysis of the left oculo-motor externus and trigeminus. In one of Bannister's cases the patient had suffered repeatedly from slight frost-bites. Among the causes which seem to be thoroughly established traumatism holds the first place. The affection could be traced to injury in a fair number of the published cases. A case is reported by Maragliano² of a child who had a fall in which she struck the left half of her face, and in consequence of which a circumscribed swelling appeared near the external angle of the left eye and remained for a few days. Shortly after this the left half of the face began to grow smaller than the right. Schuchardt³ speaks of a fall on the head which left a cicatrix on the right parietal bone below the coronary suture, the injury being followed by facial atrophy. Panas⁴ reports a case in which the wasting of the face followed a fracture of the lower jaw. In one of two cases reported by Bannister,⁵ a man, aged forty-two, is stated to have been thrown from a stage-coach, falling on his head, and not losing consciousness, but receiving a scalp wound over the coronal suture. Subsequent to this time he had cerebral symptoms, physical and mental, and unilateral facial atrophy developed.

SYMPTOMATOLOGY.—Before discussing the symptomatology I will give brief notes of the following case, which has not been before reported, and which was observed by me while in charge of the Nervous Dispensary of the Hospital of the University of Pennsylvania several years since.

C—, aged seventeen, white, a mill-operative, had a good family history. Three years before coming under observation a white spot appeared in the skin over the right malar prominence, and since that time this side of the face had gradually atrophied. When this patient was first examined the skin had a mottled appearance. Close examination showed that the skin, connective tissue, and bone were decidedly wasted, and there seemed also to be some loss of substance in the muscles of the right side of the face. The mouth, however, could be closed properly, the lips showing no puckering or drawing to one side. The right half arches of the palate were atrophied. The uvula was drawn slightly but positively to the left. Careful examination of the membrane of the drum of the right ear showed it to be atrophied. An ophthalmoscopic examination of both eyes was made, but no changes were discovered. No changes were noted in the hair of the patient on the affected side. He was able to perform all movements with the facial muscles, but the creases and contours of the face in repose and in motion were less marked on the right side than on the left. The skin of the right side of the face seemed to be bound closely to the bone. The muscles on the same side responded well to

the faradic and galvanic current. The patient had at times a peculiar sensation of stinging in the atrophied half of the face. He was treated with electricity, local massage, and tonics, and did not improve, but did not get worse while under observation, a period of several months.

At the Hospital of the University of Pennsylvania I also observed one well-marked case of unilateral atrophy of the tongue without atrophy of the face, of which, unfortunately, I have not preserved the notes. The patient was a middle-aged man with a syphilitic history. The atrophy in the reported cases has occurred much more frequently upon the left than upon the right side of the face.

Changes in the skin are among the most constant and striking phenomena. By some dermatologists the disease is regarded as a form of morphœa, the keloid of Addison. Morphœa as described by Duhring¹ occurs in the form of patches, rounded, ovoid, or irregular in outline, small or large, tough or leathery, smooth or shiny, and may also manifest itself in the form of atrophic pit-like depressions in the skin. The skin alterations differ somewhat in character; frequently one of the first signs of the disease is the appearance of a white spot on the cheek. This was the first noticeable phenomenon observed in the above case. After a time this spot or patch may change in color, becoming of a yellowish or brownish hue. A number of spots appearing and undergoing change, the skin after a time assumes a mottled appearance. In some of the reported cases a yellowish, or yellowish-gray, or brownish appearance is recorded as having been present. In these the observations were probably made after the affection had existed for some time, and in them the white spots or patches were probably at first present. In one of Romberg's cases, first recorded when the patient was nine and a half years of age, he noted the deposit of a yellowish-gray pigment which began at the median line and extended to the angle of the jaw across the lower half of the face and neck, divided here and there by portions of healthy skin. Discoloration, varying in intensity, also existed in irregular patches on the upper part of the face and on the forehead. The discolored tissues were glossy and greasy-looking. The skin adhering to the bone often gives the patient an aged appearance. Pruritus has been several times observed.

Changes take place in the hair. Sometimes it simply changes color; at other times it falls out or ceases to grow. The beard or hair of the head will thus be gray or white upon one side, or in one or two locations of one side and not of the other; or the hair may be absent or simply thinned out. Peculiar limitations in the extent to which the hair is affected are sometimes observed. In one of Romberg's cases, for example, complete absence of the eyelashes from the inner angle of the eye to the middle of the lids was noted; the hair was very thin, and in some parts altogether wanting, and the left eyebrow was almost entirely devoid of hair. The changes which take place in the color of the hair in some severe cases of chronic trigeminal neuralgia will be recalled in this connection. I have known of several instances in which a few locks of hair were turned gray or white on the neuralgic side. Anstie, author of the work on Neuralgia, was a sufferer from supraorbital neuralgia, and the eyebrow of the same side contained a white tuft. Facts of this kind

¹ *Medical News*, vol. xlv. No. 4, July 26, 1884, p. 85.

serve to corroborate and emphasize the view that unilateral facial atrophy is a tropho-neurosis.

Anidrosis, or absence of perspiration, on the atrophied side of the face is a nearly constant phenomenon. In one of Bannister's cases, a printer, attention was first called to the patient by the fact that in working a hand printing-press in the hot weather he perspired only on the right side of his face. The left side remained perfectly dry, no matter how warm the temperature or hard the labor. This hemidrosis, or unilateral sweating, was confined only to the right side of the forehead, the right cheek, side of the nose, and lip. On the chin it encroached a little on the left. Under the chin and in the throat there was a little excess of perspiration on the right side; on other portions of the body no difference was noted. Nicati¹ considers a combination of symptoms, several of which were present in a recorded case—namely, lowered temperature, stoppage of perspiration, and wasting of the side of the face—as indicating a paralysis of the sympathetic nerve in what he calls its second or more advanced stage. In true facial hemiatrophy, however, other phenomena of such paralysis are wanting. Brunner² gives a case in which perspiration, tears, mucous secretions, and temperature were all diminished on the affected side, and in which were also present exophthalmos and dilatation of the pupil. The cervical sympathetic in this case was irritated by a tumor. I agree with Bannister, however, that while we cannot exclude the possibility of the participation of the sympathetic in hemiatrophy of the face, the evidence is not sufficiently positive. Mechanical interference with the sweat-glands by pressure or otherwise has been suggested. The true view to take would seem to be that the perspiratory disorder is due to the same central or peripheral neurotic affection which gives rise primarily to the atrophy. Eulenburg says that the secretion of the sebaceous follicles is in most cases diminished or stopped on the atrophied side, while the sweat-glands often act in a normal manner; but his experience does not seem to correspond with that of the majority of other observers.

Seguin, Dreschfeld, and others have found no notable differences in surface temperature between the two sides of the face. In one of Bannister's cases the temperature was tested in both ears, and a difference of six-tenths of a degree Fahrenheit in favor of the ear of the unatrophied side was found, that of the left ear being 97.6°, and that of the right 98.2°. This examination was repeated on another occasion with nearly the same result.

Weakness of pulsation in the carotid of the affected side has been observed. Sometimes the power to blush is lost on the affected side, but this may return. In one instance the cheek, having been reddened by electrical stimulation, so remained for an hour or more.

Paræsthesiæ, such as pain, numbness, and stinging sensations, are not uncommon. A diminution of the general tactile sensibility of the skin of the affected side has been observed by Tanturri³ and by Vulpian,⁴ and perhaps by others, but anæsthesia is not commonly present.

Eulenburg and Guttmann found atrophy of the muscles supplied by the motor branch of the fifth nerve—namely, the masseter and temporal.

¹ *Sur Paralysie du Nerf sympathique-cervical*, Lausanne, 1873, quoted by Bannister.

² *St. Petersburg Med. Zeitschr.*, ii., 1871, quoted by Bannister.

³ *Il Morgagni*, 1872, quoted by Bannister.

⁴ *L'Appareil vaso-moteur*, ii, p. 430.

The changes which take place in the muscles of the affected side are, so far as can be judged, not of the character of fatty degeneration. Probably a general and uniform shrinkage of calibre of muscular fibres and bundles occurs. Certainly, this would seem to be true of the muscles supplied by the portio dura. The muscles on the atrophied side respond to both the faradic and galvanic currents, reactions of degeneration not being present. The absence of the reactions of degeneration in the facial muscles shows that normal muscular fibres remain. In one reported case the facial muscles seemed at first to react more readily than in normal conditions. The muscles of the upper lip sometimes appear to have wasted, preventing full closure of the mouth on this side. Fibrillary twitchings have been observed only very rarely. Voluntary control over the muscles of the affected side is not impaired.

In one of Bannister's cases the first upper molar of the left side sometimes ached, and the gum and bone were so wasted as to expose its roots for a considerable distance. Falling out of the teeth has been observed in a few other cases.

Atrophy of the tongue is associated with the facial wasting in a certain percentage of cases, and the uvula and soft palate are also sometimes wasted. On the other hand, atrophy of the tongue has been observed as an isolated phenomena.

Atrophy of the bones of the face is frequently present, and has been determined by careful measurements. It will show to a greater or lesser extent according to the age of the patient. When the disease arises after the bony development has been fully acquired, there will be little external evidence of osseous involvement; when it begins during the time of active growth of the bone, as it does not infrequently, the arrest in the skeleton will be very apparent. Thus in a number of cases beginning in early childhood bone atrophy has been a very marked feature.

Eulenburg says that the functions of taste, smell, hearing, and seeing are not interfered with in any of the reported cases; but Bannister reports impairment of the sense of taste in both of his cases. In one the whole left half of the tongue was involved, in the other only the left posterior third. In the first of these, in which the whole left half of the tongue was involved, both the glosso-pharyngeal and the chorda tympani nerves were affected. According to Bannister, the significance of this observation is that either the glosso-pharyngeal and fifth nerves are both involved, or that the taste-fibres for the base as well as tip of the tongue are derived from the last-named nerve. In this case, however, which was due to a severe injury, the headache, mental confusion, loss of hearing, etc. more probably indicated a widespread intracranial lesion, affecting to some degree the nucleus of the glosso-pharyngeal. In the other case, which was apparently a typical one of unilateral facial atrophy in its early stage, no history of traumatism was present, and the sense of taste, which was carefully tested several times, was seriously impaired over the left posterior third of the tongue.

Bannister discusses the probable cause of impairment of taste in each case, as follows: "The atrophy seemed to involve the region supplied by the second division of the fifth nerve as much as, or more than, the other divisions; and on this is situated the spheno-palatine ganglion which gives off the Vidian nerve, the upper division of which, the superior

superficial petrosal nerve, is supposed by Schiff to contain the taste-fibres, which return from the lingual nerve through the chorda tympani. The usual theory of this disease is that it depends upon an affection of the trophic fibres contained in the fifth nerve or one or more of its divisions. Accepting this theory, Baerwinkel,¹ noticing a case of unilateral atrophy of the face affecting only the second division of the fifth, and, as he held, indicating trouble with the spheno-palatine ganglion, its trophic centre, mentions the fact that there was no impairment of taste in the anterior portions of the tongue as rather against the hypothesis of Schiff as to the course of the taste-fibres. At the same time he gives two other observations of lesions of the trifacial and the seventh nerve that favor it. In our patient I should have expected a priori to have found the taste affected in the anterior portion of the tongue, if anywhere, but the reverse was the fact. It is difficult to suppose an accidental lesion of the glosso-pharyngeal coexisting with the one of the trigeminus that produces the atrophy when there are no more signs of nervous disorder than there were in this case. On the other hand, the taste-fibres of the glosso-pharyngeal are not generally supposed to have such connections with the fifth nerve as to be involved in its disease, while those of the chorda tympani, of the connections of which with the trigeminus there is much more physiological evidence, escape. The observation is a contradictory one, and I cannot at present explain it."

So far as I know, ophthalmoscopic changes have never been noted. In a few cases enophthalmos, or sinking in of the eye, doubtless due to the disappearance of orbital fat as the disease advances, has been recorded.

Defects of hearing, and even partial deafness, have been reported in a very limited number of cases, making it questionable whether this symptom is a coincidence or a complication. In the case reported by me careful examination of the membrane of the tympanum by W. Ziegler of the ear department of the Hospital of the University of Pennsylvania showed atrophy of this membrane.

Eulenburg speaks of one case in which the external atrophy had reached as far as the larynx, and in which the pronunciation of the letter *r* was somewhat impeded. Beverly Robinson,² reports a case accompanied with slight paralysis of the adductors of the vocal cords. The laryngeal paralysis in this case improved under treatment, which led Robinson to believe that the relation between the two affections might have been only one of coincidence.

Flascher³ has described a unique case of bilateral facial atrophy occurring in a woman twenty-three years old. When an infant she fell and injured her forehead, and soon afterward had an attack of measles without eruption. Shortly afterward the atrophy appeared. Tactile sensibility was diminished and the secretion of sweat absent. The masseter, temporal, and facial muscles and bones were atrophied. External strabismus of the left eye was present; the pupil of this eye was dilated, irregular, and non-reactile; sight was diminished, the optic disc atrophied. This case would appear to differ somewhat from true facial hemiatrophy. It was probably a peripheral nerve affection following measles.

³ *Berliner klin. Wochenschr.*, 1880, No. 31.

Mitchell¹ has reported a case of absence of adipose matter in the upper half of the body. I had an opportunity of examining this patient, who was exhibited at a meeting of the Philadelphia Neurological Society, and noticed that both sides of the face presented a striking similarity to the affected side in cases of unilateral atrophy. The muscles were apparently not affected. Mitchell suggests the possibility of separate centres capable of restraining deposits of adipose tissue.

DURATION AND TERMINATION.—The disease pursues a slow but generally progressive course. In a few instances, after having attained a certain development, it seems to have remained stationary for many years. Nothing could better illustrate the slow progress or stationery character of this affection than the study which Virchow made in 1880 of a patient whose case had been described by Romberg more than twenty years before. After comparing the patient's present condition with that described in notes taken twenty-one years before, Virchow was not able to convince himself that any material alteration had occurred in the atrophic parts; in fact, he regarded the disease as having long ago become stationary. Cases reported by Tanturri, Baerwinkel, and others bear out the same view as to the stationary character of the affection in some cases.

COMPLICATIONS.—In a case of Virchow's, in addition to the facial atrophy the patient presented atrophy which, commencing in the distribution of some of the dorsal cutaneous nerves of the scapular region, affected the musculo-spiral nerve from its origin downward, most markedly in the forearm and hand. Mendel² describes a case of facial hemiatrophy occurring in a monomaniac, the diagnosis being complicated by the somatic signs of degeneracy—congenital facial and bodily asymmetry. The patient was twenty-eight years old, and the disease could be traced back to the seventh year. In several reported cases the disease has followed or has been associated with epileptic seizures. Buzard³ has published a case in which the affection came on in a girl aged thirteen in the course of a second attack of chorea. In another it followed typhoid fever. In a case reported by Parry⁴ left hemiplegia with temporary disturbance of intelligence preceded the disease by about two years. In another, observed by Axman and Hueter, the patient, a man aged thirty-two, had suffered from irregular contractures of the left masticator muscle, which commenced in the seventh year. These spasms were associated with an increased delicacy of sensation in the region of the left trigeminus. Neuralgia is sometimes a complication. In a case reported by Holland,⁵ the patient for several years suffered from paroxysms of fronto-temporal neuralgia.

PATHOLOGY.—Up to the present time, so far as I have been able to learn, not a single autopsy in a case of typical progressive unilateral facial atrophy has been made. Conclusions as to pathology can therefore only be drawn from an analysis and study of symptoms and from comparisons with other degenerative affections. Most authorities hold that it is neurotic in origin.

¹ *Am. Journ. Med. Sci.*, July, 1885.

⁴ Eulenburg.

⁵ *American Practitioner*, vol. xxxi. No. 182, Feb., 1885, p. 72.

Lande, however, regarded it as having its origin in the connective tissue, affecting the nutrition of the other tissues by interfering with the circulation.

Different views have been held by those who have believed in its neurotic origin. Moore regarded it as a form of progressive muscular atrophy attacking the muscles supplied by the portio dura, but what has already been shown with reference to the symptomatology is sufficient to show that this is an erroneous hypothesis. The muscles supplied by the facial nerve may diminish in volume, but they do not undergo a true degeneration.

Brunner attributed the affection to continued irritation of the cervical sympathetic by some continuing lesion. Irritation of such a lesion, according to him, causes vascular spasms, diminishes blood-supply, and thus leads to the gradual development of the atrophy. This view, to say the least, has not been made out.

Virchow holds that the affection is peripheral, and not central. He believes, however, that a primary process being once set up in the nerve-trunks, owing to inflammations of the surrounding tissues it may then extend upward to the spinal and basal ganglia. The disease, according to this view, has some analogy to herpes zoster. The manner in which nerve-districts are unequally attacked is similar to what is observed in the various forms of lepra and in morphœa. The doctrine of a tropho-neurosis is the one that is best upheld by clinical facts. In the first place, various arguments can be adduced to show that the disease is neurotic in origin. It is limited to one side of the face and to special nerve-distributions. Affections of sensibility in the domain of the trigeminal nerve are frequently present. In the case given under Symptomatology, although anæsthesia was absent, the patient complained of peculiar paræsthesia in the form of stinging sensation. Either trophic centres or trophic fibres, which have the same connection and course as the trigeminal, are affected by a degenerative process. Whether nuclei, ganglia, or peripheral fibres are primarily affected has not yet been satisfactorily determined.

The case of Romberg, observed by Virchow twenty years after, was considered by the latter to entirely overthrow the vaso-motor theory, owing to the condition of the blood-vessels. While the surrounding tissues from the skin inward were wasted and shrunken, the veins and arteries of the parts appeared absolutely unchanged, the larger even projecting above the surface of the skin. Under stimulation the vessel dilated as in a normal individual, appearing to take no part in the atrophy.

DIAGNOSIS.—The chief affections from which progressive unilateral facial atrophy are to be diagnosed are congenital asymmetry of the face and head, facial paralysis, progressive muscular atrophy, and hypertrophy of the opposite side of the face.

Congenital asymmetry of the face is observed in institutions for the idiotic and feeble-minded. Such asymmetry, however, is usually associated with corresponding defects of other parts of the body, as of the head and limbs. In the nervous wards of the Philadelphia Hospital is now, for instance, a patient the entire right half of whose body is very decidedly wasted, the case being one of epileptic idiocy with paralytic and choreic manifestations which point to atrophy of the opposite half

of the cerebrum. At the Pennsylvania Training-School for Feeble-minded Children want of development of one-half of the head is often observed, but in these and in other congenital cases the special changes in nutrition, in the skin, in the color and growth of the hair, and in sensation, are absent. In some cases of congenital asymmetry of the head atrophy of the face or limbs, if present, will be upon the opposite side of the body; and this is what might be expected, as arrested development of the cranial vault will probably correspond with arrested development of the cerebrum of the same side and bodily defects of the opposite side.

Eulenburg, Maragliano, and others refer to an acquired want of symmetry of the face sometimes observed in cases of wry neck or scoliosis with deviation of the spinal column. Eulenburg especially speaks of the so-called habitual scoliosis, where a curve in the dorsal region in one direction has a compensatory cervical curve, the side of the face which corresponds to the dorsal curve being often smaller than the other. This asymmetry is supposed to result from compression of the vessels and nerve-roots in the concavity of the cervical curve. Here, again, the absence of special nutritional changes will assist in the diagnosis. A study of the spinal curvature will also be of value. Indeed, only the most careless observation would allow this mistake in diagnosis to be made.

Facial paralysis—Bell's palsy of the usual type—would not be likely, except by a careless observer, to be confounded with the disease under consideration. When the muscles in the facial distribution are involved, it is only in a very slowly progressive deterioration, which may be due to mechanical causes, as compression by the contracting skin. Moore,¹ as already stated, was wrong in speaking of the morbid changes as entirely confined to the portio dura of the left side. It is the fat, the connective tissue, and the skin which are first and chiefly affected. In unilateral facial atrophy no true paralysis of the facial muscles is present; consequently, the forehead can be wrinkled, the eye closed, the mouth drawn up or down, or sideways, etc.; in short, all the movements of the face are possible. The opposite of this, it goes without saying, is present in general facial paralysis. The drawing of the face to the side opposite the paralysis in Bell's palsy is not here observed; the mouth is sometimes drawn upward slightly on the atrophied side. In facial paralysis of any severity reactions of degeneration are present. In unilateral facial atrophy, as in progressive muscular atrophy, the muscles respond both to faradism and galvanism. As minor aids in making the diagnosis, the absence of loss of taste in one-half of the tip of the tongue, and of deflection of the tongue and uvula, are in favor of facial atrophy.

It is possible that a case of progressive muscular atrophy might begin in almost any muscle or group of muscles in the body. In progressive muscular atrophy, however, the appearance of the skin is different; it is not mottled; it is not thin, as can be demonstrated by manipulation of it; it can be raised by the fingers; it is soft and flaccid. In progressive muscular atrophy also first one muscle and then another, just as likely as not at some distance from each other, are attacked by the wasting process; in unilateral facial atrophy the affection spreads uniformly and regularly

¹ *Dublin Journal of Medical Science*, vol. xiv., August and Nov., 1852, p. 245.

over one-half of the face. According to Duchenne of Boulogne, when progressive muscular atrophy first appears in the face the orbicularis oris is the muscle most likely to be attacked, causing the lips to appear enlarged and pendent, and giving a stupid look to the patient. In unilateral facial atrophy this appearance is not present. Progressive muscular atrophy commonly begins at a later age than unilateral facial atrophy.

Hypertrophy of the opposite side of the face is suggested by Eulenburg as a possible source of mistake; but a little study, however, will suffice to exclude this affection.

The following points are given by Eulenburg with reference to vitiligo and porriigo decalvans: "In vitiligo we find the same white decoloration of the skin, the cicatricial feel, the turning gray and falling out of the hair, but not the loss of volume, which is the special characteristic of this disease. In porriigo decalvans inflammatory symptoms and cedema of the skin come first; the disease first appears in regular circular spots; the hairs fall out without previous loss of color; and finally, the disease is contagious, and fungi can be demonstrated (*microsporon Audouini*)."

PROGNOSIS.—The prognosis as to recovery is bad, but, as already shown, the disease may long remain stationary.

TREATMENT.—No well-authenticated case of cure under any method of treatment has yet been reported. Electricity, either in the form of galvanism or faradism, has been resorted to in a majority of cases. In most of these temporary benefit has been produced by the employment of these agencies. Baerensprung reports two cases as having been greatly benefited by faradism. In Moore's case it also produced temporary improvement. Carefully administered massage should be tried. With reference to friction or massage, however, it is well, as advised by Eulenburg, to be cautious, as excoriations are easily produced. Measures directed to building up the nervous centres are indicated—such medicinal agents, for instance, as the salts of silver, gold, zinc, and copper, arsenical preparations, strychnia, and iron.

DISEASES OF THE MEMBRANES OF THE BRAIN AND SPINAL CORD.

By FRANCIS MINOT, M. D.

THE membranes or envelopes of the brain and cord were formerly reckoned as three in number: the dura mater, lying next to the inner surface of the bones of the cranium and spinal column, forming an internal periosteum; the pia mater, which is in immediate contact with the brain and cord; and the arachnoid, which was described as a distinct membrane loosely attached to the pia mater, but more firmly united to the dura, and constituting a closed sac or serous cavity called the cavity of the arachnoid. This view is now abandoned by most anatomists, who regard the external arachnoid as simply a pavement epithelium covering the internal surface of the dura, and the visceral arachnoid as constituting the external layer of the pia. The term cavity of the arachnoid has, however, been generally retained for the sake of convenience; and it gives rise to no obscurity if we remember that by it we simply mean the space between the dura and the pia.

The diseases of the membranes which I shall consider are—congestion and inflammation of the dura, including hæmatoma; congestion and simple and tubercular inflammation of the pia; and meningeal apoplexy.

The membranes of the brain and those of the cord may be separately diseased, or both may be affected at the same time. Simultaneous inflammation of the cerebral and spinal meninges is apt to occur epidemically, and is supposed to be zymotic in its origin. This is described in another article. (See EPIDEMIC CEREBRO-SPINAL MENINGITIS, Vol. I. p. 795.)

Inflammation of the Dura Mater of the Brain.

SYNONYM.—Pachymeningitis. Either surface of the dura may be inflamed separately, and in many cases the symptoms are sufficiently definite to render it possible to diagnosticate the situation of the disease in this respect during life, especially when taken in connection with the causes. For this reason it is usual to speak of external and internal pachymeningitis. A peculiar form of the latter is accompanied by the effusion of blood upon the arachnoidal surface, which sometimes forms a tumor called hæmatoma. Congestion is also sometimes included in the diseases of the dura mater, but is rarely alluded to by writers on pathology or clinical medicine.

Congestion of the Dura Mater.

Except as the first stage of inflammation, congestion of the dura can hardly exist unless in connection with the same condition of the pia or of the brain. Its causes are either local, such as thrombosis of the sinuses, syphilitic or other growths in the membranes; or remote, the principal being obstructions to the general circulation, including valvular disease of the heart, emphysema and other affections of the lungs, renal disease, compression of the superior cava or jugulars by aneurism and other tumors, delayed or suppressed menstruation, etc. The symptoms cannot be distinguished from those of congestion of the pia or of the brain—namely, headache, a sensation of throbbing, pressure, or weight in the head, somnolence, etc. The absence of fever would serve to distinguish the affection from an inflammatory condition of the membranes or brain.

Inflammation of the External Surface of the Dura.

SYNONYM.—External pachymeningitis.

ETIOLOGY.—The most frequent causes of external pachymeningitis are injuries to the cranial bones from violence, caries and necrosis of the same, and concussion from blows on the head. Next in order of frequency, if not even more common, comes the propagation of inflammation from disease of the inner ear and of the mastoid cells. It is only of late years that this important subject has been brought prominently forward and the danger of ear diseases in this respect fully pointed out. The channels of communication, as indicated by Von Tröltsch¹ in his valuable article on diseases of the ear, are along the arteries and veins which pass from the skin of the meatus and the mucous periosteal lining of the middle ear to the contiguous bone, while the capillaries of the petrous bone are in direct connection with the dura mater, so that the vessels of the latter are in communication with the soft parts of the external and middle ear. The vessels of the ear and the membranes of the brain are also directly connected through the diploëtic veins of the temporal bone, which discharge into the sinuses of the dura, as well as through the venæ emissariæ, which, arising from the sinuses, pass through the bone and discharge their contents into the external veins of the head. Von Tröltsch also points out that the extension of an inflammatory process may occur along the sheath of the facial nerve, the canal of which (canalis Fallopii) is a branch of the internal auditory canal and is lined by the dura mater. The latter is separated from the mucosa of the tympanum only by a thin, transparent, and often defective plate of bone. Inflammation may also be transmitted from the scalp by means of the vessels which pass through the bones of the skull. In this way erysipelas and other diseases of the integument sometimes give rise to external pachymeningitis.

SYMPTOMS.—There are no known symptoms which are characteristic of inflammation of the external surface of the dura. In cases of death

¹ "Die Krankheiten des Gehörorganes," von Anton von Tröltsch, in *Gerhard's Handb. der Kinderkrankheiten*, Tübingen, 1879, 5 B., ii. Abt, p. 150; also English translation of the same, by J. O. Green, M. D., New York, 1882, p. 107.

from other diseases an autopsy may show traces of previous inflammation, such as thickening of the membrane and its firm adhesion to the cranial bones, which were not manifested during life by other symptoms than those which accompany meningeal disease in general; and in some instances none at all were known to have occurred. At a variable time after the receipt of an injury to the head the patient may complain of headache, followed by a chill, with high fever, vomiting, vertigo, delirium, unconsciousness, convulsions, etc., arising from compression by the products of inflammation. The same phenomena may follow the transmission of inflammation to the dura from caries or other disease of the bones, or from otitis media purulenta. These symptoms usually continue without interruption, though there is sometimes more or less complete remission of the pain, and the patient may recover his consciousness for a time, thus giving rise to fallacious hopes. In a large proportion of cases the disease extends to the inner surface of the membrane and to the pia, without any noticeable change in his condition other than coma. In chronic external pachymeningitis the principal symptom is pain in the head, which may persist for weeks or months without other manifestations except drowsiness. Sometimes, on the contrary, there is obstinate vigilance. Mental symptoms, such as loss of memory, hallucinations, dementia, or mania, are sometimes noticed, ending, as in the acute form, in coma.

PATHOLOGICAL ANATOMY.—In chronic cases often nothing is found but thickening of the membrane, which generally becomes firmly united to the inner surface of the cranium. Indeed, these appearances are not unfrequently observed, to a limited extent, when there has been no history of disease to account for them. In other chronic cases the connective tissue of the membrane is found to be in part ossified, and the osteophytes of the cranium sometimes found in pregnant women and in patients with rheumatic cachexia are supposed to be due to a chronic inflammatory process of the dura. The first changes observed in acute external pachymeningitis are increased vascularization, shown by red lines corresponding to the blood-vessels, with punctiform extravasations, swelling, and softening of the tissue. Later, there is thickening of the membrane from new formation of connective tissue, and exudation of lymph, and sometimes of pus, which latter may accumulate between the dura and the cranial bones, or in traumatic cases may escape through openings in the skull. The dura and the pia become united in most cases of acute inflammation. The lateral sinuses frequently contain thrombi, which, when ante-mortem, are firm in structure, reddish-brown in color, often closely adherent to the walls of the vessel, and may extend to other veins, sometimes reaching as far as the jugulars. When purulent inflammation of a sinus occurs, its walls are thickened, softened, and discolored, and the inner surface is roughened. The thrombus becomes more or less purulent or sanious, disintegrates, and the infecting particles are carried into the circulation, giving rise to embolism and disseminated abscesses of the lungs, kidneys, liver, or spleen. Other lesions, such as injury or caries of the cranial bones and purulent inflammation of the middle ear and of the mastoid cells, are frequently found in conjunction with pachymeningitis, to which they have given rise. When the disease of the dura extends to the pia, the adjacent portion of the brain is often found implicated in the inflam-

mation. In traumatic cases the dura may be detached from the bone and lacerated to a greater or less extent.

DIAGNOSIS.—The existence of external pachymeningitis may be suspected from cerebral symptoms following traumatic injury of the skull, erysipelas, or suppurative otitis media, but apart from the etiology it would not be possible to distinguish it from internal inflammation of the membrane, or even from leptomeningitis.

PROGNOSIS.—In cases of suspected external pachymeningitis the prognosis will depend upon the evidence of effusion of pus or blood between the dura and the skull, and the possibility of their removal. A large proportion of cases are fatal, especially those arising from caries of the cranial bones and from the propagation of disease from the middle ear, the mastoid process, or the external surface of the skull, the inflammation extending through the membrane to the arachnoid surface of the dura, and also to the pia mater. This would be shown by a high temperature, rapid pulse, pain, and delirium, followed by coma and perhaps convulsions. The frequency with which external pachymeningitis occurs in connection with diseases of the ear should put the physician on his guard in cases of otorrhœa or pain in the ear, that he may warn the patient or his friends of the possibility of danger, and may employ an appropriate treatment.

TREATMENT.—In all cases of injury to the skull or of severe concussion the possibility of subsequent external meningitis should be borne in mind. The patient should be confined to the bed and be carefully secluded from excitement. Cold applications should be made to the head, the diet should be simple and somewhat restricted, and the bowels kept free without active purging. If there be evidence or suspicion of the presence of pus or of blood between the dura and the skull, means should be taken to evacuate the effusion. In case of inflammatory symptoms leeches should be applied behind the ears, and a stimulating liniment or croton oil rubbed on the scalp. There is no specific treatment. Pain and sleeplessness must be relieved by opiates and sedatives, and the strength must be sustained by nourishing diet and stimulants.

Internal Pachymeningitis.

Internal pachymeningitis is of two kinds: 1st, simple inflammation, which may be accompanied by purulent exudation and by a corresponding affection of the pia mater: 2d, hemorrhagic inflammation or hæmatoma of the dura mater. Simple inflammation of the internal or lower surface of the dura, without the coexistence of external pachymeningitis, is rarely found in the adult. The morbid appearances differ but little from that of the external form, and the causes and the diagnosis are also similar. In children, however, it is not uncommon, according to Steffen.¹ The pus may discharge itself spontaneously through the fontanels or the sutures, or caries of the cranial bones may open a passage for its exit. It has also been evacuated artificially when the symptoms have indicated its presence. In other cases more or less extensive firm adhesions

¹ "Die Krankheiten des Gehirns in Kindesalter," von Dr. A. Steffen, in *Gerhardt's Handb.*, 5 B., i. Abt., 2te Hälfte, p. 380.

between the dura and pia mater have shown the previous existence of inflammation, but it would be difficult to say in which membrane it began. In some instances no symptoms are observed during life; in others the coexistence of inflammation of the pia, effusion into the ventricles, etc. prevent an exact diagnosis.

The TREATMENT does not differ from that of inflammation of the external layer of the pia.

Hæmatoma of the Dura Mater.

SYNONYM.—Hemorrhagic pachymeningitis.

DEFINITION.—A chronic inflammation of the dura mater, resulting in the formation upon its inner surface of successive layers of false membrane, into and between which there is usually an effusion of blood, the whole sometimes forming a large solid mass between the dura and the cavity of the arachnoid.

ETIOLOGY.—Hemorrhagic pachymeningitis never occurs in healthy persons except from traumatic causes. It is most frequently observed in advanced life, and especially in the male sex. In a large number of cases the blood is in an unhealthy condition, and hence the disease is seen in alcoholism, in scurvy, in acute articular rheumatism, and in the acute febrile affections, as typhoid fever, pleuro-pneumonia, and pernicious anæmia, of which last, according to Huguenin,¹ it complicates one-third of the cases. It is frequent among the chronic insane. It is occasionally met with in young children, but with them its causes are mostly unknown; according to Steffen,² they may consist in alterations of the blood resulting from insufficient nourishment or from the infectious diseases, and from abnormal blood-pressure, as in whooping cough, asthma, etc., as well as from blows on the head.

SYMPTOMS.—Many cases of hemorrhagic pachymeningitis complicating other cerebral diseases can be distinguished by no special symptom from the original malady. Thus, in cases of chronic insanity its existence may not be suspected during the lifetime of the patient. Steffen quotes³ the case, reported by Moses, of a child seven months old who died of catarrhal pneumonia, and who exhibited no symptom which could suggest any disease of the brain or its membranes. The autopsy revealed a pachymeningitic cyst extending over the anterior half of the right hemisphere. When symptoms are present they vary in different cases according to the acuteness of the inflammatory process, the amount and situation of the effusion, and the participation of the pia mater and brain in the disease. In the beginning they are usually indefinite, headache being the most common and often the only complaint. This may continue for weeks without any other indication of disease, but it is frequently accompanied by tinnitus aurium, vertigo, muscular weakness, and contraction of the pupils. Wakefulness and restlessness at night and slight twitching of the facial muscles or of the limbs sometimes occur. There may be no change in the condition of the patient for a

¹ G. Huguenin, "Acute and Chronic Inflammations of the Brain," in *Ziemssen's Encyclop.*, Am. translation, New York, 1877, vol. xii. p. 401 *et seq.*

² *Op. cit.*, p. 386.

³ *Op. cit.*, p. 394.

considerable length of time (weeks or months), or he may improve to some extent, owing to the absorption of the serous portion of the effusion or to the tolerance of the foreign body acquired by the brain. Sooner or later a fresh hemorrhage is followed by a recurrence, and usually an aggravation, of all the symptoms. Sometimes the patient becomes comatose, and dies speedily with apoplectic symptoms, but this is not common at an early period. The extravasation of blood generally takes place in small quantities at a time, without giving rise to unconsciousness or paralysis. After a period of uncertain duration, when the tumor has attained considerable dimensions a condition of somnolence may take place, the patient sometimes sleeping twenty-four hours or longer at a time. Distinct paralysis rarely occurs, though hemiplegia is sometimes seen, and the paralysis has been observed on the same side with the lesion. When symptoms of compression appear the pupils become dilated. Toward the end of life the patient is usually in a state of profound coma, the pulse is slow and irregular, and the sphincters are relaxed.

The distinctive features of internal pachymeningitis, therefore, so far as they are at present known, are those which would depend upon a primary cerebral irritation, followed by those of compression of the brain—persistent, often severe, headache, with contracted pupils, and occasionally motor and sensory disturbances; afterward, coma, dilated pupils, and involuntary discharges from the bowels and bladder.

The DURATION of the disease is exceedingly variable, extending from a few days to more than a year. According to a table made from carefully observed cases by Huguenin, 74 per cent. of patients die within thirty days; 18 per cent. live from one to six months; 4 per cent. live from six months to one year; and 4 per cent. live over one year.

PATHOLOGY.—A difference of opinion has existed among pathologists concerning the true nature of hemorrhagic effusions of the inner surface of the dura mater, especially as to whether the membrane in which they are enclosed is formed by a deposit of fibrin from the effused blood itself, or whether the disease consists essentially in an inflammation of the dura, followed by a pseudo-membranous deposit into which blood is afterward extravasated. The latter explanation, offered by Virchow, has been generally accepted, but Huguenin, whose opportunities for observing the disease were unusually good, believes that the first stage of hæmatoma is not the formation of connective tissue, but simply an extravasation of blood.

The disease begins with hyperæmia of the dura mater in the area of distribution of the middle meningeal artery, followed by the formation upon its inner surface of an extremely delicate membrane in small patches of a yellowish color and studded with innumerable bloody points. If the membrane be carefully raised, it is found to be connected with the dura by very delicate blood-vessels, and to contain an immense number of very wide and thin-walled vessels, much larger than ordinary capillaries.¹ At a later stage we find the membranes to be made up of several distinct layers, of which the innermost exhibits the character of the primary deposit, being thin and abundantly supplied with blood-vessels, while those of older formation have become successively thicker and are

¹ See Rindfleisch's *Manual of Pathological Histology*, New Sydenham Soc.'s translation, 1873, vol. ii. p. 302.

composed of tough, lustrous fibres of connective tissue almost as dense as that of the dura mater itself. The delicate structure of the false membranes and of the vessels which they contain leads almost inevitably to the effusion of blood, which increases in quantity with the thickness of the whole growth, so that in an advanced stage it is not uncommon to find large pools of blood, partly clotted and partly fluid, constituting what is called hæmatoma of the dura mater. The small bloody points are within the substance of the false membrane; the extravasations are interstitial, the largest being always found between the youngest membrane and the older layers. In some cases serous transudations also occur between the false membranes. In still rarer instances no blood or serum is found between or beneath the layers. Occasionally small quantities of blood escape by leakage through the delicate membrane into the cavity of the arachnoid.

The usual situation of internal pachymeningitis is the vault of the cranium, near the median line, the upper or external layer of the tumor being in relation with the dura mater, to which it is adherent, and the lower or internal with the arachnoid and pia mater. If the effusion be extensive, it spreads downward over the frontal and occipital lobes of the brain, and laterally toward the fissure of Sylvius. In the majority of cases the disease occupies both sides of the median line symmetrically, but it may be limited to one side only. According to Huguenin, 56 per cent. of the cases embrace the surfaces of both hemispheres; 44 per cent., that of one only. Hæmatoma very rarely occupies the base of the cranium. The thickness and consistency of the deposit vary in different cases, depending upon the number of successive exudations, and hence are most marked in cases of the longest duration.

Hemorrhagic pachymeningitis is occasionally met with in young children, but much more rarely than in adults. The disease is usually more acute than in older persons, but the anatomical appearances are essentially the same.¹

PROGNOSIS.—The great majority of cases end fatally. A few instances of recovery are reported in which the diagnosis seems justified by the symptoms. Moreover, it is not very rare to find, on post-mortem examination of those who have died of other diseases, evidence of the former existence of hemorrhagic pachymeningitis. According to Steffen, while the prognosis of simple pachymeningitis in children is frequently good, owing to the favorable conditions for the exit of pus through the open fontanels and sutures, in hemorrhagic pachymeningitis recovery is rare.

DIAGNOSIS.—In a disease whose symptoms are so vague the diagnosis must of necessity be difficult and often impossible. The chief elements for the formation of the diagnosis are the slow and interrupted progress of the affection, persistent headache, tendency to prolonged slumber, and final coma; the absence of paralysis of the cranial nerves, of vomiting, and of general convulsions; the age of the patient, the coexistence of alcoholism, chronic insanity, or acute rheumatism, and traumatism. The diseases for which hæmatoma would be most likely mistaken are acute inflammation of the meninges, apoplexy from cerebral hemorrhage, tumor in the substance of the brain, and necrobiosis from thrombus or embolus.

¹ For an able description of the lesions of hemorrhagic pachymeningitis in children see the third edition of Rilliet and Barthez's *Maladies des Enfants*, by Barthez and Sanné, Paris, 1884, vol. i. p. 152.

The absence of symptoms characteristic of these affections might lead to a probable diagnosis by exclusion, but in many cases the existence of the disease cannot be determined with certainty. In children it is most likely to be confounded with tubercular meningitis, from which it may be distinguished by the fact that it is most common under the age of two years, the other being rare before that period, and that the characteristic symptoms of tubercular meningitis (prodromic period, vomiting, irregularity of pulse, etc.) are wanting. But the tubercular disease in young infants may closely resemble hæmatoma, a profound coma replacing all other symptoms. Here the existence of tuberculous disease in the parents or other near relatives would point strongly to tubercular meningitis, while the absence of such antecedents would suggest hæmatoma.

TREATMENT.—If the disease be a complication of alcoholism, anæmia, scurvy, rheumatism, etc., the treatment appropriate to those affections should be employed, along with remedies addressed to the local disease. For the early symptoms of irritation, perfect rest in bed, cold to the head, bromide of potassium internally, sinapisms to the back of the neck, together with simple and nutritious diet, are the most efficient means. The bowels must be regulated, but purging is not necessary. The abstraction of blood from the head by leeches to the temples or behind the ears, or by cupping, is recommended by most authorities, especially if there be much heat of the head. Mercury may be tried, care being taken not to salivate the patient. It is obvious that this treatment, in order to be of any avail, must be instituted at the earliest stage of the disease. After the probable formation of the hæmatoma an effort should be made to promote its absorption, which sometimes actually takes place, as is proved by the autopsies of patients who, having previously suffered from this affection, have died from other causes. The iodide of potassium or the iodide of sodium should be employed perseveringly for this purpose, in the dose of from ten to thirty grains three times daily. The bromide should also be continued if necessary. The acne which sometimes accompanies the continued use of these remedies may be prevented or cured by the use of three to five drops of the liquor potassæ arsenitis, given once or twice daily after meals. Counter-irritation to the scalp by means of stimulating liniments or croton oil, and small blisters to the temples, are likely to do good. In alcoholic subjects the amount of wine or spirit taken should be regulated by allowing enough to support the strength, without too suddenly withdrawing the accustomed stimulant. In the stage of coma the treatment must be purely expectant. The state of the bladder must be regularly examined, and the catheter employed when necessary. Liquid nourishment should be carefully given as long as the patient is able to swallow.

Cerebral Meningeal Hemorrhage.

SYNONYM.—Meningeal apoplexy of the brain. Hemorrhage of or upon the membranes of the brain is closely connected with intracerebral hemorrhage. Both arise from similar causes, and the former may result directly from the latter. It is for convenience of arrangement that the two subjects are treated separately in this work.

ETIOLOGY.—The causes of meningeal apoplexy are predisposing and immediate. The most important predisposing cause consists in disease of the cerebral vessels, especially the arteries, which favors the formation of so-called miliary aneurisms, as demonstrated by Charcot and Bouchard in the case of cerebral apoplexy. Disease of the vessels in its turn arises from various conditions, among which alcoholism in adults holds a prominent place from its tendency to favor a fatty degeneration of the vascular walls. In subjects of purpura or hæmophilia (the so-called bleeders), in whom, from an inherent weakness of the capillary vessels or a deficiency of the fibrin of the blood, or both combined, there is a tendency to extravasation of the blood in various parts, hemorrhage into the arachnoid cavity may occur.¹ A new-born child under my observation had bleeding at the navel and ecchymoses in various parts of the body. Suddenly it became comatose, and it died with signs of cerebral compression. There was no autopsy, but it seems probable that hemorrhage into the cavity of the arachnoid had taken place. A sister of the patient had also had spontaneous hemorrhage from the navel and from other parts shortly after birth, but recovered. Chronic general arthritis and gout also probably predispose to the affection, as well as old age, which is accompanied by atrophy of all the tissues. The disease is most frequently met with in the two extremes of life; according to Durand-Fardel,² in adults the largest number of cases occurs between the ages of seventy and eighty years.

The exciting causes comprise injuries to the head, both with and without fracture; strong muscular effort, as in lifting, straining at stool or in labor; powerful action of the heart in cases of hypertrophy. An interesting case is reported³ by S. G. Webber of Boston, in which the effusion was evidently caused by vomiting; a clot of blood covered the greater part of the posterior two-thirds of the right hemisphere. Sometimes meningeal hemorrhage may arise from the bursting of an intracerebral apoplexy into the arachnoid cavity, as in a remarkable case occurring in the practice of Morris Longstreth of Philadelphia, of bilateral effusion.⁴ Outside the dura, corresponding with the left middle cerebral lobe, was a considerable amount of blood connected with a fracture of the skull, and on the right side a large quantity of blood in the cavity of the arachnoid, originating in the middle lobe, which was torn up. The patient had fallen in the street; he was stupid, there was no paralysis, active delirium came on, followed by coma and death in twenty-four hours. Here was cerebral apoplexy bursting into the cavity of the arachnoid on the right side, and causing the fall, which was the occasion of the fracture and hemorrhage on the left side.

In young children, especially in the new-born, meningeal hemorrhage may follow difficult and instrumental labor, either from injury to the skull or from delay in the establishment of respiration, as in breech presentation, though it sometimes occurs in cases in which the labor has been normal. In a case of breech presentation under my care in 1873

¹ A case of this kind is cited in the article "Pathologie des Méninges" in *Nouv. Dict. de Méd. et de Chirurg. pratiques*, Paris, 1876, vol. xxii. p. 101.

² *Traité clinique et pratique des Maladies des Vieillards*, par M. Durand-Fardel, Paris, 1854, p. 283.

³ *Boston Med. and Surg. Journal*, Jan. 17, 1884.

⁴ *Ibid.*, Dec. 28, 1882.

the child, a female weighing nine pounds, did not cry or breathe for some minutes after birth, although delivery had not been much delayed. Soon afterward it was noticed that it did not move the right arm, although it moved the hand and the fingers. In the course of twenty-four hours, during which time it cried much more than usual, it became comatose, and remained so until its death, three days after birth. The whole surface was livid, and the child had two or three short convulsions. At the autopsy a clot about the size of a grape was found in the pia mater on the upper surface of the cerebellum, in the immediate vicinity of the pons Varolii. The brain was so soft that the amount of injury received by the cerebellum could not be exactly ascertained, but it was probable that the clot extended into the fourth ventricle.

Thrombus of the sinuses of the dura mater, and less frequently of the cerebral arteries, is the origin, in a considerable number of cases, of meningeal hemorrhage in children, in consequence of pressure upon the delicate vessels of the membranes caused by the obstructed circulation. Bouchut¹ reports an observation of hemorrhage produced in this way.

SYMPTOMS.—In some cases the attack is preceded by indications of congestion, such as headache, vertigo, staggering, confusion of ideas, noises in the ears, feeling of weight in the head, delirium, stupor. At the time of the attack the patient frequently complains of severe pain in the head, just as in cerebral hemorrhage, and then falls to the ground with complete loss of consciousness. Sometimes the symptoms come on gradually. Hemiplegia occurs in a notable proportion of cases. Convulsions may occur at any time after the attack. In Webber's case, already referred to, the first symptom was sharp pain in the head and neck; this was followed by very severe headache and pain on motion of the head. Intelligence gradually diminished; on the sixth day there was almost no consciousness, and the patient died in about eight days. She had occasional spasms, in which both eyes were turned toward the left in extreme conjugate deviation, and the left side of the face was distorted. The spasms were followed by suspension of respiration for nearly a minute, cyanosis, and paralysis of the left hand and leg. Both the nature of the lesion and its seat were correctly diagnosed during the patient's lifetime.

As a rule, the condition of unconsciousness continues up to the time of death, but in some cases there are intermissions during which the patient responds to questions more or less promptly. Death takes place at a period varying between a few hours and several days. Durand-Fardel² reports a case in which the patient lived a month from the first attack, with preservation of the intellect and of motion. An inmate of the Home for Aged Women in Boston, eighty-eight years old, previously in good health, complained of severe pain in the head one morning before rising. She took her breakfast in bed, and immediately afterward vomited copiously. From that moment she became insensible, and remained so until her death, seven days and three hours afterward. During this time there was no stertor. No decided paralysis could be discovered, but there was some rigidity of the left arm. At the autopsy an effusion of

¹ E. Bouchut, *Clinique de l'Hôpital des Enfants malades*, Paris, 1884, p. 263. See, also, Steffen, *op. cit.*, p. 352.

² *Op. cit.*, p. 202.

blood was found in the arachnoid cavity extending from below upward on each side to a level with the top of the ear. There was a large amount of blood at the base of the brain, and both lateral ventricles were distended with bloody serum. The vessels were generally in an atheromatous condition. There was no laceration of the brain. The source of the hemorrhage could not be ascertained. In such a case the condition of the patient in respect to power of movement often cannot be ascertained with certainty, in consequence of the abolition of consciousness. Complete muscular resolution is most common when the effusion is bilateral, but when the hemorrhage is limited to one side more or less paralysis of the opposite limbs may exist. Should the blood make its way into the spinal canal, it might give rise to special symptoms, but this is not probable in view of the large amount of the cerebral effusion under the circumstances, which would produce complete insensibility or speedily cause death by pressure on the medulla.

The temperature of the body immediately after a copious cerebral or meningeal hemorrhage falls below the normal point, and remains so for several hours, after which it rises, its degree varying according to circumstances. In fatal cases the elevation is extreme, and remains so until death. If the patient recover, it gradually returns to the normal standard.

Vomiting is a frequent symptom at the beginning of the attack, just as in intracerebral hemorrhage, owing probably to compression of the pneumogastric by the effusion at the base of the brain. In Webber's case the vomiting was evidently the cause of the hemorrhage, and not its consequence, since it had been a frequent symptom for several days before the attack, and was probably due to the presence of a calculus in the pelvis of the right kidney, which was found at the autopsy, and there was no blood at the base of the brain.

PATHOLOGICAL ANATOMY.—The chief points of interest in the morbid anatomy relate to the seat and source of the effusion, the amount and condition of the blood, the state of the vessels and that of the brain, including the ventricles. In respect to the seat, the hemorrhage may occupy the space between the cranial bones and the dura mater; it may be found on the lower surface of the latter, in the arachnoid cavity, or in the meshes of the pia mater, the so-called subarachnoid space. Blood found upon the outer surface of the dura, between that membrane and the bones, is almost always the result of traumatic causes, such as blows or other injuries, with or without fracture, or of caries of the skull. If below the dura, but between that and the so-called parietal layer of the arachnoid, the lesion comes under the title of pachymeningitis interna, already described as an inflammatory disease of the dura with hemorrhagic effusion. The arachnoid cavity and meshes of the pia are by far the most common situations in which the blood is found in meningeal hemorrhage. The origin of the effusion is either the rupture of a capillary aneurism of one of the arterioles of the membrane or of one of the vessels themselves in consequence of atheromatous or other degenerations of its walls. On account of the minute size of the vessels it is seldom possible to discover the exact point at which the rupture took place. In rare instances the source of the hemorrhage is within the brain, the blood being forced through the cerebral tissue, either into the meshes of the pia

or upon the surface of that membrane. The amount of hemorrhage varies according to conditions which are mostly unknown, but is probably dependent upon the size of the ruptured vessel and the conditions under which the accident occurs, such as muscular effort, cardiac action, etc. In some cases it is so small as to give rise to no definite symptoms, as is evident from post-mortem examinations of those who have died from other causes. In these cases there may be either a single effusion or several. The amount is largest when the arachnoid cavity is the seat of the extravasation. The blood, which may be either liquid or more or less coagulated, according to the time which has elapsed since the hemorrhage, is usually found upon the convexity of the hemispheres, most frequently on one side only, and oftenest on the left. But if the rupture have taken place at the base, it often ascends on each side, as in a case mentioned above. Where a large vessel has given way, its contents may cover a great part of the surface of the brain. The coagulum is found in a thin layer, which at the end of a few days is covered with a transparent envelope, evidently composed of a deposit or separation of fibrin. Should the patient survive long enough, this membrane may become organized, receiving vessels from the adjacent pia, and in turn become the seat of new hemorrhages, exactly as in the hæmatoma of internal pachymeningitis. In cases in which absorption of most of the fluid part of the effusion takes place, the membrane remains more or less dense and vascular, and usually contains a small quantity of recently-effused blood within its meshes. Small cysts, containing transparent or reddish-brown serum, are also occasionally observed enclosed between the layers of the membrane. In very young children, whose fontanels are not yet ossified, these cysts sometimes attain to a large size, containing several pints of fluid, which is more or less limpid from absorption of the coloring matter of the blood, constituting the so-called dropsy of the arachnoid.¹ The convolutions of the brain are more or less flattened according to the amount of the effusion, and the cortical substance is correspondingly anæmic from pressure. The blood may make its way, if extravasated in large quantities, into the ventricles, over the medulla, into the spinal arachnoid cavity, or even into the central canal of the spinal cord. The arteries of the brain, especially at the base, are frequently in a state of atheromatous degeneration, and thrombi often occupy the sinuses of the dura mater.

DIAGNOSIS.—The distinction between meningeal hemorrhage and cerebral apoplexy is always difficult, and in the majority of cases impossible. Sudden pain in the head, vomiting, and lowering of the bodily temperature (the thermometer should be placed in the rectum), followed by loss of consciousness, are strongly suggestive of hemorrhage within the cranium, either cerebral or meningeal. If these symptoms are followed by coma and resolution without obvious paralysis, the diagnosis would be almost impossible between intra- and extra-cerebral extravasation. If the loss of consciousness be not complete, so that the presence or absence of paralysis can be ascertained, we can sometimes distinguish the situation of the hemorrhage. Right-sided hemiplegia, with paralysis of the face or tongue, or with aphasia, is most probably owing to hemorrhage or

¹ Charles West, M. D., *Lectures on the Diseases of Childhood and Infancy*, 6th ed., London, 1874, p. 62. These large cysts are much more frequently (perhaps solely) found in cases of hemorrhagic pachymeningitis. (See Barthez and Sanné, *op. cit.*, vol. i. p. 157.)

embolism somewhere in the left motor tract, and hence within the brain. If the absence of paralysis can be certainly ascertained, the probabilities are in favor of meningeal apoplexy. Convulsions affecting the face or limbs of one side would point to irritation of the cortical centres of those parts, and so far to extravasation on the surface of the brain (on the opposite side), as in Webber's case. Where the amount of hemorrhage is small it furnishes no diagnostic indications. In the case of new-born children the presumption is in favor of meningeal effusion.

PROGNOSIS.—If the effusion be considerable in amount, as indicated by prolonged coma with resolution, the issue is almost inevitably fatal, though life is occasionally prolonged for a surprising length of time. Slight hemorrhages are doubtless recovered from, but there are no means for their certain diagnosis.

TREATMENT.—The treatment, which is essentially the same as that for cerebral congestion, has for its object the arrest of the hemorrhage, and, if that can be effected, the absorption of the effused blood. In view of the former, the patient's head should be elevated and kept cool by the application of ice. Unless the bowels have previously been freely moved, saline laxatives, followed by enemata if necessary, must be given. The state of the bladder must be carefully attended to. Liquid nourishment alone, in moderate quantities at regular intervals, is permissible, with stimulants if there be signs of exhaustion. For the absorption of the effusion mild counter-irritation to the scalp and the administration of the iodide of potassium may be employed.

Congestion of the Cerebral Pia Mater.

The pia mater consists of two layers, separated by a loose connective tissue. The outer layer, being that which was formerly called the visceral layer of the arachnoid, is stretched smoothly over the convolutions of the brain without dipping into the sulci; the inner layer is closely connected with the surface of the brain, whose inequalities it follows. The two layers are more firmly united together over the convolutions than between them; in the latter situation the connection is loose, and the space which separates the surfaces is called the meshes of the pia. The membrane extends into the ventricles, investing the ependyma and the choroid plexuses, and over the medulla oblongata and spinal cord. In the normal condition it is loosely attached to the brain, from which it can be stripped off without loss of substance. The meshes of the pia, together with the ventricles, constitute a series of cavities connected with each other, containing a variable amount of cerebro-spinal fluid, and they communicate with the lymph-spaces surrounding the blood-vessels. Pressure within the cranial cavity, from congestion of the vessels or from the products of inflammation, is thus relieved in a measure by displacement of the cerebro-spinal fluid, which is driven out through the perivascular lymph-spaces.

Congestion or hyperæmia of the pia mater probably never occurs independently of that of the external surface of the brain, on account of the intimate vascular connection of the two. In the adult it can only exist to a limited extent, on account of the unyielding nature of the cranial

walls and of the limited compensatory action of the cerebro-spinal fluid. In young children the incomplete ossification of the skull and the delicate structure of the vessels are more favorable to congestion.

ETIOLOGY.—The causes of hyperæmia of the pia mater are in the main the same as those of congestion of the dura.

SYMPTOMS.—Since congestion of the pia always coexists with that of the corresponding part of the external portion of the brain, it is impossible to separate the symptoms belonging to each. They are therefore usually included under the head of Cerebral Congestion, to which article the reader is referred.

PATHOLOGICAL ANATOMY.—Arterial hyperæmia of the pia is seldom discovered after death, the elasticity of the vessels causing transudation of the fluid part of the blood through their walls. Venous congestion of the pia is more frequently noticed, usually in connection with that of the dura, the sinuses with their accompanying veins being distended with blood, and in cases of long standing often containing thrombi. Simple hyperæmia of the pia being rarely or never fatal of itself, these appearances are usually accompanied by those of inflammation of the membrane or of the cortical layer of the brain (effusion of lymph or pus), or by hemorrhage.

TREATMENT.—In a case of suspected congestion of the pia the treatment would be the same as that of cerebral congestion.

Inflammation of the Cerebral Pia Mater.

SYNONYMS.—Meningitis, Leptomeningitis, Acute non-tubercular hydrocephalus.

Meningitis (by which is generally understood inflammation of the pia) appears under an acute, a chronic, and an epidemic form. The latter, being a zymotic disease, is described in a separate article, to which the reader is referred.

ETIOLOGY.—Meningitis occurs both as a primitive disease and as secondary to other affections. The former is rare, the latter is more frequent. The causes of idiopathic meningitis are for the most part unknown. Exposure to the sun's rays and excessive indulgence in alcoholic liquors are thought to excite it in some instances. It has been known to follow blows and falls on the head which have produced no injury to the skull. It is rather more commonly observed in early manhood than at other periods of life. Secondary meningitis may follow injury or disease of the cranial bones or of the dura, and of the brain. A frequent cause is extension of disease of the ear to the membranes and substance of the brain. The reader is referred to the article on MEDICAL OTOTOLOGY for information concerning the symptoms of that formidable complication. Certain diseases are known to be occasionally complicated with meningitis—acute articular rheumatism; erysipelas of the scalp and of the face; Bright's disease, especially the chronic interstitial form; peritonitis; ulcerative endocarditis; pyæmia; the eruptive fevers; the puerperal state; and syphilis. Meningitis following or complicating acute rheumatism is generally supposed to be not uncommon, but the number of cases in which the existence of inflammation of the meninges has been

proved by autopsy is small. Fuller,¹ along with three cases in which dissection showed suppurative inflammation of the pia, cites several others in which no cerebral disease was found after death, although the symptoms gave every indication of it. True meningitis is rare in chronic Bright's disease, the symptoms resembling it being caused, in the majority of cases, by uræmia. Meningitis complicating pneumonia is also rare, although cerebral symptoms are common enough in that disease, especially in young children with inflammation of the upper lobes. C. Newerk² reports seventeen cases of purulent meningitis complicating acute pneumonia. It was more frequent in men, especially in alcoholic subjects, than in women. The meningitis was generally total. The lungs were in a state of gray or yellow hepatization.

SYMPTOMS.—The symptoms of acute leptomeningitis vary much in the course of the disease. This is readily explained by the complex character of the functions of the parts involved in the inflammation. It may be assumed that the cortical layer of the brain is implicated in every case unless of the most transient and limited kind; the substance of the brain, cerebellum, and medulla are subjected to pressure from the afflux of blood, from the effused lymph and pus, and from the accumulation of serum in the ventricles; the cranial nerves are exposed to pressure from the deposit of lymph, which may give rise to irritation or to suspension of function or both; parts at a distance from the seat of lesion may be functionally disordered by reflex action through communicating filaments. Finally, the general system suffers from the effects of the high fever upon the blood and the nutrition.

It is customary to speak of a stage of excitement followed by one of depression as characteristic of the course of the disease; but although active symptoms generally prevail in the early period, to be succeeded later by coma and paralysis, this disposition is by no means uniform. Sometimes sopor and paralysis constitute almost the only symptoms throughout the disease—this is especially noticed in infants—or active delirium and convulsions may persist until the fatal termination. More frequently the two conditions alternate several times with each other. A prodromic period of short duration, a few hours or a day or two, is sometimes observed in primitive meningitis, the patients complaining of headache, vertigo, vomiting, restlessness, or lassitude. Infants are irritable or drowsy, with heat of the head, quick pulse, and occasional vomiting. In secondary meningitis this period is usually masked by the symptoms of the primitive disease. In the majority of cases the beginning of acute meningitis is abrupt. Rigor is sometimes the first symptom observed, and in children is usually represented by a convulsion. More commonly, however, the disease is ushered in by severe headache, which is often referred to the forehead. The head is hot, the face is flushed, the eyes are brilliant, the pupils are contracted, the pulse is quick and hard, the temperature high (104° F. or upward). The patient is wakeful, restless, and irritable, sensitive to light and to sound. The skin is hyperæsthetic,

¹ H. W. Fuller, M. D., *On Rheumatism, Rheumatic Gout, and Sciatica*, 3d ed., Philada., 1864, p. 271. See also E. Leudet, *Clinique médicale de l'Hôtel Dieu de Rouen*, Paris, 1874, p. 133.

² *Deutsches Archiv für klin. Med.*, xxix., 1881, p. 1; and *Schmidt's Jahrbücher*, Band cxcviii., 1883, Nov. 5.

especially that of the legs. There may be wandering or even active delirium. Vomiting is not unfrequent. There is thirst, but no desire for food. The urine is scanty and high-colored, the bowels constipated. These symptoms gradually increase in intensity, especially the pain in the head and the delirium, and in many cases they are followed by convulsions, at first in the form of twitchings of the facial muscles or of the limbs, grinding the teeth, etc., which give place to tonic contractions of the limbs or of the trunk, often confined at first to one or both members of the same side, but afterward becoming general; the flexors of the forearms and of the legs are most usually affected. The upper dorsal muscles may become contracted, so that the head is drawn backward, and more rarely trismus occurs.

A diminution in the rapidity of the pulse, which may fall to the normal rate, or even below that, notwithstanding the persistence of the high temperature, indicates the beginning of the stage of depression. This change is sometimes sudden, though more often gradual in its approach. The activity of the delirium subsides, giving place to a somnolence which may seem to the inexperienced observer a favorable indication, but which soon deepens into coma. The face becomes pale, the features are sunken. Only an occasional grimace or a movement of the hand to the head shows that the patient is to some extent conscious of suffering. This condition may alternate with the previous one from time to time, the comatose state being interrupted by noisy delirium and tonic or clonic convulsions, or even a partial return of consciousness, giving rise to fallacious hopes on the part of the friends, and sometimes deceiving the physician himself into a belief that a favorable issue is at hand. Before long, however, the symptoms of brain-compression become permanent. The rigidity of the limbs gives place to complete resolution. The patient lies absolutely unconscious, with dilated pupils. The pulse becomes again rapid in consequence of compression of the medulla, and thread-like and irregular; for the same reason the respirations increase to 40, 50, or 60 in the minute. The sphincters are relaxed, and the patient dies without any recurrence of the active symptoms. In rare cases recovery takes place, although almost never after the symptoms of compression have continued without interruption for any considerable length of time. Moreover, it is seldom that recovery takes place in the adult without leaving some traces of permanent damage, such as general debility, paralysis of one or more limbs, deafness, mental weakness, epilepsy, etc. Many cases of general paralysis of the insane and other forms of so-called mental disease are the result of meningitis.

DURATION.—In the adult usually the disease lasts about a week or ten days; exceptionally, it may last two or three weeks.

COURSE.—In young children the course of meningitis differs somewhat from that which is observed in adults, though the symptoms are essentially the same. It is more sudden in its onset and shorter in its duration. The prodromal stage may be brief or hardly noticeable; but in older children restlessness, sensitiveness to light and sound, wakefulness, slight twitchings of the features or of the limbs, a half-open condition of the eyelids during sleep, occasional vomiting, etc., are more commonly noticed. Convulsions are more common than in the adult, and sometimes constitute the chief symptom. They may be confined to a single extremity, but in

general they shift from one limb to another. The muscles of the eyeball are usually implicated, causing strabismus. Retraction of the head is rarely absent, especially in young infants. These convulsions are almost always tonic, but occasionally they alternate with clonic ones. Distension and increased pulsation of the anterior fontanel is always observed in infants a few months old affected with this disease. When meningitis is secondary to some other disease, the first symptom noticed in children is apt to be vomiting, with delirium. According to Steffen, pneumonia is the disease most frequently complicated with meningitis in children. As in tubercular meningitis, the most prominent symptom may be mere sopor, sometimes with intervals of intelligence. Simple meningitis in children is generally a rapid disease, proving fatal in most cases within a week, and sometimes even in a few hours. Exceptionally, it may last much longer. A case occurring in a girl six years old, the duration of which was fifty-five days, is reported by J. Bokai, Jr.;¹ the diagnosis was substantiated by autopsy. Another case, which recovered after seven weeks, is mentioned by Henoch.²

PATHOLOGICAL ANATOMY.—The lesions, which are rarely general, may occupy a greater or less extent of the membrane. They are usually disposed symmetrically with regard to the two hemispheres, or occupy corresponding regions of the base. The vessels are in the beginning of the disease distended, the finest ramifications being injected, giving a red color to the membrane, which varies in different places from crimson to light pink. The perivascular spaces of the larger vessels are filled with a grayish or yellowish fluid composed of extravasated liquor sanguinis and white blood-corpuscles. The meshes between the two layers of the pia are soon infiltrated with pus, and the thickened membrane can be stripped off from the surface of the brain, which is, however, adherent to it in places and is torn in the process. Sometimes a thin layer of pus, which can be scraped off with the knife, is found upon the surface of the pia. The extent of the lesion varies much in different cases. It may be confined to a limited region of the hemispheres, or it may spread to the fissure of Sylvius, where two surfaces become adherent. Sometimes the concrete pus and fibrin are deposited in thick masses upon the base of the brain, often completely surrounding the cranial nerves, and even the medulla. The inflammation may extend to the lateral ventricles, which become filled with a turbid fluid containing pus-cells, and sometimes wholly purulent. The choroid plexuses are often covered with flecks of pus. When the distension of the ventricles is very great, the gyri of the brain are more or less flattened by compression against the cranium, and the outer layer of the cerebral substance is bloodless and œdematous. The cerebral sinuses are distended with blood, and frequently contain thrombi due to an early stage of the inflammatory process, besides recent coagula.

DIAGNOSIS.—The diagnosis of acute meningitis is often difficult, and sometimes impossible, especially in the early stages, when the line between congestion and inflammation cannot be drawn, and in complicated cases. The typical symptoms are sudden and acute pain in the head, with

¹ *Jahrb. f. Kinderkrankheiten*, N. F., xviii. 1, p. 105; and *Schmidt's Jahrb.*, 1882, No. 6, p. 269.

² Eduard Henoch, *Vorlesungen über Kinderkrankheiten*, Berlin, 1881, p. 277.

sensitiveness to light and sound, contracted pupils, rapid pulse, and vomiting, followed by delirium, convulsions, and coma. If these symptoms were observed in an individual previously in good health, they would be strongly suggestive of the disease, and yet many of them are often present in the beginning of pneumonia, erysipelas, typhoid, typhus, and other eruptive fevers, uræmia, and poisoning from narcotic substances. Hence it is important to eliminate these sources of error before coming to a conclusion, and a neglect of this precaution is a not infrequent source of error in the diagnosis. A careful examination of the urine will generally enable us to exclude uræmia. The presence or absence of the eruptive fevers can usually be determined by the attendant circumstances, and yet cases of scarlatina, typhoid fever, variola, etc., beginning with active cerebral symptoms, are sometimes hastily pronounced to be meningitis by inexperienced observers. In poisoning by narcotics the history will often aid us in the diagnosis; moreover, except in the case of opium, the pupils are dilated instead of being contracted. In traumatic cases, with fracture of the cranial bones, it is always difficult, and often impossible, to distinguish between the symptoms of meningitis and those due to other lesions. In concussion without fracture we must be guided in our diagnosis by the same rules as in idiopathic cases. The distinction between extreme congestion of the pia mater and meningitis must be based chiefly upon the duration of the symptoms. The former is usually brief in its course; the latter lasts one or two weeks, and in cases which recover is often followed by after-effects which are more or less permanent in their duration, such as paralysis or rigidity of the limbs, mental defects, etc. Rapid recovery from the acute symptoms would be strongly suspicious of congestion, and doubtless in many such cases the treatment has been credited with a success to which it was not entitled. The diagnosis from tubercular meningitis will be reserved for the article on that disease.

PROGNOSIS.—Acute meningitis is fatal in the majority of cases, though recovery is possible. A gradual diminution of the severity of the symptoms, especially in respect to temperature, pulse, pain in the head, and other cerebral phenomena, would afford encouragement, but we must not trust too much to the brief appearances of amendment so often observed.

TREATMENT.—The indications for treatment are threefold: 1st, to prevent or arrest the inflammation; 2d, to modify its violence and shorten its duration when arrest is no longer possible; and 3d, to place the patient in the best condition to withstand the violence of the disease and to recover from its effects. It is only by prompt action that we can hope to attain the first object, that of preventing the passage of hyperæmia into inflammation. The patient should be placed in a cool and well-ventilated apartment of good size, from which a bright light is excluded. His head, moderately raised, should be kept cool by means of pounded ice enclosed in a rubber bag or a bladder. One or more leeches, according to his age, should be applied behind the ears, or blood may be drawn from the temples or back of the neck by means of cupping. The bleeding should be encouraged by poultices if necessary, but with young children the abstraction of blood should be done with caution. An active purge should be given, such as ten grains each of calomel and jalap, followed by castor oil or infusion of senna; for chil-

dren, from three to six grains, according to age, followed by oil, would be sufficient. The medicine should be repeated in a few hours if there be no effect. Counter-irritation by means of blisters is recommended by most authorities as a valuable aid in the first stage of the disease. Unless the application be very extensive, it is not likely to be of any avail, and extensive blistering would hardly fail to greatly reduce the strength of the patient, and also is likely to irritate the kidneys. There are no medicines which can be relied upon to arrest the inflammatory process. Nevertheless, the tincture of aconite-root, in the dose of from one to three drops, according to the age of the patient, every two hours, might be given early, with the view of fulfilling the second indication by its sedative property. The bromide of potassium or of sodium, combined with small doses of chloral hydrate or of sulphate of morphia, will also calm the excitement and pain, and diminish convulsions. The success which sometimes follows the employment of ergot in the epidemic cerebro-spinal meningitis warrants its trial. Bartholow recommends the wet sheet two or three times a day if the temperature is high. Steffen advises four grains of sulphate of quinine with one grain of salicylate of soda, from two to four times daily, for young children, and in double these doses for older ones. The alimentation of the patient should be carefully attended to during this stage. Nourishing liquid food, such as milk, gruel, broth, eggs, with stimulants if indicated, should be given at proper intervals, care being taken not to overload the stomach, as is frequently done. When the patient can no longer swallow the food must be given by the rectum. During the stage of compression it is useless, in the present state of our knowledge, to expect any benefit from the further administration of drugs, and the treatment then consists mainly in giving small quantities of food at regular intervals, and in such external applications as the bodily temperature may require. The bladder must be relieved by the catheter when necessary. Simple enemata are generally sufficient to prevent constipation.

Chronic Cerebral Meningitis:

Chronic inflammation of the pia mater rarely follows the acute form, but is generally secondary to other conditions, such as inflammation and tumors of the dura, tumors and abscess of the brain, disease of the vessels of the brain, suppurative otitis, and to constitutional diseases, especially alcoholism, syphilis, and pulmonary tuberculosis. It is one of the most common lesions found after death from general paralysis of the insane. As a distinct affection, unconnected with constitutional disease, it is extremely rare, though less so, according to Flint,¹ than the acute form. He cites a case in which the symptoms were intermittent. The patient, fifteen years old, died after a month's illness. The autopsy showed cerebral hyperemia, lymph at the base of the brain, and distension of the ventricles with transparent fluid. There were no tubercles. In most cases in which the results of chronic meningitis are found after death the cortical substance of the brain is involved in the disease; hence

¹ Austin Flint, M. D., *Principles and Practice of Medicine*, 5th ed., Philada., 1881, p. 701.

the difficulty in defining its symptoms, which are usually extremely vague, and not always distinctive of cerebral disease. The principal are pain in the head, vertigo, vomiting, impairment of the memory, mental apathy, drowsiness, and muscular weakness. The anatomical changes are thickening and opacity of the membrane by the deposit of lymph upon its surface and into the connective tissue, adhesions to the dura and to the cortical substances of the brain, together with hyperæmia of the latter. These appearances are usually distributed in irregular patches of greater or less extent.

The DIAGNOSIS of chronic meningitis is often obscure or impossible. Long-continued pain in the head, accompanied by vertigo, impairment of memory, drowsiness, mental apathy, etc., without paralysis, would be suggestive of it, especially if there were occasional intermissions of the symptoms. The probability would be greatly increased if the patient had a syphilitic or alcoholic history. The diagnosis should exclude tumor of the brain, chronic pachymeningitis, and chronic hydrocephalus, but as these diseases are often complicated with chronic meningitis, the distinction might be very difficult. As already stated, chronic meningitis is almost a constant lesion in general paralysis, as well as in other forms of chronic insanity, but there are no special symptoms by which its presence can be ascertained during life.

TREATMENT.—Our aim should be to relieve pain, diminish congestion, and favor absorption. Counter-irritation to the head and nucha by means of small blisters or croton oil should be employed with moderation. Bromide of potassium, or, if necessary, small doses of morphia, may be given if the pain be severe. Should there be symptoms of cerebral congestion, such as acute delirium, flushing, and heat of head, an ice-bag should be applied to the head and leeches behind the ears, or blood may be drawn from the temples or nucha by cupping. As an absorbent the iodide of potassium is much recommended, but it is not likely to be effectual, except in syphilitic cases. The bowels should be kept free, but without active purging. The general health of the patient should be promoted by suitable diet and regimen, by relief from excitement and fatigue, or by change of scene and of climate. For the treatment of chronic meningitis complicating syphilis, alcoholism, and tuberculosis, the reader is referred to the articles treating of those diseases.

TUBERCULAR MENINGITIS.

By FRANCIS MINOT, M. D.

DEFINITION.—Inflammation of the pia mater of the brain, with effusion of lymph and pus, caused by the deposit of miliary tubercles upon its surface or into its substance.

SYNONYMS.—Scrofulous meningitis, Granular meningitis, Basilar meningitis, Acute hydrocephalus, Dropsy of the brain.

HISTORY.¹—It is only within a comparatively recent time that tubercular meningitis has been distinguished from other cerebral diseases. Up to the eighteenth century the term hydrocephalus was employed not only for the dropsical diseases of the head, including internal and external hydrocephalus, but also for meningeal inflammations, both simple and tubercular, and for congestion of the brain and of the membranes; the accumulation of water in the ventricles or between the membranes being looked upon as the disease, and not as one of its consequences. The term was even applied to external tumors, as cephalæmatoma and caput succedaneum. We owe the first accurate account of the symptomatology of acute hydrocephalus, or ventricular dropsy, to Robert Whytt of Edinburgh, whose remarkable monograph, entitled *Observations on the Dropsy of the Brain*, first published in 1768, after his death, was founded upon the study of 20 cases with 10 autopsies. No addition of importance has been made by later observers to his graphic description of the disease or to his rules for its diagnosis. Whytt, however, had no clear notion of its pathogeny, and it was not till 1815 that Gölis pointed out that acute ventricular dropsy was a secondary condition depending upon previous inflammation of the membranes or vessels of the brain.

In 1827, Guersant remarked that the inflammation of the meninges constituting acute hydrocephalus presented such peculiarities as led him to denominate it granular meningitis. He did not, however, connect the granular deposit with tubercle. This was left for Papavoine to effect, who in 1830 published two cases of tuberculous arachnitis, in one of which effusion into the ventricles, or hydrocephalus, existed. The meningeal granulations or tubercles were described with care, and their coincidence with tuberculous deposit elsewhere was remarked upon, as also the apparent occurrence of the former previous to the inflammatory action in the meninges, and in one case the existence of the tuberculous granules without the sequence of inflammation. The important pathological element of acute hydrocephalus thus clearly pointed out by Papavoine

¹See W. Hughes Willshire's valuable paper, entitled "Historic Data on Scrofulous Meningitis," in *Brit. and For. Med.-Chir. Review*, Oct., 1854.

now became apparent to observers, and obtained almost universal assent. The attention of the profession in this country was first called to it by W. W. Gerhard of Philadelphia in 1833, in an admirable paper published in the *American Journal of the Medical Sciences*,¹ containing the reports of thirty-two cases with autopsies. In every case but two tubercles were found in other organs besides the meninges. In one of these two, gangrenous cavities were found in the lungs without tubercles, though perfectly characterized miliary tubercles existed in the membranes; in the other case the lungs were not examined with care, Gerhard not being present at the autopsy.

Finally, the distinction between tubercular and simple meningitis was pointed out by Guersant in 1839, and clearly established by Barthez and Rilliet in 1843 in their systematic work on the diseases of children; and it was further elucidated by Rilliet in 1847.

ETIOLOGY.—The causes of tubercular meningitis are predisposing and exciting. Among the former are hereditary tendency to tuberculosis and to the so-called scrofulous diathesis; the previous existence of tubercle in any part of the body, especially in the lungs; and the presence of caseous degeneration in the bronchial, the mesenteric, and other glands, or in the parenchyma of various organs, as the lung, the testicle, the liver, the spleen, etc. The dependence of miliary tuberculosis of the pia upon previously-existing caseous or other inflammatory deposits in some part of the body is acknowledged by most modern pathologists. Seitz² states that out of 130 cases, with autopsies, of adults, upon which his work is based, such deposits were found in 93.5 per cent. General constitutional weakness, either congenital or resulting from grave disease or from overwork, from insufficient or unwholesome food, and from bad hygienic surroundings, also favors the deposit of tubercle in the meninges. Sometimes two or more predisposing causes exist at once. Thus, a child born of tuberculous parents may be fed with artificial diet instead of being nursed, or may live in a house whose sanitary condition is bad. Hence the disease is common among the poor, although by no means rare in the higher classes of society. In some cases it is difficult or impossible to assign any predisposing cause. A single child out of a numerous family may be stricken with the disease, while the rest of the children, as well as the parents and other ascendants, are healthy. For instance, while writing this article I had under observation a little boy six years old whose parents are living and healthy, with no pulmonary disease in the family of either. The only other child, an older brother, is healthy. While apparently in perfect health the child was attacked with tubercular meningitis, and died in seventeen days with all the characteristic symptoms of the disease. At the autopsy there was found much injection of the cerebral pia everywhere, a large effusion of lymph at the base of the brain and extending down the medulla, abundance of miliary tubercles in the pia and accompanying the vessels in the lateral regions of the hemispheres, lateral ventricles distended with nearly clear fluid, ependyma smooth, choroid plexuses covered with granulations, convolutions of brain much flattened. Careful investigation, however, will usually

¹ Vols. xiii. and xiv., 1833-34.

² *Die Meningitis Tuberculosis der Erwachsenen*, von Dr. Johannes Seitz, Berlin, 1874, p. 317.

enable us to detect some lurking primary cause, either in the family predisposition or in the history of the patient himself.

Season appears to have but little influence on the production of the disease. The largest number of cases is observed during winter and spring, owing doubtless to the influence of the temperature and weather, and to the exclusion from fresh air, in favoring the development of tubercle and the scrofulous diathesis. Males, both children and adults, are somewhat more frequently attacked than females.

In regard to the exciting causes it may be said that where a disposition to the deposit of tubercle exists, anything which tends to lower the vitality of the individual is likely to hasten the event. In infants with hereditary tendency to tubercle, an improper diet is especially liable to develop meningeal tubercle. In older children, besides unwholesome or insufficient food and unfavorable hygienic surroundings, the acute diseases common to that period of life, such as the eruptive fevers, intestinal disorders, whooping cough, etc., often act as immediate causes. Sometimes the development of the disease may be traced to over-stimulation of the nervous system by excessive study, often aided by imperfect ventilation or overheating of the school-room. Caries of the temporal bone from disease of the middle ear may act as an immediate cause of tubercular meningitis, although simple meningitis is of course a more frequent result of that condition. The disease has been known to follow injuries of the head from blows or falls. In a larger number of cases the exciting cause is not discoverable, especially when the meningeal affection is simply an extension of the disease from some other part of the body, as the lungs, the bronchial or mesenteric glands, etc. This is often the case, both in adults and in children, when tubercular meningitis complicates pulmonary consumption.

SYMPTOMS.—The disease is most frequently observed in children between the ages of two and seven years. It is much less common in adults, who are generally attacked between the ages of twenty and thirty years. In the majority of cases the invasion of the malady is preceded by a prodromic stage, usually occupying from a few days to several weeks, though sometimes extending over a considerably longer period. This stage probably represents the process of deposit of miliary tubercles in the pia mater before their presence has given rise to much structural change in the tissue. The characteristic symptoms of the prodromic stage consist chiefly in an alteration of the character and disposition of the patient, varying in extent in different cases. In general, it may be said that he becomes sad, taciturn, apathetic, irritable, indisposed to play, often sitting apart from his companions, gazing in a strange way into vacancy. There is diminution or loss of appetite and some emaciation. He is restless at night, is disturbed by nightmare, or grinds his teeth. The digestion is deranged. Usually there is constipation, but occasionally diarrhœa, or these conditions may alternate with each other. Squinting and twitching of the facial muscles are sometimes noticed. Headache may occur early in this stage, but it is usually observed later, and it then forms a prominent symptom. Vomiting is also frequent, usually not preceded by nausea, sometimes provoked by sudden movement, as in sitting up in bed, and is apt to occur when the stomach contains little or no food. These symptoms vary much in degree, and they are often so slight

that they pass unnoticed by the parents or friends. Occasionally the patient, if a child, will manifest a strange perversity or an unusual disobedience, for which he is perhaps punished under the belief that his misconduct is intentional. In older children and in adults delirium, especially at night, sometimes followed by delusions which may be more or less permanent, is frequent at this stage. The above symptoms often remit from time to time, and during the interval the patient may seem to have recovered his health. The prodromic symptoms are rarely altogether wanting in children, although they may have escaped notice from lack of opportunity of observation on the part of the physician. On the other hand, as Steffen¹ justly observes, the most characteristic symptoms may be present, and lead even an experienced observer to a confident diagnosis of tubercular meningitis during the early stage of a case of typhoid fever or of cerebral congestion without tuberculosis.

For convenience of description it is customary to divide the disease proper, after the prodromal period, into three stages—viz. of irritation, compression, and collapse. In some cases it is not difficult to observe these divisions; but it must be borne in mind that in others the symptoms do not follow any regular sequence, so that no division is possible. In infants profound slumber may be the only morbid manifestation throughout the entire disease. Steffen records such a case, and I have seen two similar ones.

First Stage: The interval between the prodromic period and the first stage is usually so gradual that no distinction between the two can be detected. In other cases the disease is ushered in suddenly by some striking symptom, such as an attack of general convulsions, with dilated pupils and loss of consciousness. This is not often repeated, though partial twitchings of the limbs or of the muscles of the face may follow at intervals. In young children a comatose condition, with unequal pupils, is apt to take the place of these symptoms. The principal phenomena of the first stage are headache, sensitiveness to light and sound, vomiting, and fever. The latter varies much in intensity from time to time, but is not usually high, the temperature seldom rising above 103° F., and usually, but not always, higher at night than in the morning; but there is no characteristic curve. The pulse varies in rate, but is usually slow and irregular or intermittent. The respiration is irregular, with frequent sighing. The tongue is dryish and covered with a thin white coat. The bowels are costive. Delirium is frequent at night, and the sleep is disturbed, the patient tossing about and muttering or crying out. The eyes are half open during sleep. These symptoms become more marked from day to day. The pain in the head is more frequent and severe; the patient presses the hands to the forehead or rests the head against some support if sitting up. During sleep he occasionally utters a loud, sharp cry, without waking. There is increasing apathy, and some intolerance of light, shown by an inclination to turn toward the wall of the room or to lie with the face buried in the pillow. The appetite is lost, the constipation becomes more obstinate, the slowness and irregularity of the pulse persist. With the rapid emaciation the belly sinks in, so that the spinal column can be easily felt. Soon the child falls into a state of almost con-

¹ "Meningitis Tuberculosa," by A. Steffen, in *Gerhardt's Handb. der Kinderkrankheiten*, 5 B., 1ste Abth., 2te Hälfte, p. 465.

tinual somnolence, from which, however, he can be awakened in full consciousness, and will answer correctly, generally relapsing again immediately into slumber. His restlessness diminishes or ceases altogether, and he lies continuously on the back with the head boring into the pillow. He becomes more passive under the physician's examination, in strong contrast to his previous irritability. At the end of a week or more from the beginning of this stage symptoms of irritation of some of the cerebral nerves begin to show themselves, in consequence of pressure from the increasing exudation at the base of the brain and into the ventricles. Strabismus (usually convergent), twitching of the facial muscles and grimaces, grinding of the teeth, or chewing movements of the mouth are noticed. The somnolence deepens into sopor, from which it becomes more and more difficult to arouse the patient, who gradually becomes completely insensible.

Notwithstanding the alarming and often hopeless condition which this assemblage of symptoms indicates, intervals of temporary amendment not unfrequently take place. The child may awake from his lethargy, recognize those about him, converse rationally, take his food with relish, and exhibit such symptoms of general improvement that the parents and friends are led to indulge in fallacious hopes, and sometimes the physician himself ventures to doubt the accuracy of his diagnosis. Such hopes are of short duration; the unfavorable symptoms always return after a brief interval. The duration of the first stage may be reckoned at about one week.

Second Stage: This period is not separated from the preceding one by any distinct change in symptoms. The patient lies in a state of complete insensibility, from which he can no longer be aroused by any appeal. The face is pale or of an earthen tint, the eyes are half closed. If the anterior fontanel be still open, the integument covering it is distended by the pressure beneath. Often one knee is flexed, the opposite leg extended; one hand applied to the genitals, the other to the head. Sometimes one leg or arm is alternately flexed and extended. The head is apt to be retracted and bores into the pillow. The pupils are dilated, though often unequal and insensible to light: the sclerotica are injected; a gummy exudation from the Meibomian glands forms on the edges of the lids.* The patient sighs deeply from time to time, and occasionally utters a loud, piercing cry. Paralysis, and sometimes rigidity of one or more of the extremities, are often observed, and occasionally there is an attack of general convulsions. The pulse continues to be slow and irregular, the emaciation progresses rapidly, and the abdomen is deeply excavated. The discharges from the bladder and rectum are involuntary. The average duration of the second stage is one week.

Third Stage: No special symptoms mark the passage of the second stage into the third, which is characterized by coma, with complete resolution of the limbs. The constipation frequently gives place to moderate diarrhoea. The distended fontanel subsides, and often sinks below the margin of the cranial bones. A striking feature of this stage is a great increase in the rate of the pulse, the heart being released from the inhibitory influence of the par vagum in consequence of the complete paralysis of the latter from pressure. The pulse varies in rapidity from 120 to 160 or more in the minute. For the same reason the respiration also

increases in frequency, though not to the same degree. The eyelids are widely open; the pupils are dilated and generally motionless, even when exposed to a bright light. The eyes are rolled upward, so that only the lower half of the iris is visible; the sclerotica is injected from exposure to the air and dust. Convulsions may occur from time to time. Death terminates the painful scene, usually in from twenty-four to forty-eight hours, but sometimes the child lives on for days, unconscious, of course, of suffering, though the afflicted parents and friends can with difficulty be brought to believe it.

Certain points in the symptomatology of tubercular meningitis demand especial consideration.

I have already observed that the division of the disease into definite stages is purely arbitrary, and is employed here merely for convenience of description; in fact, few cases pursue the typical course. A period of active symptoms and another of depression can often be observed, but these frequently alternate. Stupor and paralysis may characterize the early stage, and symptoms of irritation, with restlessness, screaming, and convulsions, predominate toward the end. Certain characteristic symptoms may be wholly or in part wanting, such as vomiting, constipation, or stupor.

The temperature shows no changes which are characteristic of the disease. Throughout its whole course it varies from time to time, without uniformity, except that it usually rises somewhat toward night. It seldom exceeds 102° or 103° F., unless shortly before death, when it may rise to 104° F., or even higher, and may continue to rise for a short time after death.

During the premonitory stage the pulse offers no unusual characteristics. Its frequency is often increased, as is usual in any indisposition during the period of childhood, but it preserves its regularity. Toward the close of this period, and especially during the first stage of the disease proper, a remarkable change takes place. It becomes slow and irregular, the rate often diminishing below that in health. The irregularity varies in character; sometimes the pulse intermits, either at regular or irregular intervals. An inequality in the strength of different pulsations is also observed. These peculiarities of the circulation are due to the irritation of the medulla and the roots of the par vagum, by which the inhibitory function of that nerve upon the action of the heart is augmented. During the last period, on the other hand, the increasing pressure on the vagus paralyzes its function, and the heart, freed from its control, takes on an increased action, the pulse rising to 120 beats, and often many more, in the minute. Robert Whytt, in his interesting memoir,¹ dates the beginning of the second stage from the time that the pulse, being quick but regular, becomes slow and irregular; the change again to the normal frequency, or beyond it, marking the commencement of the third stage.

In the early stage the respiration presents nothing abnormal, but when the pulse becomes slow and irregular the breathing is similarly affected. Sighing is very common in the prodromal period and first stage. Toward the end of the second stage the increasing paralysis

¹ "An Account of the Symptoms in the Dropsy of the Ventricles of the Brain," in the *Works of Robert Whytt, M. D.*, published by his son, Edinb., 1768, p. 729.

of the respiratory centre gives rise to the phenomena known as the Cheyne-Stokes respiration, consisting of a succession of respiratory acts diminishing in force until there is a complete suspension of the breathing, lasting from a quarter to three-quarters of a minute, when the series begins again with a full inspiration. In general, the variations in the rate of the respiration follow those of the pulse, though the correspondence is not always exact.

In the early stage of the disease the pupils are usually contracted and unequal. They are sluggish, but still respond to the stimulus of light. At a later period they become gradually dilated, and react even more slowly to light or not at all, the two eyes often differing in this respect. Ophthalmoscopic examination frequently shows the appearance of choked disc and commencing neuro-retinitis. In rare cases tubercles are seen scattered over the fundus of the eye. They are about the size of a small pin's head, of a yellowish color, and of sharply-defined contour. Neuro-retinitis and choked disc are not, of course, pathognomonic of tubercular meningitis, and choroidal tubercles are so rarely seen as to be of little avail in diagnosis. In fact, they are less frequent in this disease than in general tuberculosis without meningitis. In twenty-six cases of tubercular meningitis examined by Garlick at the London Hospital for Sick Children they were found only once.¹ The effect upon the conjunctiva of the unclosed lids has been already described.

The tongue is somewhat coated soon after the beginning of the disease, and the breath is offensive. The appetite is lost, and there is decided emaciation in many cases during the prodromic period. The thirst is usually moderate. Vomiting is one of the most constant symptoms during the first period, and its occurrence on an empty stomach is characteristic of tubercular meningitis. It is not usually preceded by nausea, and often takes place without effort, by mere regurgitation, the rejected fluid consisting chiefly of bile mixed with mucus. Although constipation is the most common condition in the early stage, and is often rebellious to treatment, yet in some cases diarrhoea is observed, which may mislead the physician in respect to the diagnosis. From the beginning of the second stage, and sometimes earlier, the discharges from the bowels and the bladder are involuntary.

DURATION.—The duration of tubercular meningitis, apart from the prodromic period, which often can hardly be determined, averages from two weeks to two weeks and a half. In exceptional cases death may take place in a few days or a week, and occasionally a patient may linger for several weeks,² the difference being apparently due to the rapidity of the tubercular deposit and of the resulting inflammation and exudation. The patient usually takes to his bed at the beginning of the first stage, but he may be up during a part of the day until the beginning of the second. In rare instances the child will be about, and even out of doors, until a few days before death.

PATHOLOGICAL ANATOMY.—The essential lesion of tubercular menin-

¹ W. R. Gowers, M. D., *Manual and Atlas of Medical Ophthalmoscopy*, Philada., 1882, p. 148. See, also, Seitz, *op. cit.*, p. 347; Steffen, *op. cit.*, pp. 452 and 472; and "Tubercle of the Choroid," *Med. Times and Gazette*, Oct. 21, 1882, p. 498.

² Such a case is reported by Michael Collins in the *London Lancet*, March 8, 1884.

gitis consists in a deposit of miliary tubercles in the pia mater of the brain, giving rise to inflammation of that membrane and exudation of serum and pus. In the early stage both surfaces of the pia are reddened and more or less thickened, and present an opaline appearance, while between them—that is, in the meshes of the pia—we find a colorless and transparent fluid which is effused in greater or smaller amount, resembling jelly when viewed through the arachnoid. These conditions are sometimes observable on the convexity of the hemispheres, but are much more abundant on the lateral surfaces, and especially at the base. More distinct evidence of inflammation is shown by the presence of a yellowish or greenish-yellow creamy deposit on the surface of the pia, consisting chiefly of pus, which is also much more abundant at the base than elsewhere, especially about the optic commissure, infundibulum, pons Varolii, and the anterior surface of the medulla. The cranial nerves may be deeply imbedded in the deposit, which often extends into the fissure of Sylvius, gluing together the adjacent surfaces of the lobes, and accompanies the vessels, forming narrow streaks along the sides of the brain up to the convexity.

The miliary tubercles or granulations consist of semi-transparent bodies, grayish or whitish in color, varying in size from that of the head of the smallest pin, indeed almost invisible to the naked eye, to that of a millet-seed (whence their name). Larger masses are frequently seen, formed by the aggregation of smaller granulations. The tubercles are usually found on the inner surface of the pia, always in the immediate neighborhood of the blood-vessels, which they accompany in their ramifications, and are also scattered, in greater or less numbers, throughout the purulent exudation from the surface of the pia. They are most abundant at the base of the brain, ascending the sides along the course of the vessels. Sometimes, though rarely, they are more abundant on the convexity. The total number varies; it is usually very large, but sometimes only a limited number exists, even in well-marked cases, and along with intense inflammation of the pia. The granulations are found in different degrees of development—sometimes all of them similar in color, size, and consistency, at others in various stages of fatty degeneration. The distribution may be symmetrical in the two hemispheres or irregular. Under the microscope (after suitable preparation of the part) the bacillus tuberculosus in considerable numbers may be found in the pia, in places adjacent to the arterioles.¹

The ventricles of the brain are usually distended with a clear or opalescent, rarely bloody, fluid, the amount of which generally corresponds to the intensity and extent of the meningeal inflammation, although sometimes it is not above the normal quantity. The two lateral ventricles are affected in an equal degree; the third and fourth ventricles are more rarely implicated. According to Huguenin,² it is doubtful whether acute inflammation of the ependyma takes place in tubercular meningitis. Steffen also³ says that the ependyma is not inflamed, and that it is not the seat of the deposit of tubercles. This latter statement is denied by other authorities, and Huguenin is inclined to believe that they may exist

¹ See a case reported by Y. Dawson in the London *Lancet*, April 12, 1884, in which tubercles were visible only by the microscope with numerous bacilli.

² G. Huguenin, *op. cit.*, p. 499.

³ *Op. cit.*, p. 449.

in that membrane. In the following case, under my care, abundant granulations were found on the surface of the ependyma :

Olaf M—— (male), æt. 8 years, born in Denmark, entered Massachusetts General Hospital Sept. 13, 1881.

Maternal grandmother died of consumption ; paternal grandfather lived to the age of ninety-five years. One brother had some disease of hip. Patient was the child of poor parents and lived in an unhealthy suburb of Boston. During the two preceding winters he had a bad cough. He was apparently well till four weeks before his entrance, when he complained of bellyache, and became listless, but he was out of doors ten days before he came to the hospital. It was noticed that he was sensitive to sound. No vomiting, no diarrhœa, no epistaxis, no cry ; some cough. He had been somnolent, and was observed to swing his arm over his head while asleep. June 14, when first seen by me, he was lying on his back, unconscious, eyes half closed, pupils dilated, jaw firmly closed, much emaciated, belly retracted, left leg occasionally flexed and extended. No priapism. The optic discs were reddened. June 15, there is some intelligence, he answers questions ; keeps one hand on the genitals. June 16, pupils contracted, does not swallow. June 18, left eye divergent, conjunctiva injected, whole surface livid, cries out occasionally. Died at midnight.

FIG. 30.

Autopsy.—General lividity of surface, much emaciation. Much fine arborescent injection on outer surface of dura mater. Numerous Pacchionian bodies. Yellow matter beneath arachnoid along course of vessels on each side of anterior lobes. Abundant fine granulations along course of vessels on each anterior lobe, on upper margins of median fissure, along fissure of Sylvius, and on choroid plexuses. Very little lymph at base of brain. Six or eight ounces of serum from lateral ventricles, and abundant fine transparent granules over ependyma of both. Numerous opaque granulations in pia mater of medulla oblongata. Surface of right pleura universally adherent. Mucous membrane of bronchia much injected ; a considerable amount of pus flowed from each primary bronchus. No tubercles in lungs nor in peritoneum. No ulcerations in intestines. No other lesions.

The choroid plexuses are generally involved in the inflammatory process, and are sometimes covered with yellow purulent exudations. As in the above case, large numbers of tubercles may be found in them, notwithstanding the opinion of Huguenin that their number is always small.

The substance of the brain in the vicinity of the tubercular deposit is generally found in a more or less œdematous condition, owing to the obstruction of the circulation resulting from compression of the vessels

by the tubercles and effused lymph. Softening, sometimes even to diffluence, not unfrequently occurs in the neighborhood of the deposit, probably from ischæmia (necrobiosis). If there be any considerable amount of exudation in the ventricles, the convolutions are flattened by compression against the cranial bones.

The above-described lesions are not confined to the brain, but may extend to the cerebellum, the pons, the medulla, and the spinal cord. If examinations of the latter were more frequent in autopsies of this disease, we should doubtless find, as has been done in some instances, that the membranes often show the characteristic alterations of tubercular meningitis, and even the presence of granulations in the cord itself. The lesions may extend throughout the cord, and are especially noticed in the dorsal region and in the vicinity of the cauda equina. Their presence explains some of the symptoms evidently due to spinal origin, such as retraction of the head with rigidity of the neck and of the trunk, contractions of the limbs, tetanic spasms, priapism, paralysis of the bladder and rectum, etc., which are common in simple spinal meningitis.

The deposit of miliary tubercles in the pia mater, with little or no accompanying meningitis, is met with in rare instances. The tubercles are few in number, but vary in dimensions, being sometimes united together in masses of considerable size, which are frequently encysted. Beyond thickening and opacity of the membrane, their presence seems to excite but little inflammatory reaction, but they are generally accompanied by ventricular effusion which by its pressure gives rise to characteristic symptoms.

The principal lesions found in other organs of the body consist of tubercle in various stages of development, caseous matter, diseases of the bones, etc. Miliary granulations are chiefly seen in the lungs, peritoneum, intestinal mucous membrane, pleura, spleen, liver, and kidneys. The bronchial and mesenteric glands often contain caseous masses, some of which are broken down and suppurating. The testicles sometimes present the same appearances. In adults, the most frequent lesion which is found external to the brain is pulmonary tuberculosis in a more or less advanced stage. Tubercles are also sometimes present in the eye. Angel Money¹ states that out of 44 examinations made at the Hospital for Sick Children, London, the meninges were the seat of gray granulations in 42. The choroid (one or both) showed tubercles 14 times (right 3, left 5, both 6), and 11 times there were undoubted evidences of optic neuritis. Twice the choroid was affected with tubercle when the meninges were free; in one of these instances there was a mass of crude tubercle in the cerebellum; in the other, although there were tubercles in the belly and chest, there were none in the head. So that 12 times in 42 cases of tubercles in the meninges there were tubercles in the choroid—*i. e.* about 31 per cent.

DIAGNOSIS.—In many cases tubercular meningitis offers but little difficulty in the diagnosis. Although the symptoms, taken singly, are not pathognomonic, yet their combination and succession, together with their relation to the age, previous health, and antecedents of the patient, are usually sufficient to lead us to a correct opinion. The prodromic period

¹ "On the Frequent Association of Choroidal and Meningeal Tubercle," *Lancet*, Nov. 10, 1883.

of altered disposition (irritability of temper or apathetic indifference), headache, constipation, vomiting, and emaciation, followed by irregularity and slowness of the pulse, sighing respiration, sluggishness and irregularity of the pupils; the progress from somnolence to unconsciousness and coma; the sudden lamentable cry; the convulsions and paralysis; the return of rapid pulse and respiration in the last stage,—are characteristic of no other disease. Our chief embarrassment arises during the insidious approach of the malady, before its distinctive features are visible or when some important symptom is absent. Its real nature is then apt to be overlooked, and, in fact, in some cases it is impossible to decide whether the symptoms are indicative of commencing cerebral disease, or, on the other hand, are owing to typhoid fever, to a simple gastro-intestinal irritation from error in diet, to worms in the alimentary canal, to overwork in school, or to some other cause. Under these circumstances the physician should decline giving a positive opinion until more definite signs make their appearance. It must be remembered that very important symptoms may be absent in cases which are otherwise well marked. In all doubtful cases the family history should, if possible, be obtained, especially whether one or both parents or other near relatives have been consumptive or have shown symptoms of scrofula or tuberculosis in any form, and whether the patient himself has signs of pulmonary tuberculosis, of enlarged or suppurating glands, or obstinate skin eruptions. The presence or history of those conditions would add greatly to the probability of tubercular meningitis.

The diseases for which tubercular meningitis is most liable to be mistaken are acute simple meningitis, typhoid fever, acute gastro-intestinal affections, eclampsia of infants and children, worms in the intestines or stomach, the hydrencephaloid disease of Marshall Hall, and cerebro-spinal meningitis.

Acute meningitis is distinguished from the tubercular disease by its sudden invasion without prodromatous stage, by the acuteness and intensity of the symptoms, the severity of the headache, the activity of the delirium, the greater elevation of the temperature, and by its brief duration, which rarely exceeds one week. In those exceptional cases of tubercular meningitis in which the prodromal period is absent or not observed and the course is unusually rapid, it would be perhaps impossible to distinguish between the two diseases. A family history of tubercle, or the discovery of the granulations in the choroid by ophthalmoscopic examination, might save us from error under such circumstances. The great rarity of idiopathic simple meningitis should be remembered. Meningitis from disease of the ear sometimes resembles the tubercular affection, but the history of the attack, usually beginning with local pain and otorrhœa, will in most cases prevent any confusion between the two forms of disease.

The early period of typhoid often bears considerable resemblance to that of tubercular meningitis. Headache, languor, restlessness, and mild delirium are common to both. Typhoid can be distinguished by the coated tongue, the diarrhœa, the enlargement of the spleen, the tympanites, abdominal tenderness and gurgling, the eruption, and, above all, by the characteristic temperature-curve, which, if accurately observed, is convulsive. The course of typhoid fever is comparatively

uniform, while that of tubercular meningitis is often extremely irregular. It should not be forgotten that the two diseases may coexist.

The presence of worms in the alimentary canal may cause symptoms somewhat like those of tubercular meningitis, and the symptoms of the latter disease are occasionally erroneously attributed to those parasites. The administration of an anthelmintic, which should never be omitted in doubtful cases, will clear up all uncertainty.

Cerebro-spinal meningitis is usually an epidemic, and therefore not likely to be confounded with the tubercular disease. In sporadic cases it can be recognized by its sudden onset and acute character, by the eruption, and by the prominence of the spinal symptoms.

The so-called hydrancephaloid disease of Marshall Hall is a condition of exhaustion and marasmus belonging to infancy, caused by insufficient or unsuitable nourishment, by diarrhœa, and by the injudicious depletive treatment so much in vogue in former times, when the affection was much more common than at present. Some of its symptoms, such as sighing respiration, stupor, pallor, and dilated pupils, bear a certain resemblance to those of tubercular meningitis, though it would be more easily confounded with chronic hydrocephalus. The absence of constipation, headache, convulsions, and vomiting, and the favorable results of suitable nourishment and stimulants, serve to distinguish it from cerebral disease.

Eclampsia, or sudden convulsion, is common in infants and young children, and, since the occurrence of a fit may be the first or the most striking symptom in tubercular meningitis, it is important to ascertain its origin. In the majority of cases convulsions in children arise from some peripheral irritation, such as difficult dentition, worms in the alimentary canal, constipation, fright, etc., acting through the reflex function of the spinal cord, which is unusually sensitive in the early period of life. The absence of previous symptoms, and the discovery of the source of the irritation, with the favorable effect of its removal by appropriate treatment, will in most cases suffice to eliminate structural disease of the brain. In others we must withhold a positive opinion for a reasonable time in order to ascertain whether more definite symptoms follow. Convulsions also occasionally form the initial symptom of the eruptive fevers, especially scarlatina. Here the absence of prodromal symptoms, and the speedy appearance of those belonging to the exanthematous affection, will remove all sources of doubt. Convulsions, with or without coma, occurring in the early stage of acute renal inflammations, may simulate the symptoms of tubercular meningitis. An examination of the urine will show the true nature of the disease.

In addition to the above diseases there are some cerebral affections of uncertain pathology which resemble tubercular meningitis, but which are not generally fatal. As Gee justly remarks,¹ "Every practitioner from time to time will come across an acute febrile disease accompanied by symptoms which seem to point unmistakably to some affection of the brain, there being every reason to exclude the notion of suppressed exanthemata or analogous disorders. After one or several weeks of coma, delirium, severe headache, or whatever may have been the prominent symptom, the patient recovers, and we are left quite unable to say what has been the

¹ "Tubercular Meningitis," by Samuel Jones Gee, M.D., in *Reynolds's System of Medicine*, Philada., 1879, vol. i. p. 832.

matter with him. To go more into detail, I could not do otherwise than narrate a series of cases which would differ from each other in most important points, and have nothing in common excepting pyrexia and brain symptoms. There is, generally, something wanting which makes us suspect that we have not to do with tubercular meningitis. "Brain fever is as good a name as any whereby to designate these different anomalies; cerebral congestion, which is more commonly used, involves an explanation which is probably often wrong, and certainly never proved to be right." No doubt such cases are occasionally cited as examples of recovery from tubercular meningitis.

PROGNOSIS.—Although there are on record undoubted instances of recovery from tubercular meningitis, yet their number is so small that practically the prognosis is fatal. It is safe to say that in almost all the reported cases of recovery the diagnosis was erroneous.¹ Even should the patient survive the attack, he is usually left with paralyzed limbs and impaired mental faculties, and dies not long afterward from a recurrence of the disease or from tuberculosis of the lungs or other organs.

TREATMENT.—In view of the fatality of the disease, and of its frequent occurrence in childhood, the prophylactic treatment is of great importance. Every effort should be made to protect children whose parents or other near relatives are tuberculous or scrofulous, and who are themselves delicate, puny, or affected with any constitutional disorder, from tubercular meningitis, by placing them in the best possible hygienic conditions. Pure air, suitable clothing, whole some and sufficient food, and plenty of out-of-door exercise are indispensable. Sedentary amusements and occupations should be sparingly allowed. Especial pains should be taken to prevent fatigue by much study, and school-hours should be of short duration. The hygiene of the school-room is of paramount importance, and if its ventilation, temperature, and light are not satisfactory, the child should not be permitted to enter it. The bed-chamber should be well ventilated night and day. A sponge-bath, cold or tepid according to the season or to the effect on the patient, should be given daily, followed by friction with a towel. The bowels must be kept regular by appropriate diet if possible, or by simple laxatives, such as magnesia or rhubarb. For delicate, pale children some preparation of iron will be useful. The choice must be left to the practitioner, but one of the best in such cases is the tartrate of iron and potassium, of which from two to six grains, according to the age, may be given three times daily after meals. Cod-liver oil is invaluable for scrofulous patients or where there is a lack of nutrition. A teaspoonful, given after meals, is a sufficient dose, and it is usually taken without difficulty by children, or if there be much repugnance to it some one of the various emulsions may be tried in proportionate dose. Along with this, iodide of iron will in many cases be found useful or as a substitute for the oil when the latter cannot

¹ Hahn, "*Recherches sur la Méningite tuberculeuse et sur le Traitement de cette Maladie* (*Arch. gén. de méd.*, 4^e Série, vols. xx. and xxi.), claims to have cured 7 cases, but of 5 of them there is no evidence that they were examples of tubercular meningitis at all. The subject of the curability of tubercular meningitis is ably treated by Cadet de Gassicourt (*Traité clinique des Maladies de l'Enfance*, vol. iii., Paris, 1884, p. 553 *et seq.*). His conclusion is that most of the alleged cures are cases of meningitis of limited extent, arising from the presence of tubercular tumors, syphilitic gummata, cerebral sclerosis, and neoplasms of various kinds.

be borne. It is best given in the form of the official syrup, in the dose of from five to twenty drops. Change of air is useful in stimulating the nutritive functions, and a visit to the seashore or mountains during warm weather will often be followed by general improvement.

Since it is not possible to arrest the disease when once begun, the efforts of the physician must be directed toward relieving the sufferings of the patient as far as possible. In the early period the restlessness at night and inability to sleep will call for sedatives, such as the bromide of sodium or of potassium, in the dose of ten or fifteen grains at bedtime or oftener. This should be well diluted with water, sweetened if necessary. The addition of five to twenty drops of the tincture of hyoscyamus increases the effect. Sometimes chloral hydrate, either alone or combined with the bromide when the latter fails, will procure quiet sleep. From five to ten grains may be given at a dose, according to the age. Compresses wet with spirit and water or an ice-cap may be applied to the head if there be much pain in that region, or it may be necessary to give opium in some of its forms by the mouth, such as the tincture or fluid extract, in doses of from one to five drops. Constipation is best overcome by means of calomel in three- to five-grain doses, to which may be added, when necessary, an equal amount of jalap powder, or an enema of soapsuds may be administered. Active purging should be avoided. Liquid nourishment, such as milk, gruel of oatmeal, farina, or barley, beef-tea, broths, etc., must be given in moderate quantities at intervals of a few hours so long as the patient is able to swallow. Occasional sponging of the whole surface with warm or cool water, and scrupulous attention to cleanliness after defecation, especially when control of the sphincters is lost, will add to his comfort. He should occupy a large and well-ventilated chamber, from which all persons whose presence is not necessary for his care and comfort should be excluded. He should be protected from noise and from bright light, and should lie on a bed of moderate width for convenience of tending.

There is no specific treatment at present known which is likely to be of any benefit in this disease, any more than in tuberculosis of other organs than the brain. Common experience has shown that mercury, which formerly had so high a reputation in the treatment of cerebral diseases of early life, not only fails completely, but adds to the sufferings of the patient when pushed to salivation. The iodide of potassium is recommended by almost all writers, but, so far as I know, there is no proof that it possesses any virtue in meningeal tuberculosis. It has the high authority of Charles West,¹ however, who thinks the remedy is more encouraging than any other, and who mentions one instance in which recovery took place under its employment. He recommends that two grains be given every four hours to a child three years old, the bowels being kept free. Most authorities recommend much higher doses, such as ten or fifteen grains, three or four times daily.

Counter-irritation to the head or back of the neck was formerly much employed, but is now generally abandoned, as giving rise to much discomfort without obvious beneficial effect. In the cases reported by Hahn, already alluded to under the head of Prognosis, recovery is attributed to the energetic application of tartar-emetic ointment to the scalp, produ-

¹ *Op. cit.*, p. 102.

cing extensive ulceration, which in one of them lasted more than ten months before cicatrization took place. A careful examination of the reports of these cases satisfies me that but two out of the seven were really examples of tubercular meningitis. How far the recovery in the successful cases is to be attributed to the treatment is very doubtful. Small blisters applied to the vertex or back of the neck are alluded to favorably by West, but he quotes no observations in which they were followed by benefit.

Tubercular Meningitis in the Adult.

Tubercular meningitis may occur at any age, but after the period of childhood it is most frequent between the ages of sixteen and thirty years. About 75 per cent. of the patients are males, and 25 per cent. females.¹ The disease does not differ essentially in its course and symptoms from that in children. A family history of tuberculosis is common, or the patient may be already suffering from phthisis, scrofulous glands, cheesy deposits in various organs, caries of the bone, syphilis, or other constitutional affections. According to Seitz, in 93.5 per cent. out of 130 cases with autopsies chronic inflammatory conditions or caseous deposits were found in various organs of the body. Many cases are examples of acute tuberculosis in which the brunt of the disease has fallen upon the brain rather than the other organs.

When cerebral symptoms supervene upon acute disease, such as typhoid fever, pericarditis, acute rheumatism, pneumonia, the exanthemata, etc., the diagnosis between tubercular and simple meningitis is important, because the latter is not necessarily fatal, while the former is almost never recovered from. If the patient were previously healthy and presumably free from tubercular disease, the chances would be in favor of the simple form. A rapid course of the disease would also speak for acute meningitis, and recovery would almost certainly preclude tubercular meningitis. In some cases the diagnosis is difficult or impossible in the beginning.

In cases beginning without acute antecedents—in adults as in children—there is no pathognomonic symptom, but the combination and succession of the phenomena are usually sufficient for the diagnosis. Headache, depression or irritability of temper, delirium, half-closed eyes, ptosis of one lid, squinting, inequality and sluggishness of the pupils, moderate fever, sunken belly, vomiting, constipation, slow and irregular pulse, sopor gradually deepening to coma, with occasional convulsions or paralysis of the limbs, followed in the course of two or three weeks by death, especially if occurring in a patient who has already presented signs of tuberculosis in other organs, point almost unmistakably to tubercular meningitis. Some of the symptoms may not be strongly pronounced, one or two may be absent, but the general picture will suggest no other disease. According to Seitz, tubercle of the choroid is rare in tubercular meningitis of the adult. It is usually associated with tuberculosis of other organs, the pia being free. The subjoined cases are illustrations of the disease in adolescence and adult life :

Case I.—A lad sixteen years old, always somewhat delicate, with a

¹ Seitz, *op. cit.*, p. 9.

cough and morning expectoration of some months' standing, exerted himself immoderately in gymnastic exercise on the afternoon of Sept. 24, 1875. That night he was awakened by cough and hæmoptysis. Signs of consolidation were found at the apices of both lungs. In three months there were swelling, induration, and suppuration of one testicle. Some months later, pain in the right arm, stiffness of the shoulder-joint, and an abscess communicating with the joint, from which small spicula of bone were discharged. He was about, and even attended school, for more than a year from the time of the attack of hæmoptysis. About Jan. 1, 1877, he began to complain of severe pain in the forehead, with nausea (but no vomiting) and constipation. Jan. 27th he took to his bed, complaining chiefly of pain in the forehead and eyes. Feb. 1st he was drowsy, irritable, and delirious. Feb. 3d incontinence of urine and constant delirium. Up to this time the pulse had not been above 76 in the minute, and on this day it was 64. The next day, Feb. 4th, he was wholly unconscious; pulse 96, pupils dilated. Feb. 5th, left hand in constant motion; pulse 112. From this time the pulse steadily increased in frequency. Feb. 6th he swallowed food, notwithstanding his stupor. Feb. 7th he answered questions; there was oscillation of the eyeballs, and epistaxis from constant picking of the nose. He died Feb. 9th, the pulse being 144 and the respirations 60 in the minute for several hours previous. The temperature never rose above 101.7° F. There was never any vomiting. The duration of the case was thirteen days, in addition to the prodromic period of twenty-seven days.—Autopsy by R. H. Fitz: The pia of the base of the brain from the medulla to the optic thalamus contained a large number of gray miliary tubercles, old and recent, and the same condition was found in the surfaces of the fissure of Sylvius. Ventricles distended with fluid, ependyma thick and translucent. A moderate-sized cavity in the apex of the left lung, with cheesy contents. Both lungs contained an abundance of hard, gray, miliary tubercles. Left kidney contained a wedge-shaped, cheesy mass of the size of a walnut, with numerous tubercles. Left testicle contained a cheesy mass of the size of a walnut; both epididymes were cheesy. The mucous membrane of the bladder contained tubercles near the neck. The vesiculæ seminales contained softened cheesy masses with openings into the urethra. There was a fistulous opening into the right shoulder-joint.

Case II.—Emeline K. L.—, 32 years old, single, nurse, had become much exhausted by taking care of a difficult case, and entered Massachusetts General Hospital March 6, 1883, complaining since four days of a little cough, slight expectoration, and chilliness, but no rigor. She seemed hysterical. There was complaint of severe pain in the head, chest, and abdomen. A slight systolic murmur was found at the apex of the heart, and a few moist râles at the base of the chest on both sides behind. The urine was normal. Temperature, 103° F. Three weeks after entrance she began to be delirious, especially at night. April 13th, five weeks and three days after entrance, she was semi-conscious, but would put out her tongue and open her eyes when requested to do so; the abdomen was distended, the pupils were dilated and unequal; there was twitching of the muscles of the right side of the face. Careful examination only disclosed occasional fine râle at the base of right chest.

She died April 16th, having been completely unconscious for twenty-four hours. There was no vomiting throughout the case. The temperature was very irregular, ranging between 100° and 103° F., and once as high as 104° F.; it was usually one or two degrees higher at night than in the morning. Pulse, generally from 100 to 110; it rose steadily during the last few days to 160 at the time of death.—Autopsy: Pia mater of brain œdematous, slightly opaque; its lower surface, especially at the base of the brain, showed numerous minute gray tubercles; enlarged cheesy glands at the base of the neck; small, opaque, gray tubercles scattered rather sparsely throughout both lungs. There was also miliary tuberculosis of the liver, spleen, and kidneys.

CHRONIC HYDROCEPHALUS.

By FRANCIS MINOT, M. D.

SYNONYMS.—Dropsy of the brain, Dropsy of the head.

DEFINITION.—A gradual accumulation of serous fluid in the brain, occupying either the ventricles or the cavity of the arachnoid, or both, occurring chiefly in infants or very young children.

The term hydrocephalus, which was applied by the older writers to accumulations of serous fluid both within and also without the cranium, termed distinctively internal and external hydrocephalus, is now restricted to dropsical effusions either between the meninges or within the ventricular cavities. These may be acute or chronic, and they arise from the same conditions which are followed by the effusion of serum in other parts of the body; that is to say, from an alteration in the serous membrane lining a cavity, from an obstruction in the capillary circulation with increased tension in the larger vessels, from an altered condition of the blood, etc.

Chronic hydrocephalus is almost entirely confined to young children, and is probably due to an arrested development of the brain, as shown by its being usually congenital, by the dwarfed intellectual condition of the patient, and by its frequent association with spina bifida. The pathogeny of the disease is, however, still obscure. Whether the abnormal accumulation of serous fluid is to be ascribed to a chronic alteration of the ventricular walls or of the choroid plexuses, allied to inflammation, such as occurs in the pleura, for example, causing an increased secretion, or to a closure of the communication between the ventricles and the spinal cavity, as suggested by the late John Hilton, resulting in dropsy by retention, or to some other cause, is not yet determined. Hilton says:¹ "In almost every case of internal hydrocephalus which I have examined after death I found that this cerebro-spinal opening [between the fourth ventricle and the spinal canal] was so completely closed that no cerebro-spinal fluid could escape from the interior of the brain; and, as the fluid was being constantly secreted, it necessarily accumulated there, and the occlusion formed, to my mind, the essential pathological element of internal hydrocephalus." Sieveking, commenting upon Hilton's theory, says:² "While giving these facts due weight, it must be pointed out that we are yet far from understanding either how the fluid is poured into the cerebral cavities or how it is removed, and that we do not positively know that the spinal canal has any better means of getting rid of an excess of

¹ John Hilton, *Lectures on Rest and Pain, etc.*, 2d ed., New York, 1879, p. 22.

² Jones and Sieveking's *Pathological Anatomy*, 2d ed., London, 1875, p. 248.

fluid than the cerebral cavities have.” An arrest of the growth of the brain is supposed by some pathologists to account for ventricular as well as arachnoidal dropsy by the creation of a vacuum in the cavity of the cranium, which is filled by exudation of the more fluid portion of the blood from the vessels or of lymph from the lymphatics.

ETIOLOGY.—That chronic hydrocephalus in young children is in a large proportion of cases an hereditary disease is shown by the fact that it is frequently congenital, that more than one child in a family is occasionally affected by it, and that while one child is hydrocephalic others may be idiotic. A scrofulous taint in the family history is noticeable in many cases, the evil effect of which is frequently enhanced by unfavorable sanitary conditions of life, especially by residence in dark, damp, ill-ventilated, and badly-drained apartments and by insufficient or unwholesome food. Hence the disease is more frequently met with among the poor than in the well-to-do classes of society. There is a difference of opinion as to whether it ever arises in consequence of external violence, such as a blow on the head, or of some strong impression, like fright or grief, acting on the mother of the child during pregnancy. The probability is that such causes would not be efficient except in cases where a predisposition to hydrocephalus had already existed. West¹ mentions the case of a healthy child five months old who fell out of the arms of her nurse, and was taken with a fit the same day. She apparently recovered, but when a year old had frequent returns of convulsions. At the age of fifteen months the head began to enlarge, and it continued to increase in size until she was three years old, when she was attacked by measles, and died in a few days with convulsions and coma. The symptoms, both bodily and mental, were typical of hydrocephalus, and the diagnosis was fully confirmed by the autopsy.

The causes of chronic hydrocephalus in older subjects and in adults are, in addition to the above mentioned, chiefly mechanical. Any lesion which hinders the exit of venous blood from the cranium may be followed by dropsy of the arachnoid cavity or ventricles. The principal ones are tumors of the brain or its membranes, the effusion of lymph in the neighborhood of veins, thrombosis of the cerebral sinuses, compression of numerous small vessels by tubercular granulations, obstructions outside the cranium, including tumors of the neck, aneurisms, obstructive disease of the heart, emphysema and cirrhosis of the lungs, besides diseases giving rise to general dropsy, as the different forms of nephritis, marasmus, the various cachexiæ, etc.

SYMPTOMS.—When the disease is already somewhat advanced before birth, the head is often abnormally large, the cranial bones are separated, the fontanels are distended and fluctuating, and it occasionally happens that delivery of the distended head can only be effected after the fluid has been evacuated by puncture. Even when there is no abnormal increase in the size of the head, indications of cerebral disturbance are sometimes apparent from birth, such as strabismus or convulsions recurring with more or less frequency, along with signs of failure of the general health. In the course of some weeks, or, it may be, months, the attention of the parents is attracted to the prominence of the child's forehead, strongly contrasting with the comparatively diminutive size of

¹ *Op. cit.*, p. 127.

the face. Soon an enlargement of the fontanels is perceived, the sutures between the cranial bones become broader, and the head assumes a globular shape from the pressure of the contained fluid. The separation of the bones at the vertex of the skull causes the os frontis to protrude forward, the parietals backward and outward, and the occipital backward and downward. The orbital plates of the frontal bone yield to the pressure of the fluid behind them, and from a horizontal position tend to assume a vertical one, protruding the eyeballs, which have a peculiar downward direction. The sclerotica is visible above the iris, and the latter is partially covered by the lower eyelid. The enlargement of the head is progressive, though not uniformly so, there being pauses of weeks or months during which it is arrested. If it be considerable, the cranial bones are usually thinned, so that the skull becomes translucent when opposite a bright light. When there is a wide separation of the bones there is an unusual development of ossa triquetra in the sutures.

In cases in which the ossification of the cranium is considerably advanced before the beginning of the disease, the enlargement of the head is apt to be correspondingly less. If all the sutures are consolidated, there may be no increase in size, and this is especially true of the mechanical dropsy of adult life. The dropsical effusion, which is then moderate in amount, finds room through compression of the brain-substance, and part of it escapes into the spinal canal.

The size of the hydrocephalic head varies considerably. Where there has been an early arrest of the disease it may be but slightly above the normal. On the other hand, the dimensions are sometimes enormous. In the Warren Museum of Harvard University is a cranium which measures $27\frac{1}{2}$ inches in its greatest circumference, and $20\frac{1}{2}$ inches from one auditory foramen to the other over the top of the head. Its internal capacity is 257 cubic inches. The patient, who died at the age of three years, was never able to sit up and support the head, or even to turn it from the left side, on which she continually lay; she never spoke, and seemed to have no intelligence. The skull of the celebrated James Cardinal measured $32\frac{1}{4}$ inches in its largest circumference.¹ Even more remarkable instances are on record. The dimensions of the fontanels, particularly the anterior, usually correspond with those of the skull in general. During any strong muscular effort on the part of the patient the membrane covering them is seen to be bulged out by pressure from the fluid beneath. The enlargement is not always uniform; it may be in part or wholly confined to one side, owing to consolidation of the sutures of the opposite side, or because only one of the lateral ventricles is affected. The scalp is traversed by numerous distended veins. The hair is very scanty. The head has a soft, fluctuating feel, and the walls sometimes seem to crackle beneath the fingers, like parchment.

In cases of moderate severity there may be few or no symptoms of active cerebral disturbance, such as convulsions or paralysis, but the child does not learn to talk, to walk, or to control the sphincters even at the age of three or four years, and the signs of imperfect mental development are evident. He is apt to be irritable or mischievous, and even when not actually idiotic is very backward in evincing signs of intelligence. There are, however, not a few exceptions to this, and some chil-

¹ *Reports of Medical Cases, etc.*, by Richard Bright, M. D., London, 1831, vol. i. p. 431.

dren with large hydrocephalic heads are intelligent and amiable. The cranium of a girl who died at the age of sixteen years is preserved in the Warren Museum. It measures $24\frac{1}{4}$ inches in circumference and $17\frac{1}{4}$ inches from one auditory meatus to the other over the vertex, and the bone is in no place more than one-eighth of an inch in thickness. The child was an inmate of a house of industry, where she was instructed in the usual branches of knowledge taught in our common schools, until at length, such was her capacity, she was entrusted with the teaching of the other pauper children, and she had an excellent character for intelligence and moral worth. She died of phthisis. On post-mortem examination "the brain was found floating, as it were, in a large collection of water." As in other chronic diseases, there are often pauses, from time to time, of variable duration, in which there is some improvement in the condition of the patient, as well as a temporary arrest in the enlargement of the head. The growth of the child in stature is often retarded, and when life is prolonged the individual is more or less dwarfed. In some cases there is a considerable increase in the amount of adipose tissue, and the appetite is often voracious. L. Fürst reports¹ the case of a hydrocephalic girl, sixteen years old, whose height (or, rather, length, for she was unable to stand) was 81 centimeters (nearly 32 inches), corresponding to the stature of a child between three and four years old. The periphery of the head measured $51\frac{1}{2}$ centimeters ($20\frac{1}{4}$ inches). The anterior fontanel was still open. The age was verified by reference to the registry of birth at the police-office.

The symptoms of cerebral disturbance in chronic hydrocephalus are much less striking than one would expect, doubtless because the increase of pressure upon the brain is so gradual. Actual paralysis, especially of the limbs, is rare, but convulsions are not infrequent, as is the spasmodic constriction of the glottis known as laryngismus stridulus or spasmodic croup. A general state of uneasiness and restlessness is common. Vision is often impaired and sometimes wholly lost. Strabismus is frequently present, or there may be an involuntary rolling movement of the eyeballs. The pupils are often dilated and insensible to light. In consequence of the increased weight of the head, the child is unable to support it, and in most cases is compelled to keep the bed. Vomiting is common. The digestive functions are disturbed. Constipation is an almost constant symptom, and the sphincters are relaxed in the advanced stages of the disease. Although in some cases, as already stated, the child may grow fat, the reverse of this is the rule; there is usually progressive emaciation, especially of the lower extremities.

The duration of the disease varies much in different cases. The earlier the characteristic symptoms manifest themselves the more rapid is its course. Most children born hydrocephalic survive but a few days or weeks. In cases which are more slow in their development the patient may live some years, and in rare instances attain adult life. But his feeble vitality usually makes him an easy prey to the ordinary complaints of childhood, and a large proportion of cases succumb to inflammation of the lungs or of other organs, to diarrhoea, whooping cough, or the eruptive diseases. Most of those who escape these intercurrent maladies

¹ "Exquisite Wachsthumshemmung bei Hydrocephalus chronicus," von Dr. Livius Fürst, *Virchow's Archiv*, June, 1884.

perish from defective nutrition, the result of malassimilation of food, or else are cut off by acute cerebral inflammation, with convulsions, etc.

PATHOLOGICAL ANATOMY.—It is rarely that a large amount of serum is found in the cavity of the arachnoid unless a free communication has been established between it and the ventricles by the destruction of cerebral tissue. In the pia the quantity may be more abundant than normal, filling the subarachnoid spaces, separating the convolutions from each other, and occasionally forming little sac-like elevations on the surface of the membrane; but it should be borne in mind that a certain amount of serous infiltration of the tissue of the pia is by no means rare in cases of death from various diseases, owing to the obstruction to the circulation during the last hours of life, and should not be considered pathological unless it exceed the usual limits. The amount of effusion into the ventricles varies between very wide limits, from some ounces to two or three pints. It may be transparent, or turbid from particles of cerebral tissue or epithelial or pus-cells, and is occasionally slightly tinged with blood. Its specific gravity is nearly identical with that of water, and it contains a trace of albumen. The effusion usually occupies the two lateral and the middle ventricles. Less frequently the dropsy is unilateral, in consequence, apparently, of an obliteration of the foramen of Monro. The tissues composing the walls of the ventricles are compressed and hardened. The ependyma of the walls and of the plexus is thickened and roughened by the formation of minute elevations, which the microscope shows to be composed of proliferated and sclerosed connective tissue. The brain in cases of large effusion is reduced to a membranous sac, flattened, with hardly any trace of its original structure at first sight apparent. In the case of James Cardinal, before alluded to, Bright says, "The brain lay at its base [of the skull] with its hemispheres opened outward like the leaves of a book." Closer inspection shows that all the parts are present, although atrophied by pressure. The convolutions are flattened and the brain-substance is pale and softened. The cranial nerves are often softened and flattened.

In the dropsy of the head in adults which is the result of mechanical pressure or of cachexia the appearances are widely different. The effusion may occupy the cavity of the arachnoid, and even the space between the dura and the skull, as well as the ventricles. The amount of fluid is much less than in the chronic hydrocephalus of children. The ventricular walls present no signs of inflammatory changes.

DIAGNOSIS.—Chronic hydrocephalus is usually recognized without difficulty. The chief points of diagnostic importance are the progressive enlargement of the head, the separation of the cranial bones, with their peculiar change of position, as already described, and the evident signs of arrested intellectual development. If the head be but little enlarged, the case might be mistaken for that of chronic hypertrophy of the brain, but this is a very rare disease, and is not accompanied with defective mental development.

PROGNOSIS.—The elements of prognosis include the size of the head at birth, its rate of enlargement, the general condition of the child, both physically and intellectually, his hereditary antecedents, and the hygienic influences to which he may be subjected. A large proportion of children born hydrocephalic live but a short time; a few survive one or more

years. The number of those who reach adult life is extremely small. The favorable indications are a tardy appearance of the dropsy and its slow progress, without marked evidence of defective mental and bodily development.

TREATMENT.—The treatment of chronic hydrocephalus is general and local, the first being the most important, although in many cases it is difficult to enforce it, from lack of intelligence and of means on the part of those in charge of the patient. Proper ventilation, good drainage, and cleanliness are essential. The child should be bathed daily, and should be protected against changes in temperature by suitable clothing. If his strength allow, he should be taken into the open air daily in fine weather. A wet-nurse should be provided for infants whose mothers are unable to suckle them. Older patients should take milk, cream, animal broths, farinaceous substances, etc., with wine or brandy. Tonics, especially cod-liver oil, hypophosphite of lime, and some preparation of iron or of the iodide of iron, are important, the choice being determined by the effect apparently produced. The internal and external employment of mercurial preparations, once in vogue, is now almost entirely abandoned by the best authorities. The evacuation of the fluid by puncture, followed by compression of the head by bandaging, has been occasionally resorted to, and in a few instances with success, but the cases in which it is indicated are rare. Thomas Young Thompson¹ reports a case in which puncture was followed by recovery. The child, fourteen days old, fell, apparently without ill effects, but three weeks afterward a protuberance appeared on the crown of the head which continued to enlarge, and the signs of chronic hydrocephalus were unmistakable. In three months the circumference over the parietal eminences measured 20 inches, and a year afterward 24½ inches. In spite of energetic internal and external treatment the enlargement continued to progress, until the head was punctured, and about three hundred grammes of a clear, transparent fluid, free from albumen, were evacuated. Five weeks later a second puncture was made, and sixty grammes of a milky fluid withdrawn. The child recovered, and two years later was in good health, the head not being disproportioned to the rest of the body. West considers the cases in which the effusion is apparently external—that is, confined to the arachnoid cavity, rather than ventricular, and in which there are no indications of active cerebral disease—to be the most favorable for the operation. The proper situation for the puncture is the coronal suture, about an inch or an inch and a half from the anterior fontanel. A few ounces of fluid only should be withdrawn at a time, and compression should be carefully applied both during the escape of the fluid and afterward.

¹ *Med.-Chir. Transactions*, vol. xlvii., 1864.

CONGESTION, INFLAMMATION, AND HEMORRHAGE OF THE MEMBRANES OF THE SPINAL CORD.

BY FRANCIS MINOT, M. D.

Congestion of the Spinal Membranes.

THE blood-vessels of the spinal membranes communicate freely with the general circulation, and there is less opportunity for their obstruction than in the case of the meninges of the brain. Hyperæmia of the dura and pia mater is therefore seldom met with, except in connection with disease of the cord; and, indeed, but little is known on the subject, which is only alluded to as possible by authorities of the present day, although the affection was formerly supposed to be a common one, giving rise to various symptoms, such as numbness and formication of the extremities, muscular weakness, and even paraplegia—symptoms which are now known to be caused by structural diseases of the cord only. As Erb¹ remarks, “It is hardly possible that any considerable hyperæmia of the meninges should exist without a similar condition existing in the cord also, as the vascular supply of both is the same.”

ETIOLOGY.—Hyperæmia of the spinal membranes is found after death from convulsions, especially in cases of tetanus, hydrophobia, eclampsia, strangulation, poisoning from narcotics, etc., in which the effect is evidently due to asphyxia. An interesting case of extensive hyperæmia of the spinal membranes, as well as of those of the brain, complicating mania, is reported by M. R. G. Frommüller.² A girl of eighteen years, previously well, being accused of theft, fell into a state of melancholia, passing into mania, with frequent convulsions, screaming, etc. There was no spinal tenderness. The urine contained no albumen. The temperature was never elevated. No opisthotonos. The sphincters became relaxed, and she died at the end of about three weeks. The dura was found to be normal, but the pia mater of the brain, cerebellum, medulla oblongata, and cord was strongly injected. The brain and cord were normal; no ventricular effusion. Here the meningeal hyperæmia was doubtless caused by asphyxia resulting from the convulsions.

Congestion of the spinal membranes has been attributed to sudden suppression of the menstrual flow or of hemorrhoidal bleeding, and to portal obstruction, but the evidence of this is very meagre. Exposure

¹ “*Krankheiten des Rückenmarks*,” von Wilhelm Erb, in *Ziemssen's Handbuch*, Leipzig, 1876; Am. trans., vol. xiii. p. 99.

² See *Schmidt's Jahrbücher*, 1883, No. 7.

to cold and wet, as from sleeping on the damp ground, is an alleged and plausible cause.

The SYMPTOMS attributed to hyperæmia of the spinal membranes are pain in the back extending to the legs, with numbness and tingling of the toes, sensation of weight in the limbs, muscular weakness, appearing suddenly without fever and usually of transient duration. There is no evidence that it gives rise to paralysis. Considering that temporary congestion of the membranes must occasionally happen from convulsions, as in epilepsy, etc., it is remarkable that no symptoms attributable to it have been observed under these circumstances.¹

MORBID ANATOMY.—We must be careful not to mistake post-mortem staining of the tissues from imbibition of the coloring matter of the blood—the result of decomposition aided by the position of the body—for true congestion. The latter is recognized by fine vascular arborization covering the surface of the dura or pia, often accompanied with small punctate hemorrhages. More extensive extravasations in the connective tissue, surrounding and between the membranes, are sometimes found. The spinal fluid is usually increased in amount, and often tinged with red. On account of the free vascular connection between the membranes and the cord the latter almost always partakes of the congestion.

DIAGNOSIS.—From what has been said it follows that simple hyperæmia of the spinal membranes can hardly be distinguished from that of the cord. (See the article on DISEASES OF THE SUBSTANCE OF THE BRAIN AND SPINAL CORD.) When the symptoms are unaccompanied by fever, are of very moderate severity, and of short duration, we may perhaps infer that the lesion is confined to the membranes.

The TREATMENT is the same as that for congestion of the spinal cord.

Acute Inflammation of the Spinal Dura Mater.

SYNONYM.—Acute spinal pachymeningitis.

Acute inflammation of the spinal dura mater is chiefly confined to the outer surface of the membrane (peripachymeningitis), and is almost always consecutive to either injury or disease of the vertebræ (fracture, dislocation, caries), to wounds penetrating the spinal cavity, or to suppurative disease in neighboring organs or tissues, which makes its way into the peridural space through the intervertebral openings. The symptoms are complex—in part caused by the original disease, and in part by the pressure of the products of inflammation exercised upon the nerve-roots, and even upon the cord itself. Pain in the back, corresponding to the seat of the disease, is rarely absent, and all movements of the trunk are extremely painful. When the exudation is sufficient to compress the nerve-roots, the pain will extend to the trunk and the limbs, and other signs of irritation, such as a feeling of constriction by a tight girdle, and tingling, numbness, and cutaneous hyperæsthesia in the limbs, will be observed, varying in situation according to the seat of the lesion. In some cases the compression of the cord may be sufficient to cause paraplegia. General symptoms will vary according to the complications of the

¹ See *Epilepsy and other Chronic Convulsive Diseases, etc.*, by W. R. Gowers, M. D., London, 1881, p. 106.

case. Severe injury or extensive disease of the vertebræ will be accompanied with high fever; but if the external inflammation be moderate and the meningeal complication be limited in extent, the fever may be subacute.

MORBID ANATOMY.—The connective tissue between the dura and the bone is the seat of inflammatory exudation, usually purulent, of greater or less extent, and more abundant in the posterior than the anterior part of the spinal cavity, owing to the position of the patient. A more or less abundant exudation, either of pus or of dry caseous matter, is found upon the outer surface of the dura or infiltrating the connective tissue between it and the bony walls. The dura is thickened, and sometimes the exudation is seen upon its inner walls, but the pia is seldom involved in the inflammation. The cord may be compressed or flattened when the amount of exudation is large, and may in consequence show signs of inflammation in its vicinity. The spinal nerves likewise are sometimes compressed, atrophied, softened, and inflamed. The disease rarely occupies the cervical region, on account of the close union of the dura with the bones of that part; hence there is an absence of pain in the neck and of retraction of the head.

DIAGNOSIS.—The diagnosis is founded on the presence of general symptoms of spinal disease—pain in the back, but not extending to the neck, increased by movements of the trunk; cutaneous hyperæsthesia, tingling, or numbness in various parts of the surface of the body; paresis or paralysis of the lower extremities in severe cases; along with a history of vertebral disease or injury or of suppurative disease in the neighborhood of the spine. The history of the case will generally be sufficient to exclude myelitis, tetanus, or muscular pain (rheumatism, lumbago). From acute leptomeningitis the diagnosis must also be made by the history, but it should be borne in mind that the pia may be involved at the same time with the dura.

PROGNOSIS.—In complicated cases the prognosis is grave if the spinal symptoms are well marked and severe, especially when there is evidence of much pressure on the cord (paraplegia). If the signs of spinal irritation were moderate, the danger would depend upon the nature and extent of the external lesion.

TREATMENT.—This would be addressed mainly to the primitive disease. For the spinal symptoms the treatment would not differ materially from that of inflammation of the spinal pia mater.

Chronic Spinal Pachymeningitis.

This affection generally coexists with chronic inflammation of the pia. Like the acute inflammation of the dura, it is seen in connection with disease or injury of the vertebræ, and it may also arise from tumors of the membrane (chiefly syphilitic) and from myelitis. It is frequent among the chronic insane, and in them is sometimes associated with hemorrhagic effusions analogous to the hæmatoma of the cerebral dura mater. Chronic inflammation of the spinal dura is of unfrequent occurrence, and but little is known of its history and pathology. In a case reported by Wilks¹ the membrane was thickened to nearly its whole

¹ *Transactions of the Pathological Society of London*, vol. vii., 1856.

extent, and in the cervical region presented numerous bony plates. The pia was also thickened at this part and adhered closely to the dura. The symptoms, which seemed chiefly due to disease of the cord from compression, were retraction of the lower limbs and violent jerking from excessive reflex action.

A special form of the disease, occupying chiefly the cervical region, was first described by Charcot.¹ The membrane is thickened by a deposit of successive layers of fibrin, compressing the cord, which is flattened from before backward and inflamed. The nerve-roots are also more or less compressed. The course of the disease may be divided into two stages: First, that of irritation of the spinal nerves, with pain in the back part of the neck, extending to the head and along the upper limbs. The pain is permanent, but liable to exacerbations, and is accompanied with stiffness of the neck and a feeling of numbness and tingling, with muscular weakness of the arms. Sometimes the skin of the arms is the seat of trophic changes, as shown by the presence of bullæ or pemphigus. The second period is that of extension of the disease to the cord. The pain ceases, and is followed by paralysis or muscular atrophy, especially in the domain of the ulnar and median nerves, resulting in extension of the hand on the forearm, with flexion of the fingers toward the palm, giving rise to a claw-like appearance (*main en griffe*). In some cases an upward extension of the disease implicates the root of the radial nerve, and the hand then assumes a prone position from paralysis of the extensor muscles. The lower portion of the cord may also become involved, with similar results in the lower extremities. Although the disease is generally progressive, it is not always so, and Charcot cites one case in which great improvement took place in the course of some years, though not apparently in consequence of any special treatment.

Acute Spinal Meningitis.

SYNONYM.—Leptomeningitis spinalis acuta.

By the term spinal meningitis is usually meant inflammation of both the arachnoid and the pia, the two being, as already stated, in reality one membrane. In connection with meningitis of the brain it constitutes a distinct disease which is usually epidemic, and probably zymotic in its origin. (See EPIDEMIC CEREBRO-SPINAL MENINGITIS.) Sporadic spinal meningitis is a rare disease. It may be acute or chronic.

ETIOLOGY.—Among the causes of acute spinal meningitis are injuries to the vertebral column, such as fracture and dislocation from falls, blows, etc.; wounds by stabbing or shooting; violent bodily effort, as in lifting heavy weights, etc. Other causes are local exposure to wet and cold, as from sleeping on the wet ground or standing long in water while at work. Like cerebral meningitis, it may complicate constitutional diseases, as rheumatism, pyæmia, etc., but less frequently than the former. Syphilitic inflammation of the spinal membranes is, however, not unfrequently met with, but chiefly of the chronic form. (See the article on SYPHILIS

¹ *Leçons sur les Mal. du Syst. nerv.*, par J. M. Charcot, Paris, 1875, vol. ii. p. 246. See, also, *Maladies du Syst. nerv.*, par A. Vulpian, Paris, 1879, p. 127; and *Clinique méd. de l'Hôpital de la Charité*, by the same.

OF THE BRAIN AND SPINAL CORD.) In tubercular meningitis of the brain the pia mater of the cord is often implicated in the disease. Acute spinal meningitis is most frequently met with in young persons, and is more common in men than in women.

SYMPTOMS.—The onset of the disease is generally sudden, and it is rarely preceded by the usual inflammatory symptoms of chilly sensations, restlessness, headache, etc. A sharp rigor is the first indication of disease in most cases. This is followed by fever, with high temperature and a quick, full, hard pulse. Pain in the back follows, either confined to a limited region or extending throughout the whole extent of the spine, soon becoming acute, and aggravated by any movement of the trunk or even of the limbs. There is usually but little tenderness on pressure upon the spinous processes, and often none at all. The pain extends around the body and throughout the limbs. In the course of a few hours muscular contraction in the region of the back, and also of the limbs, is observed. When the disease is situated in the cervical region, the head is drawn backward, and cannot be moved without severe pain. If it occupies a considerable extent of the spine, the dorsal muscles become rigidly contracted and the body is arched forward (*opisthotonos*), as in tetanus, so that the patient may even rest upon his occiput and sacrum. Owing to the implication of the muscles of respiration, more or less dyspnoea is common, and may even cause death by asphyxia. There is no paralysis of the limbs, unless there be complication of myelitis, but the patient abstains as far as possible from any movement from dread of pain. Reflex irritability is exaggerated. Retention of urine and constipation are common, probably for the same reason. Hyperæsthesia of the surface of the body in limited areas is sometimes noticed, owing to the irritation of the posterior spinal roots. Provided the extent of the inflammation be comparatively limited, recovery is possible, though rare, at this stage of the disease.

When the course of the disease is unfavorable, symptoms of paralysis appear, from compression of the cord by the products of inflammation. The hyperæsthesia of the skin gives place to insensibility; the muscles lose their reflex function and their reaction to electricity; the bladder and rectum become paralyzed. The invasion of the medulla by the disease, which is announced by paralysis of the muscles of the œsophagus and of the tongue, is a fatal complication. The pulse and the respiration become rapid and irregular from compression of the vagus, the temperature rises to 106° or 108° F., and death ensues through asphyxia or failure of the heart.

The course of acute spinal meningitis is rapid. It sometimes terminates fatally within two or three days, and the average duration of fatal cases is about a week, but exceptionally the disease may last for several weeks or even months. Even then complete recovery may take place, though permanent effects are usually left behind, such as paresis or paralysis of the lower extremities, muscular contractions, muscular atrophy, etc., from injury to the nerve-roots or the cord.

The mind is generally clear in the early stage; afterward there may be delirium, especially along with cerebral complication.

MORBID ANATOMY.—It is rarely that the pia mater is the only tissue involved in the inflammation. Frequently the inner surface of the dura

is the seat of a fine injection, with delicate false membranes, and the cord itself—at least its exterior portions—probably always participates more or less in the congestion. The pia is reddened and thickened, the surface showing small bloody extravasations, and the space between its two layers is the seat of a fibro-purulent deposit. The spinal fluid is turbid and flocculent. The seat and extent of the morbid appearances vary in different cases; they are always more abundant in the posterior than the anterior part of the cord, and may be confined to a limited space or extend throughout its whole length. It is remarkable that the region of the medulla oblongata is generally free or only slightly affected; but since bulbar symptoms are often prominent in grave cases, Leyden¹ accounts for it by supposing that the exudation is washed away by the constant movement of the cerebro-spinal fluid. If the cord be involved in the inflammation, it is softened and injected, the nerve-sheaths are destroyed, and the axis-cylinders swollen in places. The nerve-roots show hyperæmia, infiltration of the interstitial tissue with round cells, and destruction of the nerve-sheaths.

DIAGNOSIS.—Spinal meningitis is easily recognized in most cases by its sudden onset and the severity of its symptoms. The distinguishing symptoms are sudden and acute pain in the back, extending around the body and into the limbs, which is increased by every movement of the trunk, rigidity of the back, hyperæsthesia of the skin, retraction of the head, with difficulty of breathing and of swallowing. The diseases from which it must be distinguished are muscular rheumatism (so called), tetanus, and myelitis. In rheumatism of the dorsal muscles the pain is confined to the back, does not extend to the limbs, and is only excited by movement. The fever is moderate or absent; there are no symptoms of spinal complication, such as cutaneous hyperæsthesia, retraction of the head, paresis of the limbs, etc.; and the result is uniformly favorable. Tetanus is almost always due to some well-marked traumatic cause; the muscles of the jaw are usually first implicated (trismus); and the attacks of general muscular spasm are easily excited by peripheral irritation. Myelitis can be distinguished by the absence of pain in the limbs and by paraplegia, but it must be borne in mind that myelitis and spinal meningitis may coexist.

PROGNOSIS.—Acute spinal meningitis is always a grave disease, hence a guarded opinion should be given even in apparently favorable cases. General mildness of the symptoms, with no indication of extension to the medulla oblongata, would afford ground for encouragement. The unfavorable symptoms are those showing compression or inflammation of the cord, such as paresis, paralysis, twitching of the limbs, muscular contractions, cutaneous anæsthesia, etc. The extension of the disease to the medulla, as shown by difficulty of swallowing, speaking, or breathing, is almost necessarily fatal.

TREATMENT.—During the first stage of the disease an effort should be made to reduce the hyperæmia of the membranes by the local abstraction of blood. This is best effected by cupping along each side of the spine and by the application of leeches to the anus; the bleeding should be promoted by poultices. Free purging is likely to be of service, and is best obtained by means of ten grains each of calomel and jalap (for an

¹ *Klinik der Rückenmarks-krankheiten*, von E. Leyden, Berlin, 1874, vol. i. p. 407.

adult), followed by saline laxatives. Counter-irritation to the back may be induced by the application of blisters or by painting the skin with a strong tincture of iodine (one or two drachms of iodine to an ounce of sulphuric ether). After the effusion of lymph and pus, as shown by symptoms of compression of the nerve-roots and cord, absorbents should be tried, of which the iodide of potassium, in doses of five to ten grains, four times daily, is most likely to be of benefit. Pain must be relieved by opium or morphia and chloral hydrate. The latter, either alone or combined with hyoscyamus and bromide of potassium, will be useful to allay spasmodic twitching, opisthotonos, or muscular contraction. The patient should be enjoined to lie on each side alternately, or on the face if possible, in order to equalize the hyperæmia of the membranes and cord. Liquid nourishment must be freely administered, such as milk, broths, gruel, etc., together with wine and other stimulants in case of exhaustion and threatening of collapse. During convalescence the patient should be carefully protected against cold and fatigue, and the strength must be supported by quinine and iron with suitable diet.

Chronic Spinal Meningitis.

SYNONYMS.—Chronic inflammation of the pia mater of the spinal cord, Chronic spinal leptomeningitis.

Chronic spinal meningitis may follow the acute form, or it may arise from chronic disease of the vertebræ or of the cord, especially myelitis and sclerosis. It is most apt to accompany sclerosis of the posterior columns, and it is often difficult to say in any particular case whether the meningeal affection preceded or followed that of the cord. Probably some cases of chronic myelitis, especially of the disseminated form, owe their origin to chronic meningitis.¹ It has been thought to follow blows on the back, and also to arise from general concussion without traumatism, and has been considered as a frequent result of accidents from railroad collisions, etc. This view has been disputed by Herbert W. Page,² who says: "Of the exceeding rarity of spinal meningitis as an immediate result of localized injury to the vertebral column we are well assured. . . . And we know of no one case, either in our own experience or in the experience of others, in which meningeal inflammation has been indisputably caused by injury to some part of the body remote from the vertebral column." Chronic alcoholism and syphilis, especially the latter, predispose to the disease. In many cases no adequate cause can be assigned.

SYMPTOMS.—Gowers³ remarks that a large number of symptoms formerly assigned to chronic spinal meningitis have nothing to do with that pathological state, but are now known to be owing to alterations within the cord which are frequently associated with it. The symptoms which are really due to the meningeal inflammation—namely, those aris-

¹ Leyden, *op. cit.*, vol. i. p. 442.

² *Injuries of the Spine and Spinal Cord, without Apparent Mechanical Lesion and Nervous Shock, in their Medico-legal Aspects*, London, 1883, p. 128.

³ *The Diagnosis and Diseases of the Spinal Cord*, by W. R. Gowers, M. D., 2d ed., Philada., 1881, p. 73.

ing from interference with the nerve-roots in their passage through the thickened membranes—do not differ essentially from those of chronic pachymeningitis of the spine; the principal are pain in the back, especially on movement, extending to the trunk and limbs, hyperæsthesia of the skin in various regions within the domain of the irritated sensory roots, with diminution or loss of the knee-jerk, and areas of anaesthesia due to their more complete compression. The compression of the motor roots gives rise to symptoms which are similar to those of disease of the anterior cornua, consisting chiefly of muscular wasting, with impairment of motion in corresponding regions, without fever.

The anatomical appearances, which are most pronounced in the posterior aspect of the cord, and diminish from below upward, are often of considerable extent. The membrane is thickened, opaque, and often adherent to the cord. On the inner surface are seen numerous small bodies composed of proliferating connective tissue.¹ These, according to Vulpian, are chiefly found in the lower dorsal and lumbar region and on the cauda equina. The dura is very frequently involved in the inflammation; it is thickened, and its inner surface is adherent to the pia, often showing numerous miliary bodies similar to those found in the pia.

DIAGNOSIS.—Chronic spinal meningitis so rarely exists apart from disease of the dura or of the cord that its separate diagnosis must be mainly a matter of conjecture. Leyden justly says we must usually be content to diagnosticate chronic meningitis without attempting any further distinction, except in cases which originate in disease of the vertebræ or of their neighborhood, and afterward penetrate into the spinal canal, and which would probably give rise to pachymeningitis. The diseases with which chronic meningitis of the spine is most likely to be confounded are posterior sclerosis (locomotor ataxia) and chronic degeneration of the anterior cornua (progressive muscular atrophy).² From the former it is distinguished by the absence of ataxia; from the latter, by the irregular distribution of the symptoms; and from both, by the existence of limited areas of anaesthesia and of extensive spinal pain. It must be remembered that inflammation of the cord complicating that of the meninges, or pressure upon the cord by the thickened membranes may give rise to mixed symptoms. The latter is especially observed in syphilitic cases.

PROGNOSIS.—Simple chronic spinal meningitis is rarely if ever fatal. How far it is capable of amelioration or of cure is not, in the present state of our knowledge, known. When complicated with disease of the cord the prognosis will depend upon that of the latter. Syphilitic chronic meningitis is to a certain extent amenable to appropriate medication.

TREATMENT.—The treatment should have for its object (1st) to relieve pain; (2d) to arrest the progress of the inflammation, and especially to prevent it from extending to the cord; (3d) to promote the absorption of the exudation. For the first object the internal or hypodermic employment of morphia should be combined with external applications, such as fomentations, liniments, ice, etc. Counter-irritation by means of dry cupping, blisters, iodine, etc., with leeches, shampooing, and douches of hot water, may be of some use in retarding the progress of the inflam-

¹ Leyden, *op. cit.*, vol. i. p. 144; A. Vulpian, *Mal. du Syst. nerv.*, Paris, 1879, p. 126.

² Gowers, *op. cit.*, p. 74.

mation, and should be aided by the administration of mercurials and the preparations of iodine. The biniodide of mercury would be useful for this purpose in the dose of one-sixteenth to one-eighth of a grain three times daily, its effect being carefully watched in order to prevent salivation. The same means will also aid in favoring the absorption of lymph. In syphilitic cases an appropriate specific treatment is indicated.

Spinal Meningeal Hemorrhage.

SYNONYMS.—Spinal meningeal apoplexy, Hæmatorrhachis.

Spinal meningeal hemorrhage may take place between the dura mater and the walls of the vertebral canal, or between the dura and the pia mater—*i. e.* into the arachnoid space.

ETIOLOGY.—Penetrating wounds, injuries to the vertebræ, fractures and dislocations, and violent blows are apt to give rise to more or less hemorrhage into the spinal canal. Violent convulsions, as in tetanus, epilepsy, uræmic eclampsia, hydrophobia, may be followed by meningeal hemorrhage, owing to the disturbance of the circulation from asphyxia; and excessive muscular effort, as in lifting heavy weights, etc., has been said to cause it. In cerebral meningeal hemorrhage and in effusion into the substance of the brain the blood sometimes escapes into the spinal canal. An aneurism of the aorta has been known to communicate with the canal; such a case was reported by Laennec.¹ In certain diseases with hemorrhagic tendency, as purpura and scurvy, spinal extravasation is occasionally observed.²

SYMPTOMS.—These vary according to the conditions under which the hemorrhage is produced and to the amount of bleeding. In traumatic cases the signs of hemorrhage are often completely overshadowed by those of the injury of the vertebræ, the membranes, or the cord, and are undistinguishable. When a large amount of blood is suddenly introduced into the spinal canal, it usually gives rise, by pressure on the cord, to paraplegia, which, however, is sometimes of only short duration. Thus in Laennec's case the bursting of an aneurism into the spinal cavity was signalized by a sudden paraplegia, but in half an hour the power of movement returned, though sensation did not. The patient died in a few hours from hemorrhage into the left pleural cavity. The amount of blood in the spinal cavity is not stated, and, in fact, it would appear that the spine was not opened. When the amount of blood is smaller the symptoms indicate irritation of the spinal nerves and of the cord. Pain in the back is always present, extending into the limbs, and is sometimes severe. Its seat corresponds to that of the effusion. There may be a feeling of tingling and numbness in the lower extremities, with anæsthesia or hyperæsthesia of the skin and more or less paresis. A feeling of constriction around the waist or the chest is sometimes complained of. In slight effusions the symptoms may be limited to numbness and formication of the extremities, with slight paresis. There is rarely fever in the early stages, unless the amount of blood is suffi-

¹ *Traité d'Auscultation médiate*, 4th ed., Paris, 1837, vol. iii. p. 443.

² A case of scorbutic spinal hemorrhage is reported in the *British Med. Journal*, Nov. 19, 1881.

cient to give rise to inflammatory conditions of the cord or membranes. If the extravasation be moderate it is generally absorbed, with relief to the symptoms, although slight numbness and paresis of the extremities may continue for a long time.

PATHOLOGICAL ANATOMY.—In hemorrhage outside the dura the loose cellular tissue between the membrane and the bony canal contains more or less coagulated blood according to the circumstances of the case, especially in the posterior region of the canal and covering the nerve-roots. The dura is reddened by imbibition of the coloring matter of the blood. When the amount of the effusion is large, as in traumatic and aneurismal cases, or where cerebral hemorrhage has extended into the spine, the cord may be compressed by it. Hemorrhage into the arachnoid sac, except in cases of violence, etc., is usually of limited amount, sometimes only in the form of drops of blood upon the surface of the dura or pia. When more abundant it may surround the cord more or less completely, but in most cases it is limited in longitudinal extent, being confined to the space of one or two vertebræ. The cord may be more or less compressed, reddened, and softened. In all cases the spinal fluid is discolored and reddened in proportion to the amount of the hemorrhage.

DIAGNOSIS.—When the complications are such that symptoms attributable to hemorrhage are not observed, the diagnosis of spinal hemorrhage is impossible. This may happen in the case of wounds and injuries of the vertebræ and of the passage into the spinal canal of blood from an apoplectic effusion of the brain. In the convulsions of tetanus, epilepsy, etc. the amount of the hemorrhage is rarely sufficient to give rise to distinctive symptoms. In idiopathic and uncomplicated cases the chief diagnostic marks are suddenness of the attack; pain in the back, usually at the lowest part; disturbances of sensation in the extremities (anæsthesia, formication, etc.); paresis or paralysis of the legs; the absence of cerebral or spinal inflammatory symptoms; and, in many cases, the favorable course of the disease. Sometimes an ostensible cause, such as scurvy, purpura, suppressed menstruation, or hemorrhoidal flux, will aid in the diagnosis. The disease for which spinal hemorrhage is most likely to be mistaken is acute myelitis, but this is not sudden in its onset, is accompanied with fever, and gives rise to paralysis both of motion and sensation, and to loss of control over the sphincters, to bed-sores, etc. Hemorrhage of the cord would be accompanied by paraplegia and loss of sensation in the lower extremities and slight tendency to spasmodic manifestations; it is fatal in the majority of cases, or else is followed by permanent paralysis. Hysteria might be confounded with spinal hemorrhage, but the history of the case and the transient duration of the symptoms would clear up all obscurity.

PROGNOSIS.—In traumatic cases the hemorrhage is usually only one element in the gravity of the situation, which depends chiefly upon the character and extent of the original injury. In idiopathic and uncomplicated cases the prognosis, which must always be doubtful, will vary according to the severity of the symptoms as corresponding to the amount of the effusion. The danger is greatest during the first few days; if there should then be diminution of the more important symptoms, an encouraging opinion may be given. The immediate effects may, however, be

less grave than the remote, such as bed-sores, cystitis, etc. Except in the very mildest cases the patient is likely to be confined to bed for several weeks. In more severe ones the convalescence may be very protracted, and permanent lameness, etc. may result.

TREATMENT.—In the early stage absolute rest in bed, with cold applications to the back and moderate purging, should be employed. Large doses of ergot are recommended, but there is little evidence of benefit from this medicine. In traumatic cases no rules for treatment of the hemorrhage can be laid down. If the extravasation evidently depends upon a constitutional diathesis, as in purpura, scurvy, etc., the remedies appropriate for these diseases should be employed, especially tonics and astringents, such as the tincture of the chloride of iron, in doses of from fifteen to thirty drops three times daily, quinine, and the vegetable acids. Should there be evidence of blood-pressure from suppressed discharge, as in amenorrhœa, arrested hemorrhoidal flow, etc., leeches should be applied to the anus, and blood may be taken from the region of the spine by cupping. In the later stages an attempt may be made to aid the absorption of the effused blood by the administration of the iodide of potassium or the protiodide of mercury, and by the application of blisters or strong tincture of iodine to each side of the spine. Pain must be relieved and sleep obtained, when necessary, by means of opium, chloral hydrate, or other anodynes. Electricity, rubbing, bathing, etc. will be useful for combating the paralytic symptoms which may remain after the disease itself is relieved.

SPINA BIFIDA.

By JOHN ASHHURST, JR., M. D.

DEFINITION.—By the term spina bifida is meant a congenital malformation of the vertebral column, consisting in the absence of a part—commonly the spinous processes and laminae—of one or more of the vertebrae, and thus permitting a protrusion of the spinal meninges, which, with their contents, form a tumor of variable size and shape, usually in the lumbo-sacral region.

SYNONYMS, ETC.—Of the various names which have been proposed for this affection, most are objectionable, as not expressing with sufficient definiteness what is meant. Thus, hydrorachis (the term generally employed by French writers), hydrorachitis, spinal hydrocele, etc., convey merely the notion of an accumulation of fluid within the spinal canal, and are as applicable to simple serous effusions in that part, whether occurring as a complication of hydrocephalus or as the result of injury, as to the special affection under consideration. Again, myelochysis—pouring out or protrusion of the spinal marrow—would imply that the cord itself was necessarily involved in the tumor, which is certainly not always the case. The terms schistorachis (cleft spine) and atelorachidia (defective spine—a name suggested by Bécларd) would be preferable, and are really more accurate than the name spina bifida, since, as a matter of fact, the spinous processes are, as a rule, not bifid, but totally deficient. The latter term, however, has the advantage of being more familiar, and may be retained simply as a matter of convenience. It is said by Itard to have been first employed by the Arabian physicians.

HISTORY.—Spina bifida does not appear to have been known to the ancients, the earliest recorded observations of the affection being found in the writings of Bauhinus (1560–1624), of Tulpus (1593–1674), of Bonetus (1620–89), and of Ruysch (1638–1731). Good accounts of the affection may be found in the *Dictionnaire des Sciences médicales* (tome xxii., Paris, 1818), and particularly in Holmes's *Surgical Treatment of the Diseases of Infancy and Childhood* (2d ed., London, 1869), in Follin and Duplay's *Traité de Pathologie externe* (tome iii.), and in Treves's article on "Malformations and Injuries of the Spine" in the *International Encyclopædia of Surgery* (vol. iv., New York, 1884).

ETIOLOGY.—There are two conditions essential to the formation of a spina bifida: (1) an arrest of development, or at least a defective closure, of the vertebral arches; and (2) a dropsical condition either of the central canal of the spinal cord or of the subarachnoid spaces; but which

of these is the antecedent condition it is, as justly remarked by Erb, impossible to decide. Spina bifida often occurs as a complication of hydrocephalus, and is itself often complicated with an atrophic and deformed condition of the lower extremities—a circumstance which led Tulpus to suggest that the malformation was caused by a malposition of the fœtus in utero, an explanation which it seems hardly necessary to waste time in considering. Salzmann observed spina bifida in two children born of the same mother, and Camper noticed it in twins.

SYMPTOMATOLOGY.—Spina bifida forms a tumor—or, more rarely, several tumors—in the region of the vertebral column, usually discovered at birth, but occasionally not noticed until a later period. Thus, Lancisi mentions a case in which the tumor first made its appearance in a hydrocephalic child at the age of five years, and J. L. Apin one in which the patient reached the age of twenty before any swelling was manifested. If these records are accepted as authentic, the only satisfactory explanation is that of Itard—viz. that the bony deficiency existed from the time of birth, and that the dropsical protrusion did not occur until afterward: this seems to me more reasonable than the suggestion of the younger Andral, that the vertebræ underwent a process of secondary softening and absorption. The part most frequently affected is the lumbar region, but cases are not wanting of the occurrence of spina bifida in the cervical, dorsal, and sacral regions, and even, in at least one case (Genga's), in the coccyx. The tumor almost invariably occupies the median line, and projects directly backward: in at least four cases, however, recorded by Bryant, Emmet, and Thomas, the tumor protruded anteriorly from deficiency of the vertebral bodies.

The size of a spina bifida varies from that of a walnut to that of a child's head, or even larger: in some rare instances, such as those recorded by Lezelius and Richard, the whole spinal column has been cleft, and the tumor has extended from nucha to sacrum; but cases of this kind seldom come under the surgeon's observation, as children with such extensive deformity usually perish shortly after birth. The shape of the swelling is rounded, or more often oval; it is commonly sessile, but occasionally pedunculated; and it is sometimes lobulated, the lobules being separated by more or less distinct sulci. The skin covering the tumor is in some cases normal, with more or less fat in the subcutaneous connective tissue, but more often thin, tightly stretched, red, shining, and occasionally ulcerated; more rarely it is thickened and leathery, as in a case referred to by Sir Prescott Hewett. Sometimes a navel-like depression is found at some part of the surface, corresponding, as pointed out by Follin and Duplay, and by Erb, to the place of attachment, on the interior of the sac, of the terminal extremity of the spinal cord. The cutaneous investment is sometimes altogether wanting, the spinal dura mater itself forming the external covering of the tumor. It is in these cases especially that ulceration and rupture are apt to occur.

Spinæ bifidæ are usually soft and fluctuating, and occasionally partially reducible; their tension and elasticity are increased when the child is in the upright position or during the acts of expiration and crying, and are diminished during inspiration or when the child is laid upon its face. When the part is relaxed a bony prominence can be felt on either side, and the aperture in the vertebral column can be more or less distinctly

outlined. The swelling is apt to be painful on pressure. If the tumor is of moderate size and covered with healthy skin, there are usually no constitutional symptoms, and, even where ulceration and rupture occur, the opening may heal and a spontaneous cure may possibly ensue. More often, as the tumor increases in bulk—or at any time if pressure be made upon it—various nervous symptoms are observed: drowsiness, muscular twitchings, convulsions, and often paraplegia and paralysis of the sphincters. Rupture is usually followed by the development of spinal meningitis, or may prove directly the cause of death by the loss of cerebro-spinal fluid which it causes; in other instances, however, if the rupture be a small one, healing may occur (as already mentioned) or a fistulous opening may persist; in rare cases the fluid may escape by a process of transudation without rupture, as in an example recorded by Laborie.

As may be inferred from what has already been said, the course of spina bifida is usually rapid and toward a fatal termination. In some instances, however, as in cases observed by Holmes, and more recently by Lithgow, spontaneous recovery has followed the obliteration of the channel which unites the sac with the cavity of the spinal membranes; and in other instances, without a cure having been effected, life has been prolonged for very many years. Thus, Behrend reports a case in which a patient with spina bifida lived to the age of fifty, and Holmes refers to another in which death resulted from an independent disease at the age of forty-three. But a still more remarkable case was recorded by Callender, the patient in this instance having reached the age of seventy-four.

PATHOLOGY AND MORBID ANATOMY.—The most important points for consideration in respect to the anatomy of spina bifida are the relations which the spinal cord and spinal nerves bear to the sac, and the nature of the contained fluid. It is ordinarily said that the spinal cord itself commonly enters the sac of a spina bifida—the report of the London Clinical Society's committee gives the proportion of cases in which it does so at 63 per cent.—and Holmes figures a specimen from the museum of St. George's Hospital, London, in which this condition is obviously present; on the other hand, Mayo-Robson in eight operations only once found the cord implicated; and the late John B. S. Jackson of Boston—whose name will be recognized as one of high authority in regard to all questions of morbid anatomy—once assured me that he had made very many dissections of spinæ bifidæ, and that he had invariably found that the cord stopped short of the sac, and that only the nerves entered the latter: this, as negative evidence, cannot of course contravene such positive evidence as that of the specimen referred to by Holmes, but it would seem to show that the condition was a less common one than is generally supposed, and that in at least a fair proportion of cases the cord itself did not form part of the sac contents. This remark applies especially to those cases in which the fluid is accumulated in the subarachnoid space, and in which, as pointed out by Sir P. Hewett, the cauda equina or spinal nerves are pushed by the vis a tergo into the sac; but when the dropsical effusion occupies the central canal of the cord, this is apt to be flattened and spread out like a thin lining to the sac, just as the brain is spread over the inner wall of the skull in cases of internal hydrocephalus; and, on the other hand, when the accumulated fluid fills the cavity of the arachnoid the cord is apt to be pushed forward, and the

sac may be entirely devoid of all nerve-structures. Such, too, according to Giraldès, is the case in spina bifida of the cervico-dorsal region.

The committee of the London Clinical Society classify cases of spina bifida in three divisions: (1) Those in which the membranes only protrude (spinal meningocele); (2) those in which the protrusion involves both the cord and membranes (meningo-myelocele); and (3) those in which the central canal of the cord itself forms the cavity of the sac (syringo-myelocele). The last variety is the rarest, as the second is the most common. In meningo-myeloceles the spinal cord with its central canal is continued within the median, vertical portion of the sac, and at this part there is no covering of true skin; the nerve-roots which traverse the sac arise from this intramural portion of the central nervous system.

Humphry of Cambridge, England, makes a somewhat similar classification of spinæ bifidæ, recognizing as the most common variety the hydrorachis externa anterior, in which the fluid occupies the subarachnoid space in front of the spinal cord, and in which "the cord and the nerves are stretched backwards and outwards upon the sac, and are there confluent, together with the arachnoid, pia mater, and dura mater, or their representatives, in the thin membrane which forms the hindmost part of the wall of the sac;" rarer forms are the hydro-meningocele, or hydrorachis externa posterior, in which the fluid accumulates behind the cord, which does not enter the sac, and the hydro-myelocele or hydrorachis interna, in which the fluid occupies the central spinal canal.

The theory which, according to the Clinical Society's committee, best explains the pathological anatomy of spina bifida is that which assumes a primary defect of development of the mesoblast from which the structures closing in the vertebral furrow are developed.

The fluid of spina bifida appears to be identical in character with the cerebro-spinal fluid. Bostock found that it was very slightly clouded by the application of heat, and that it contained, in 100 parts, 97.8 of water, 1.0 of chloride of sodium, 0.5 of albumen, 0.5 of mucus, 0.2 of gelatin, and some traces of lime. Five specimens more recently analyzed by Hoppe-Seyler gave an average of 98.8 parts water, 0.15 parts proteids, and 1.06 extractives and salts. Turner found a reaction somewhat similar to that of grape-sugar, as had been previously found by Bussy and Deschamps in cerebro-spinal fluid itself, but in two specimens analyzed by Noad for Holmes it was at least very doubtful whether sugar was actually present. "The first specimen was found to be completely neutral; its specific gravity was 1.0077; it contained phosphates, but no reaction could be obtained resembling that of sugar. The second specimen . . . did give a reaction with copper like that of sugar, but no trace of fermentation could be obtained." Three analyses, however, made by Halliburton for the London Clinical Society's committee showed uniformly a decided trace of sugar, with a diminution in the quantity of proteids, which appeared to consist entirely of globulin.

In some cases the sac of a spina bifida contains, besides nerve-structures and cerebro-spinal fluid, both fibrous and fatty tissues.

DIAGNOSIS.—Ordinary fatty tumors have been mistaken for spinæ bifidæ, but such an error could only be committed through carelessness: more difficult is the diagnosis from certain forms of congenital cyst, occupying the median line of the back, and still more difficult the diag-

nosis from the several affections known as false spina bifida. In the former case the distinction might be made by noting the irreducibility, constant shape, and unchanging tenseness of the cyst, and perhaps, as suggested by T. Smith, by tracing the line of spinous processes beneath it; some information, too, might perhaps be gained by chemical examination of the fluid obtained by puncture. Under the name of false spina bifida Holmes includes three distinct conditions: these are—(1) a true spina bifida, in which the connection with the spinal membranes has in some way been obliterated, the sac then communicating with the vertebral canal, but not with the theca; (2) a congenital, cystic, or fatty tumor, taking its origin within the vertebral canal, and projecting through an opening caused by a gap in the laminæ; and (3) a tumor containing fœtal remains, and properly regarded as an example of included fœtation. In any of these cases a positive diagnosis might be impossible, and the probable nature of the tumor could only be inferred by noting the absence of one or more of the characteristic symptoms of true spina bifida.

PROGNOSIS.—The prognosis of spina bifida is without question unfavorable; at the same time the affection is by no means to be considered, as it was formerly, one of an invariably fatal character, for, apart from the fact already mentioned that several cases are on record in which patients with untreated spina bifida have reached adult life, and even old age, the modern method of treatment has proved so much more successful than those formerly employed that in favorable cases surgical interference affords at least a reasonable prospect of recovery. The circumstances which especially furnish grounds for an unfavorable prognosis are the rapid growth of the tumor, the thinning or ulceration of its coverings, and the occurrence of nervous symptoms, and particularly of paralysis or convulsions.

TREATMENT.—This may be either palliative or radical. If the tumor be not increasing materially in size, the surgeon may properly content himself with palliative measures—applying equable support and perhaps slight pressure by the use of a well-padded cap of gutta-percha or leather, an air-pad, or, as advised by Treves, a simple pad of cotton smeared with vaseline, and a bandage; if the tumor be small and covered with healthy integument, painting its surface with collodion may be of service through the contractile property of that substance. Radical measures are only indicated when the child, otherwise healthy, seems to have his life threatened by the rapid growth of the tumor, causing risk of ulceration and rupture, or giving rise to convulsions or paralysis. The principal modes of treatment to be considered under this heading are—(1) simple tapping or paracentesis; (2) injection of iodine; (3) ligation of the neck of the sac; and (4) excision.

(1) Paracentesis, a simple evacuation of the fluid contents of the sac, is the only operation ordinarily justifiable in cases attended by paralysis or other grave nervous manifestations. The puncture should be made in the lower part of the sac and at a distance from the median line (in the course of which the nerve-structures are particularly distributed), and only a small quantity of fluid—a few drachms or at most one or two ounces—should be removed at a time, the instrument being at once withdrawn if convulsions follow, and the wound being instantly closed with lint dipped in compound tincture of benzoin. Either an aspirator-tube or a

small trocar may be used, and the operation may be repeated if necessary, pressure being maintained during the intervals. Paracentesis has occasionally though not often proved curative.

(2) Injection of Iodine.—This mode of treatment was introduced about the same time by Velpeau and by Brainard of Chicago. The latter surgeon's method consists in injecting, after only partially emptying the tumor, a solution of iodine with iodide of potassium (iodine, 5 grs.; iodide of potassium, 15 grs.; water, 1 fl. oz.), allowing it to flow out again, washing out the sac with water, and finally reinjecting a portion of the cerebro-spinal fluid originally evacuated; and the former's, in completely evacuating the tumor, and then injecting a mixture of iodine and iodide of potassium, each one part to ten parts of water. Each of these plans has met with a fair measure of success;¹ but the modification introduced by James Morton of Glasgow is a great improvement, and affords what is actually the most successful mode yet devised for dealing with spina bifida. Morton employs a solution of iodine in glycerin (iodine, 10 grs.; iodide of potassium, 30 grs.; glycerin, 1 fl. oz.), which has the advantage of being less diffusible than the aqueous solution, and therefore less liable to enter the spinal canal. The tumor is about half emptied, and a small quantity—from fʒss to fʒiij of the solution—is then slowly injected, and allowed to remain. The operation is repeated after a few days if necessary. Of 50 cases known to Morton as having been treated in this way up to May, 1885, 41 were regarded as successful; but of 71 cases collected by the London Clinical Society's committee, only 39 had been benefited by the operation.

The introduction of iodine into the sac of a spina bifida is, according to Morton, only justifiable in cases unattended by paralysis; under opposite circumstances I should be disposed to try a plan recently employed with success by Noble Smith in a case of meningocele—viz. injecting the iodo-glycerin solution into the coverings of the sac, and as close to it as possible without perforating it.

(3) and (4). Ligation and excision have each occasionally effected a cure, but more often have but helped to precipitate a fatal issue. A successful case of ligation followed by excision has been recently recorded by Löbker. The elastic ligature, applied around the neck of the sac (if this be pedunculated), has been employed by Laroyenne, Ball, Colognese, Baldossare, Mouchet, and other surgeons, and of 6 cases collected by Mouchet, 3 ended in recovery. Another success has been recently recorded by Turretta. The *écraseur* has been used, but its employment cannot be recommended. Compression by clamps is advised by Schatz of Rostock. Ligation is best adapted to cases occurring in the cervical and dorsal regions, in which, as pointed out by Giraldès, nerve-elements are less likely to be involved. Excision, supplemented by transplantation of a strip of periosteum from a rabbit, has been successfully resorted to by Mayo-Robson and by R. T. Hayes of Rochester, N. Y.; and simple excision, with suture in separate lines of the sac and integuments, by Mayo-Robson, Atkinson, and Jessop. The Clinical Society's committee in all refers to 23 cases treated by excision, 16 of which are said to have been successful.

¹ In a case recently recorded by Woltering, however, iodine injection was followed by death within half an hour.

ANÆMIA AND HYPERÆMIA OF THE BRAIN AND SPINAL CORD.

By E. C. SPITZKA, M. D.

Cerebral Hyperæmia.

UP to within a few years it was a favorite mode of explaining the results of the administration of certain narcotic and stimulant drugs, and certain of the active symptoms of mental derangement, to attribute them to an increased blood-supply of the nerve-centres. This view seemed to harmonize so thoroughly with the physiological dictum that functional activity depends on the supply of oxygenated blood that the first attempts at questioning it were treated as heresies. To-day, however, few authorities can be found to adhere unreservedly to this once-popular and easy explanation. The drift of physiological and medical opinion is in the direction of regarding some subtle molecular and dynamic state of the nerve-elements as the essential factor in intoxications as well as in maniacal and other forms of insane excitement: if they be complicated by active or passive congestions, this is probably a secondary occurrence of modifying but not of intrinsic determining power. While this change in our views is the natural result of progress in experimental pharmacology and pathology, it does not justify the extreme assertion that there is no disorder of the brain functions deserving the name of congestion and hyperæmia. This assertion seems to have been provoked by the careless manner in which these terms have been employed to designate conditions which are in reality the most different in nature that can be well conceived. No one familiar with the extent to which the term "congestion of the base of the brain" has been abused in this country will marvel that the reaction provoked by it has overstepped the boundaries of cautious criticism. That there are physiological hyperæmias of the brain is now universally admitted; the most recent experimental observations, indeed, conform most closely to the claims of the older investigators. It naturally follows that pathological hyperæmias are both possible and probable, and even if the observations in the dead-house do not strongly sustain the existence of pathological hyperæmias and congestions independently of gross disease, clinical analysis and the gratifying results of appropriate treatment justify us in retaining these designations in our nomenclature with the limitation here implied.

One great difficulty in determining the precise nature of the disorders which the physician is called upon to treat on the theory of hyperæmia lies in the number of factors which may contribute to or modify its devel-

opment. If, for example, the action of the heart be increased through hypertrophy, the result to the cerebral circulation will obviously be different in a plethoric and in an anæmic person; it will be also very much different in the event of the stimulation of the centres which contract the calibre of the cerebral blood-vessels from what it would be if there were a state of vascular relaxation. Should the cardiac hypertrophy be associated with renal disease, other disturbing elements may be introduced, such as arterio-fibrosis, or the presence in the blood of certain toxic substances having direct effects of their own on the nerve-elements. The picture may be still more complicated by variations in the intracranial pressure. It is impossible to prove, either by direct or indirect evidence, that there is such a pathological state as a simple cerebral hyperæmia; indeed, there is one fact which militates strongly against, if it be not fatal to, such an assumption. Were a physiological hyperæmia to become intensified to a pathological degree, we should have corresponding clinical phenomena. In other words, the culmination of the morbid process should be preceded by an exaggerated physiological excitation similar to that observed with intoxications. But this is rarely the case, and we accordingly find that the more cautious writers, like Nothnagel,¹ do not commit themselves to the view that the results of mental overstrain² are to be classed as simple cerebral hyperæmia. Similar restrictions are to be made regarding the established congestive states, such as those following sunstroke. It has been usually supposed that insolation directly produces cerebral hyperæmia, even to the degree of engorgement, and that the after symptoms in persons who recover are due to the non-return of the meningeal and cerebral blood-vessels to their normal calibre, and to other more remote results of vascular stasis. The latter half of this proposition is in part correct; the former is contradicted by numerous pathological observations. Thus, Arndt,³ who had the opportunity of studying over one hundred cases occurring in the course of a forced march of a division of infantry from Berlin to Pankow, many of which terminated fatally, found almost uniformly a pale brain, with peculiar color-changes, denoting rather structural than circulatory trouble.⁴ The

¹ *Ziemssen's Cyclopædia*, "Nervous System," i. p. 39, 2d German ed.

² It has repeatedly happened during the past decade that young persons competing for admission to higher institutions of learning in New York City through the channel of a competitive examination died with symptoms of cerebral irritation; the death certificates in several such cases assigned meningitis or cerebral congestion as the cause of death, and attributed the disorder to mental overstrain. It is not so much the intellectual effort that has proved hurtful to the pupils as the emotional excitement attending on all competitive work, the dread of failure, the fear of humiliation, and anxiety developed by the evident futility of the cramming process. Some years ago I recorded the results of some inquiries on this head in the following words: "The mental-hygiene sensationalists, who periodically enlighten the public through the columns of the press whenever an opportune moment for a crusade against our schools and colleges seems to have arrived, are evidently unaware of the existence of such a disease as delirium grave, and ignorant of the fact that the disorder which they attribute to excessive study is in truth due to a generally vitiated mental and physical state, perhaps inherited from a feeble ancestry. Our school system is responsible for a good deal of mischief, but not for meningitis" (*Insanity, its Classification, Diagnosis, and Treatment*). Since then I had an opportunity of obtaining an excellent description of such a case which had been attributed to the combined effects of malaria and educational overstrain, presenting opisthotonos, fulminating onset, and an eruption!

³ *Virchow's Archiv*, lxiv.

⁴ The observations of Gärrntner (*Medicinische Jahrbucher*, 1884, 1) harmonize with this. He found that radiant heat contracts the blood-vessels of the frog's mesentery.

whole list of causes of what is commonly designated cerebral hyperæmia, congestion, and engorgement may be gone through with and similar modifying statements be found to apply to them. The nearest approach to an ideal cerebral congestion is that found with acute alcoholic intoxication. This is at first accompanied by cerebral hyperæmia, which, with the comatose climax, becomes an engorgement; accordingly, many of the results of acute alcoholic intoxication are attributed to the circulatory condition alone. The congestive troubles due to alcoholism which come to the special ken of the physician, however, are those found with the chronic form, and here a more complex pathological condition is found to underlie it; the organization of the brain is altered, the vascular channels more or less diseased, and the vaso-motor mechanism continuously deranged. This disorder, as well as the apoplecticiform states attributed to vascular stasis, and the active and passive hyperæmias associated with tumors, meningitic and other gross diseases of the brain, as well as with the status epilepticus, are usually included in the discussion of cerebral congestion, and serve to swell up the chapters devoted to it. They will be found discussed in more appropriate situations in this volume. In this place it is proposed to consider only those congestive states which present themselves to the physician, independently of conditions which, if associated, preponderate in clinical and therapeutic importance.¹

ETIOLOGY.—An individual predisposition to cerebral congestion was one of the unquestioned facts of the older medical writers. It undoubtedly exists, and to-day we attribute it to inherited vascular conditions either affecting the calibre and coats of the blood-vessels or the vigor of the vaso-motor apparatus. I have remarked the transmission of that weakness of the latter which underlies the congestive phenomena of later life much more frequently in the female than in the male sex.

It has been claimed that external refrigeration produces hyperæmia of the brain, as of other internal organs, and that this accounts for the greater frequency of the disorder in cold weather. Niemeyer indeed speaks of persons who, suffering from this condition, appear and act in such a way as to convince the laity that they are intoxicated; and Andral, Falret, and Hammond note the occurrence of a much larger number of cases in the winter than in the summer months. I apprehend that the condition described by Niemeyer must be extremely uncommon, both from individual experience and the rarity of its mention as an independently observed fact. With regard to the alleged greater frequency of the disorder in winter, it must be remembered that all the three observers cited include in their computation a number of cases in which congestion was a collateral feature; they did not limit themselves to the disorder as

¹ The same applies to conditions which are discussed under this head in textbooks, although they have either only a medico-legal bearing or are inconstant factors, such as the injection of the brain in death from strangulation. I need but instance the vascular condition of brains of criminals executed by hanging. In the case of one where the strangulation had been slow I found an engorgement of all the vessels and arachnoidal as well as endymal hemorrhages; in a second, where the criminal had been carried half fainting to the drop, and death ensued quickly and without signs of distress, the brain was decidedly anæmic.

It has been also considered best to omit treating of the collateral hyperæmia of the brain sometimes found with erysipelas of the face and scalp. This I regard as essentially of the same nature as the metastatic meningitis of erysipelas, if it be not in reality a first stage of the latter.

spoken of here. Certainly, the physician will see few if any persons who consult him because of the hyperæmia-producing effects of a cold day.

The suppression of habitual discharges, of the hemorrhoidal flux, and the cessation of menstruation are associated in many instances with the more formidable grades of cerebral hyperæmia. Many phenomena of so-called climacteric insanity depend on congestive states. The sudden closure of an old ulcer or the removal of hemorrhoids in advanced life has in some well-established instances provoked alarming seizures not unlike those noted with parietic dementia. The chain of proof establishing the direct influence of physiological and pathological discharges on the vascular controlling apparatus of the brain is most complete. Not alone cumulative clinical observation, but the occasional happy result of the therapeutic procedure based on this supposed interdependence, support it. Thus, the congestive cerebral state is recovered from when the menstrual or hemorrhoidal flow is re-established, or an issue is formed in the nape of the neck, or an old ulcer is allowed to reopen.¹

The origin of most cases that are brought to the physician's attention is more or less complicated. A business-man, lawyer, or student suffering from worry incident to his profession, living so irregularly as to provoke gastric disturbances, becomes afflicted with insomnia, and in addition is also constipated. Straining at stool, he finds a dull, heavy sensation affecting the upper part of his head; attempting to resume his work, this is aggravated, and after a series of temporary remissions the condition to be later described becomes continuous. In such a case the insomnia, usually due to neural irritability, if not aggravated by an existing dyspepsia, leads to such a one, and a *circulus vitiosus familiaris* to all physicians is established. Each of the factors concerned involves strain of the cerebral vaso-motor apparatus, but none more so than the insomnia. It is not so much the intensity of the strain as its long duration and the exhaustion of the centre which in sleep is supposed to be at comparative rest. This rest is not obtained, and, in conformity to the laws of neural exhaustion, that centre becomes morbidly irritable. Now, gastric irritation is competent to produce a reflex influence on even the healthy cerebral organ; to do so it must be a severe one; but with the class of persons alluded to the slightest indiscretion in food or drink is sufficient to set up reflex vertigo or headache. The current theory regarding these symptoms is that they are due to stimulation of the vaso-constrictors and ensuing cerebral anæmia; but the subjects before us will usually be found to flush up instead of becoming pale, as in simple vertigo a *stomacho læso*, or if there be initial paleness, there is a

¹ The treatment of parietic dementia, particularly of the congestive type, is also based on this relation. The irritating antimonial ointment and issues in the nape of the neck, etc. have been lauded by older observers, and in two of my own cases had the best results—in one, indeed, with established *restitutio ad integrum* of now nearly two years' duration. I am inclined to suppose that its abandonment is due to an improper selection of cases; in the ordinary premature senility and syphilitic types such treatment is altogether ineffective. It is applicable to but a minority of cases at best, and to them only at an early period. It is probably to a similar form of congestion that Bouchut refers when (*"Les Névroses congestives de l'Encéphale," Gazette des Hôpitaux, 1869*) he speaks of a cerebral hyperæmia developing under the mask of a meningitis—an expression that may be allowed if understood in the same sense as the comparison between hydrocephaloid and hydrocephalus.

secondary flush, as if the tired arterial muscle had become exhausted by the effort at obeying the reflex stimulus. In addition, a profuse perspiration sometimes breaks out on the upper part of the body.

The influence of traumatic causes and insolation in producing a tendency to repeated and severe cerebral congestion is recognized, particularly among alienists. It is supposed that an abnormal irritability of the vaso-motor apparatus is provoked by these causes. Abundant evidences are sometimes found in the brains of such persons of an altered state of nutrition of the brain and its membranes, and which point in the direction of congestion.

In the conditions thus far alluded to it can be fairly assumed that the determination of blood to the cerebral blood-vessels is more or less active. Passive congestion due to impeded return circulation is of secondary interest, as the primary disease, be it a pertussis or a laryngeal, cardiac, pulmonary, or surgical condition, will constitute the main object of recognition and management. Certain quasi-physiological acts, as coughing, hurried breathing, holding the breath while straining at stool, and placing the head in a dependent position while acting in the direction of passive hyperæmia, are to be considered in connection with the active forms of congestion which they may momentarily aggravate.

MORBID ANATOMY.—Owing to the non-fatality of the commoner forms of cerebral hyperæmia, no pathological observations of them are at our disposal, nor can we assume from analogy that the appearances would be well marked if they could be made. What little knowledge we have is derived from a study of more serious conditions of which cerebral hyperæmia is an initial, collateral, or episodial feature.

In pronounced cerebral hyperæmia the entire brain is, as it were, tumefied, so that the dura appears tensely stretched over its surface and the gyri are flattened; both the meningeal vessels proper and those of the pia are injected. According as the hyperæmia is active or passive the color of this injection varies, being of a brighter red in the former, of a purple or bluish color in the latter case. The purest instances of active cerebral hyperæmia which I have seen were found in patients dying in the apoplectiform phases of paretic dementia (progressive paralysis of the insane). Here the cortex on section exhibited a beautiful rosy tint, which was distributed in darker and lighter strata in correspondence with the distributional areas of the short and the long cortical arteries; there were numerous puncta vasculosa both in the cortex and in the white substance, and in some instances the arachnoid or the ventricular fluid was tinged with blood, albeit no vascular rupture could be discovered. The red blood-corpuscles undoubtedly escape by diapedesis from the surface as well as the endymal vessels; the same thing occurs in the intracerebral blood-vessels, whose adventitial spaces are often crowded with accumulations of red blood-discs, while groups or single ones are found scattered in the surrounding parenchyma, and even in the periganglionic spaces. Occasionally accumulations of pigment found near the vascular channels remain to attest the former existence of other hyperæmias, and indeed slight accumulations of this kind are found in the brains of most persons who have reached adult life. These are to be regarded as remnants of the physiological hyperæmias to which all active individuals are subject. It is only when the accumulations become considerable and numerous, as in the chronic insane, or are associated with those changes in the blood-vessels

which are discussed in the articles on thrombotic and hemorrhagic cerebral disease, that they can be regarded as indications of a pathological condition.

Acute simple meningitis is ushered in by cerebral hyperæmia of the active form. This is not alone demonstrated by the early symptoms of this disease, but also by the fact, which I have observed in two cases, that where this form of meningitis originates on one side, as from extension of the middle-ear trouble, the opposite cerebral hemisphere exhibited intense congestion of the ideal type.

In that serious form of mental disease known variously as grave or acute delirium and typhomania (Luther Bell) a form of cerebral hyperæmia is observed which in its intensity approximates inflammatory congestion. The surface of the brain appears marbled and mottled; blood seems to exude from the gyri after the pia is removed; the cortical lamination is invisible, owing to the hyperæmic discoloration of the gray substance; and the parenchymatous elements themselves appear to be in a state of cloudy swelling. In one case I have observed transudation of a hyaline proteinaceous substance and an exudation of fibrin around the larger arterioles. In some cases of typhus fever a less intense but similar congestive hyperæmia is found. The hyperæmias of paretic dementia, of acute delirium, and of typhus fever agree in this one feature: that all districts of the brain, from the cortex and white substance of the cerebral hemispheres to the medulla oblongata, are involved nearly to the same degree. In the hyperæmia of simple meningitis of the convexity it is chiefly confined to the pia mater and the most superficial cortical strata.

Congestion of the brain from stagnation of the venous return circulation should not be confounded with active hyperæmia. With this condition, which may be due to thrombosis of the sinuses, morbid growths near the jugular foramen or in the neck around the internal jugular veins, or, finally, to certain cardiac and pulmonary disorders, there is rather a lesser than a greater amount of blood sent to the brain; and it is not infrequently found that while the surface of the brain appears congested, owing to the prominence of the cerebral veins, the deeper parts are quite anæmic; and if the injection be general, it will be found that the blood, whether in arteries or veins, has the venous character. An excellent example of this form of congestion is afforded by persons dying in the status epilepticus. In their brains the venous channels stand out, filled to their extreme capacity with blood almost black in color; and in prepared sections, particularly such as are taken from the pons and medulla oblongata, a beautiful natural injection of the vessels is found. But that rosy color which is so characteristic of active hyperæmia is absent, the tissues appearing purplish, bluish, or chocolate-colored.

SYMPTOMATOLOGY.—There are few symptoms attributable to the nervous system which have not been enumerated among the characteristics or the occasional manifestations of cerebral hyperæmia. Thus, Hammond not only follows Andral in enumerating apoplectic, convulsive, comatose, and maniacal symptoms as acute manifestations of active cerebral congestion, but assures us that aphasia may occur under the same circumstances. In the course of his work on the subject, "an absolute want of power to get correct ideas of even simple matters," confusion of ideas, weakening of the judgment, vacillation of purpose, diminished logical power, illu-

sions and hallucinations of every sense, delusions, morbid apprehension of impending evil, imperative, suicidal, and other impulses, suspicion, hypochondriasis, furious delirium, and the use of profane and obscene language, are enumerated among the characteristic or prominent symptoms of various forms and cases of cerebral hyperæmia.¹ Not one but several of the recognized forms of insanity have yielded a fair quota of their symptoms to this long array. Among somatic signs he in like manner names neuralgic pains, numbness, spasms, paralysis, false impotence, hyperæmia of the tympanum, choked disc, abolition or perversion of the sense of smell, taste, and sight, fibrillary or fascicular twitches, various states of the urinary excretions, diplopia, and monoplegias. It is here equally evident that the initial symptoms of a considerable number of organic and clearly defined affections have been included. It is on account of the confusion engendered by this wide interpretation of the meaning of the term congestion of the brain that I have determined to limit the term as previously indicated, and to consider only the active form here.

A feeling of head-pressure, associated with a more or less severe dull pain, aggravated by mental exertion, by stooping down, by straining at stool, or when out of breath, and accompanied by a subjective sense of mental dulness, is the most constant feature of the ordinary cases. There is usually a vertiginous sensation, and an irritability of the eye and ear not unlike that described in the article on Cerebral Anæmia. Sleep is at first disturbed by vivid and sometimes frightful dreams; later, it becomes interrupted, and ultimately complete insomnia may develop. The action of the heart is accelerated and exaggerated in some cases; in that event increased pulsation of the carotids, flushing of the face, injection of the conjunctiva, and a subjective sense of heat in the head and face are experienced. Hammond, in accord with Hasse and Krishaber, believes that febrile symptoms may develop under these circumstances; most authorities, however, deny this for the uncomplicated form. I have never found an objective rise of the general temperature.

Such a condition as that described is usually slowly produced, several weeks, or even months, being occupied in its development. At first the unpleasant symptoms occur only at certain hours of the day, with temporary exacerbations and remissions. It may be arrested with comparative ease at any time; if neglected, the mental faculties become affected, not in the grave sense in which Hammond and the older authors describe it, so as to carry the patient into actual dementia or delusional insanity, but rather in the way of diminished working-power. It is more difficult to fix attention, to recollect words, names, and figures, or to keep up a protracted mental effort, than in health, but the formal judgment does not suffer. I have known patients to be in this condition for many months, and several for more than one year, without any grave deterioration. It is true that in the prodromal periods of some forms of insanity, such as acute mania, there is a condition very similar to that of these patients;

¹ *A Treatise on the Diseases of the Nervous System*, 7th ed., pp. 1-53. The natural inference following a perusal of this chapter, as well as the monographs to which their author refers, is that he has gathered together all states in which cerebral hyperæmia was an associated factor, as well as those in which he appears to assume its existence on theoretical grounds, and designated them as cerebral congestion. In some instances he uses the terms hypochondria and cerebral hyperæmia interchangeably (p. 50, *loc. cit.*).

and this has led to regarding mania as a possible phase of cerebral hyperæmia. But the very fact that, typically, mania is preceded by such a stage—which is always of brief duration—that maniacal excitement is a constant and unavoidable consequence upon it, while, as far as known, the condition here described may last for years without leading to a true psychosis, should prevent one regarding the two conditions as identical, however similar they may be for the time being.

In sufferers from cerebral hyperæmia who pass into the chronic state of this disorder the disturbance of sleep and of the digestive organs becomes very prominent, and continually reinforces the acting causes of the disorder. In a large number of cases the head-sensations become more or less localized; that is, while the general feeling of pressure or dull ache may continue, a special area, which can be covered by the palm of one hand, either in the middle part or to one side—usually the left—of that part of the vertex, is the seat of a more severe pain, complained of as a hot pressure. The patients frequently claim that the temperature is higher at this spot, and, contrary to what might be anticipated on a priori grounds, the statement will be confirmed, not alone by the coarse method of using the hand, but by the surface thermometer. The locality where this occasional rise of temperature and the more common sense of pressure are experienced corresponds to that part of the longitudinal sinus where the largest cerebral veins enter. It is a noteworthy fact that nearly all the important adunctories of this sinus empty into it within the short space of two inches at this point.

Not all sufferers from cerebral hyperæmia give a history of a gradual development of their symptoms. A few date their trouble from some single intellectual, physical, or emotional strain. In one case, complicated by marked evidences of cerebro-spinal exhaustion, the patient, a lady, had during an illness of her husband, being deserted by her servants, and the water-supply having been cut off, carried all the water required for the invalid and domestic as well as sanitary purposes up three flights of stairs for two unusually hot days in July. In two others, strikingly similar in many details of their cases, both being cornet-players, both attributing their illness to an extra call upon their instrument, it was brought on in the older patient within a few hours after playing on a hot day at the State Camp at Peekskill, and in the second at Narragansett Pier as he left the sultry concert-room and became exposed to a draught. In both these cases, as in a large number since examined, some stomach trouble could be positively determined to have antedated these symptoms. I mention this because it is only in such cases that I have found the nausea or vomiting which some writers regard as an occasional occurrence of, and due to, the lighter form of cerebral hyperæmia.

There are no ophthalmoscopic evidences of cerebral hyperæmia of this form. I have never found the optic disc presenting variations in tint beyond those found within normal limits, except in a case of saturnine encephalopathy with predominant signs of cerebral congestion. I believe that the statement of Hammond¹ as to the existence of choked disc in cerebral hyperæmia is generally regarded as due to the interpretation of organic diseases as congestive states. It is not confirmed by authorities.

I have never found the tympanic membrane hyperæmic independently

¹ *Loc. cit.*, p. 41, lines 29–36.

of ear disease, even when tinnitus was marked. It is claimed to exist by Hammond, and he adduces as analogous the observation of Roosa that quinine produces an injection around the handle of the malleus.¹

The congestive states which follow traumatism and insolation are properly considered in connection with the traumatic neuroses and certain forms of insanity. But there are some milder cases in which the symptoms remain within such compass as is comprised in this section. The patient, after a fall or a blow on the head, suffers from insomnia, has a sensation of fulness and ache in the head, complains of a pulsating feeling in the occipital region and an inability to concentrate his thoughts on subjects which previously were parts of his routine. Under appropriate treatment recovery ensues, but there remains behind an intolerance of alcoholic beverages, and at times the patient experiences momentary fits of abstraction, which may be regarded as mild analogies of the more serious episodes of the full-blown traumatic neurosis. Thus, he may be walking along the street and suddenly lose his train of thought for an instant, to regain it on observing that he has inadvertently made a misstep. Or in the midst of an address a previously fluent orator in attempting to find a certain by-law in the rules of a society is unable to recollect which he was in search of, and is compelled to take his seat with a rambling apology. But for the fact that similar sequelæ are noted in cerebral hyperæmia from other causes, it would be questionable whether it be proper to attribute them to the congestive element engendered by the traumatic influence. They are usually noted when the hyperæmic phenomena proper have become latent or disappear, and, with other symptoms customarily treated of as mere results of circulatory trouble, may be regarded as signs of neural exhaustion or inadequacy rather than of insufficient ensanguination.

A more serious form of cerebral hyperæmia occurs in females in conjunction with the climacteric period, and in both sexes in consequences of the suppression of any habitual discharge in advanced, and exceptionally in middle and juvenile, life. The advent of the symptoms is rapid, a few hours or days sufficing for the development of the attack. The face is flushed, the carotids throb violently, the general cutaneous surface is congested, and the patient is incoherently talkative. The one side, usually the right, is heavy and tremulous, the fingers are devoid of their usual skill, and the speech is more or less thick. The sleep is disturbed or replaced by a stuporous condition, whose similitude to an apoplectic seizure is sometimes heightened by stertorous breathing. After one or several days the patient emerges from this condition by degrees or suddenly with complete *restitutio ad integrum*. But the attack may recur, and ultimately it is noted in the event of repeated attacks that the return to the normal state is slower and less complete: the disorder then undergoes a transition into the congestive type of paretic dementia described in another portion of this volume.

DIFFERENTIAL DIAGNOSIS.—In some of its clinical aspects cerebral hyperæmia closely resembles cerebral anæmia. This is not surprising

¹ It certainly is not necessary to look to the injection of the tympanum as an explanation for the tinnitus of cerebral hyperæmia, based on such an analogy. The tinnitus of cinchonism is more central in location, being producible in persons who have pathological or no tympanic membranes, just as the tinnitus of cerebral hyperæmia occurs indifferently under like circumstances.

when we bear in mind that both constitute nutritive disturbances of the same organ, and that, notwithstanding the apparent difference in the surface injection of an anæmic and a hyperæmic brain, the state of affairs in the ultimate capillary districts may be much more alike than might be anticipated on theoretical grounds. In congestion we have wider vessels, and perhaps, though not necessarily, a better quality of blood; but at the same time the intracranial pressure may be such that the venous emunctories can labor but slowly: the result will be that although there is more blood in the brain, the lessened rate of flow places the nerve-elements under nearly the same nutritive disadvantage that they are placed under with the narrower and vitiated but more rapid blood-column of ordinary anæmia.¹ It is particularly the symptoms dependent on those nerve-centres and tracts which are, so to speak, dynamically sensitive, which resemble each other so much that an intrinsic difference—both being placed side by side—is not always determinable. This is true of the aural and optic symptoms. Tinnitus, photophobia, scotomata, and blurring or darkening of the visual field occur in both, and in about the same varieties. In my experience the acuteness of hearing is more apt to be interfered with by the subjective sounds with hyperæmia than with anæmic tinnitus. The scotomata of hyperæmia are more distinct and coarser than those of anæmia; darkening of the visual field is more apt to occur with sudden rising in anæmia, while in hyperæmia it is provoked by coughing, straining at stool, or other cause operating directly or indirectly on the return circulation. It may be stated, as a general rule, that if any of these symptoms are aggravated on lying down or stooping, they are due to hyperæmia; while if the same procedures are resorted to in anæmia, amelioration ensues. But in many chronic cases these symptoms seem to continue as indications of a permanently altered activity of the nerve-elements themselves; that is, as a sort of pathological habit. In that case the position test may not be decisive. In one respect there is a decided difference between the anæmic and hyperæmic forms; there is never amaurosis in the latter, while it is approached, and occasionally fully developed, in the former. Much more importance attaches to the differentiation of tinnitus due to nutritive brain disorders and that due to aural disease. As a rule, the tinnitus from cerebral hyperæmia is symmetrical; if unilateral, it is of short duration. The procedure of Valsalva² aggravates the tinnitus of hyperæmia, and relieves that which is due to the commoner forms of ear disease; the former is aggravated and the latter relieved by noise.

In the table on p. 671 I have attempted to formulate the principal differential relations of the protracted forms of cerebral anæmia and hyperæmia.

There are a number of so-called functional nervous states which, aside from the fact that they are unwarrantably confounded with cerebral congestion, do not require mention in a differential relation. Such are the

¹ It is also admitted that the blood stagnating in the larger veins and accumulating in the arteries, the limits of compressibility of the other cerebral contents being passed, the capillaries will suffer, so that with injected and turgescient arterioles and venules there may be capillary anæmia.

² I would caution against Politzer's method in cases of ear disease coexisting with cerebral congestion. In a patient now under my treatment each session at the aurist's was followed by a distinct exacerbation of the cerebral symptoms.

| Symptomatic State. | In Cerebral Anæmia. | In Cerebral Hyperæmia. |
|---|---|--|
| Pupils | Usually dilated and mobile. | Usually small or medium. |
| Respiration | Often interrupted by sighing or by a deep breath, even when at rest. | Normal. |
| Headache | Either sharp and agonizing, and then in a limited area, or a general dull ache, intensified in the temples and over or behind the eyes. | If localized, accompanied by a subjective and objective (always?) feeling of heat; if general, is compared to a bursting or steady pressure. |
| Activity | There is lassitude. | There is indisposition to exertion, yet patient is restless. |
| Temperament | Lethargic, with exceptions. | Choleric, with exceptions. |
| Intellect | Inability to exert. | Rather confusion than inability of. |
| Sleep | Insomnia, interrupted by trance-like conditions, in which the patient is comparatively comfortable. Dreams often pleasant. | Insomnia, with great restlessness, variegated by unpleasant and confused dreams. |
| Influence of upright position of body. | Aggravates all the symptoms. | Either without influence or beneficial. |
| Influence of recumbent position of body and dependent position of head. | Amelioration. | Aggravation. |
| Influence of acts involving deep inspiration, such as blowing, straining at stool, sneezing, etc. | If any, a sharp headache may ensue, but the other symptoms are not aggravated. | Aggravated. |

masturbatory neurosis, certain hysterical states, and the asthenia resulting from nervous shock and overwork. These states have found a provisional resting-place under the comprehensive and non-committing title of neurasthenia or nervous exhaustion—a term which includes conditions fully recognized by Robert Whytt and Isenflamm in the last century.

TREATMENT.—Ergot of rye with its preparations may be regarded as the cardinal drug in cerebral hyperæmia. There are few drugs in the domain of neurological therapeutics which are so directly antithetical to the pathological state as this one. There is scarcely a case of cerebral hyperæmia that is brought to the physician's attention but may be regarded as being in part due to an over-distension of the cerebral vascular tubes. This is directly overcome by ergot, and the quantity which such patients will sometimes bear without showing signs of ergotism is something remarkable, in notable contrast with the subjects of cerebral anæmia, who are usually very sensitive to it. About three grains of Bonjean's ergotin may be regarded as a safe trial-dose for an adult, and unless a distinct effect is produced within two or three days this dose may be raised to six grains twice or three times within twenty-four hours. It is not advisable to combine strychnia with the ergotin, as is often done; the effect of that alkaloid is to increase the psychical and sensorial irritability of the patient. Chloral hydrate or bromide, or both in combination, is as useful an adjuvant here as it would be hurtful in cerebral anæmia.

It is not usually necessary to employ special hypnotics in cerebral congestion. The same drug whose beneficial effect is so potently marked during the daytime that tinnitus, cerebral pressure, and subjective drowsiness will disappear before it, if not as rapidly, more enduringly, than the symptoms of cerebral anæmia disappear before nitrate of amyl, will also overcome the insomnia in the majority of cases. Where it fails, warm pediluvia or sitz-baths will prove more efficient than the majority of hypnotics. Their use, at all events, involves no hurtful effect on a—possible already—disordered stomach, and their certainty of action is

much more even. Their temperature should be about 40–42° Centigrade, and the immersion continue from fifteen to twenty-five minutes.¹

In those cases where the subject sensations accompanying hyperæmia, active or passive, are intensified in the posterior segment of the head or the nuchal region, leeches at the mastoid process, or cupping, wet or dry according to the severity of the symptoms, will often give immediate relief. Burning with the actual cautery, or, what is equivalent and a much neater application, the heated glass rod, has an equally happy effect in that class of cases where throbbing and pain are intensified low down. It should be done as near the spot indicated by the patient's complaints as possible.²

The diet of patients who are suffering from or subject to cerebral hyperæmia should not be stimulating nor difficult of digestion. It is much more important to avoid distension or overstrain of the stomach than to reduce the nutritive value of the food in the majority of cases, for true plethora is much less common than is supposed. The bowels should be so regulated that the patient have at least one, and that an easy, movement a day. The saline cathartics, particularly the Carlsbad salt, are to be used to effect this if necessary. The clothing around the neck should be free and not compress the parts.

In those severe forms of cerebral congestion attending the climacteric period, or occurring in consequence of the suppression of discharges, and similar causes, the symptoms are often so alarming as to render energetic measures, such as bleeding, immediately necessary. This may be affected by applying leeches to the nose, the temples, or by bleeding at the arm. If due to the suppression of hemorrhoidal discharges or menstruation, the leeches should be applied to the anus and hot sitz-baths taken. In the milder forms a pill composed of aloes, podophyllin, and ox-gall, recommended by Schroeder van der Kolk, will be found effective.

Cerebral Anæmia.

The oft-confirmed observation of Treviranus, that the brain is paler in the sleeping than in the waking state, supplemented as it has been by more elaborate observations, which show that the difference between the intracranial blood-amounts, as estimated in these opposite states, is equivalent to one-twenty-fourth part of the total blood-amount of the body, has been made the basis of much dazzling theory and premature speculation. Hyperæmia of the central nervous apparatus or of certain of its provinces becomes regarded as synonymous with over-activity, and anæmia, general or provincial, as the expression of the opposite functional state. Elaborate directions may be found, even in recent treatises on the subject, how to diagnose, not alone hyperæmia and anæmia of the brain

¹ A number of experiments, the most recent of which were by Musso and Bergesio (*Rivista sperimentale di Freniatria e di Medicina legale*, 1885, xi. p. 124), have shown that in such baths the cerebral pulsations become less excursive and that the volume of the brain decreases. The same applies to general warm baths.

² In a case of gliomatous hypertrophy of the pons oblongata transition marked by the development of numerous tortuous and enlarged blood-vessels the episodes of the disease were found to be of the congestive type, and yielded to no other treatment than that with the cautery.

and spinal cord, but also of special lobes of the former and particular columns of the latter. These directions are in most instances based on assumptions which are not supported by direct or tangible evidence, and the consequence is that they have failed to stand the tests of experience, where this gauge is applicable, and necessarily failed to advance in any way either our theoretical or practical knowledge of those states of the brain mechanism which are due to alterations in its nutrition.

Much of the unsatisfactory state of our knowledge on this head is due to the grouping together of the physiological anæmia of sleep and the pathological anæmia with which the physician has to deal. The anæmia of the brain in a sleeping person is probably a secondary factor; it ensues after the person falls asleep, the first step in the latter process being probably an altered dynamic state of the brain which lessens the requirements of that organ for blood. This can be readily demonstrated in the case of infants whose anterior fontanelle has not yet closed. In deep sleep the fontanelle is deeply sunken in, but this sinking in does not occur simultaneously with the child's falling asleep, but shortly thereafter. On the other hand, the fontanelle does not rise simultaneously with the child's awakening, unless it cry, which adds a disturbing factor. There are a number of other facts which show that while a comparison between the sleeping state and cerebral anæmia may be made for the purposes of theoretical discussion, yet there are many important points in which they are at variance. To illustrate this I need but refer to the fact that in deep sleep the pupils are in a state of immobility and pinhole contraction,¹ while in chronic cerebral anæmia of young persons a dilated and mobile pupil is the commoner condition. In acutely-produced cerebral anæmia an initial contraction has been noted, but it is not then persistent.

One of the main reasons of our imperfect knowledge of the nutritive disorders of the brain is the unsatisfactory state of their post-mortem evidence. Little has been learned in this field, except in those extreme cases where the suddenness and intensity of the circulatory catastrophe were sufficient to prove fatal. Even where all observations made during life justify us in supposing that the amount of blood sent to the brain is small, that the velocity of its current is reduced, and its quantity poor, the autopsy may reveal conditions apparently conflicting with the supposition based on ante-mortem observations. This is amply illustrated by the experience of alienists who have studied the relation between nutritive states of the brain and certain forms of insanity. It is generally held that in so far as the antithetical forms of mental disorder known as anæmia and melancholia can be connected with nutritive disorders, the former is indicative of hyperæmia and the latter of anæmia. A number of facts can be adduced in support of this view, particularly as regards the latter condition. It is found, however, in some examinations made of the brains of patients dying melancholic that the brain is apparently hyperæmic; the length of time elapsing before an autopsy is made, the form of somatic disease with which the patient dies, the position of the

¹ Inability to counterfeit this feature is one of the most reliable tests of simulation, and served to convince me that in the well-known case of a colored cadet, who was tried by a court-martial on charges involving simulation, the latter was proven. There are persons who can voluntarily contract the pupils, but as they are compelled to innervate all the muscles supplied by the third pair, in so doing they are compelled to converge the optic axes—an act which does not take place in sleep.

body after death,—all these may play a part in the production of cerebral injections which do not correctly indicate the condition of the brain as it existed prior to the moribund period, and when the symptoms of supposed anæmia or hyperæmia could be satisfactorily differentiated.

ETIOLOGY.—The best studied form of cerebral anæmia is that ensuing after extensive hemorrhages or from compression and ligature of either of the common carotid arteries.¹ In the latter case symptoms are produced which are in harmony with the doctrine of localization, and permit us to form a conception of the mode in which a diminution of the cerebral blood-supply influences the functions of the brain. The chief symptoms are noted on the side of the body opposite to that on which the common carotid artery is tied. Thus if the left artery be tied, there is at first felt a tingling or pricking feeling on the right half of the body; this is followed by a warm, sometimes a cold, and ultimately by a numb, feeling. This sensory disturbance may become of what might be called the capsular type—that is, a complete hemianæsthesia; but at first it is distinctly like that which is found with cortical and subcortical disease, being limited to the muscular sense and the intelligent contact-perceptions of objects, the æsthesiometer showing but little or no impairment of the cutaneous space-sense. With the loss of muscular sense the movements become heavy, and later true paresis may appear with perhaps total anæsthesia. Aphasia is sometimes noted in such cases, and, in obedience to the predominant location of the speech-faculty in the left side of the brain, is rarely if ever found² when the right common carotid artery is the one ligated.

In this series of symptomatic sequelæ it is seen that the functional manifestations of the highest centres are the first to be involved, and this establishes that of all parts of the cerebrum the cortex and subcortical tracts are the more vulnerable to the influence of a deficient blood-supply.³ As we shall see, it is precisely to the insufficient nutrition of these parts that the more important symptoms of the cerebral anæmia of ordinary practice are attributable.

¹ As the conditions of the cerebral circulation resulting from surgical and other rare causes are not apt to be brought to the physician's attention separately from conditions of more immediate importance, their symptoms are discussed in the etiological portion of this section in order to avoid complicating the semeiological picture of cerebral anæmia of every-day experience. For similar reasons the anomalies of the cerebral circulation of an embolic and thrombotic nature, and those associated with eclampsia and epilepsy, are not mentioned in this connection, as their full discussion properly belongs to other portions of this work.

² I am unaware of the record of any case where aphasia occurred with ligature of the right common carotid artery. There is a singular observation by Hagen-Torn of permanent paralysis of the right hypoglossal nerve after such an operation, but the report to which I have access does not state whether this may not have been due to some peripheral involvement of that nerve.

³ To this there is an apparent exception: when blindness occurs in consequence of ligature of one carotid artery, it is monocular and limited to the side of the ligation. The visual disturbance of cortical and subcortical disease is bilateral, being of the character known as hemianopsic. The blindness due to tying of the carotid is, however, not due to cerebral, but to retinal, anæmia, and its monocular character does not therefore invalidate the observation in the text. Litten and Hirschberg (*Berliner klinische Wochenschrift*, 1885, No. 20) found complete bilateral amaurosis in a chlorotic girl of fifteen, and on ophthalmoscopic examination the peripheral origin of the blindness was conclusively proven by the existence of an exquisite choked disc. Both the morbid ophthalmoscopic appearance and the amaurosis disappeared under tonic regimen. It is well to recollect that choked disc may occur in chlorosis, and thus be perhaps erroneously attributed to a coexisting hysteria, as was done in some cases at least by Rosenthal in his textbook.

With bilateral ligature¹ of the primary carotids—and this applies in the main to cerebral anæmia from profuse hemorrhages or sudden changes in the blood-pressure, such as occur in enteric affections, ruptures of aneurisms, in obstetric practice, and after brusque tapping for ascites—the same phenomena noted with unilateral compression are observed on both sides of the body, and usually in slighter intensity. In addition, there is a profound and characteristic disturbance of respiration; a cold sweat breaks out; the senses of sight and hearing become greatly impaired or perverted; the mind becomes clouded, consciousness blurred; complete syncope may ensue, and pass to a fatal termination. In other cases vertigo preponderates or vomiting, and finally convulsions appear. It would seem that the respiratory centre exceeds even the cortex in susceptibility to the evil influence of anæmia. It differs from them in two features: firstly, it appears to require bilateral involvement of the brain for its production; secondly, although the respiratory disturbance precedes that of the higher cerebral functions, it does not become as intense, for at a time when the intellectual functions are abolished, as in anæmic coma and syncope, the respiratory function, however disturbed, is in most cases sufficiently well carried on to bear the organism safely through the crisis. The disturbance is marked by the following characters: The respiration is at first deep and sighing, perhaps frequent; it later becomes slow, and is associated with a subjective sense of oppression; the patient feels as if he could not fill his lungs properly; there is an unsatisfied sensation, as if a deeper breath should be taken, and when, in obedience to this subjective need, a full deep breath is taken, the patient feels as if he had stopped short of completing the act, and remains as unsatisfied as before.² Yawning and moaning are often accompaniments of this symptom.³ As we shall see, these signs are often among the chief sources of complaint in the less grave forms of anæmia of every-day experience. In the serious condition before us the Cheyne-Stokes phenomena may follow.

Anæmia of the brain may develop at any period of life, not excluding the intra-uterine period. Kundrat and Binswanger regard the deformity of the brain known as porencephaly as the result of an anæmic (non-embolic) necrosis of brain-substance, developed either in the fetal or the infant.

¹ I exclude the observations of Flemming, Hammond, and Corning on carotid compression by external pressure, owing to the difficulty of determining whether or no, and what, other important structures are compressed at the same time.

² The occurrence of this functional respiratory trouble is a feature of toxic as well as of anæmic irritation of the respiratory centre; it is accordingly found in cases of profound alcoholic poisoning.

³ It is somewhat difficult to understand why in cases of anæmia induced in both carotid districts the symptoms of anæmia should be marked in the functions of that part of the brain-axis which through the basilar trunk derives its blood from the vertebral arteries. Here the blood-current must necessarily be increased. That the disturbance of breathing, the yawning, and the sighing belong to the group of irritative symptoms due to anæmia is in harmony with the general physiological law which is illustrated in the initial contraction of the pupil, which is found in experimental cerebral anæmia. Observations on anæmia of the brain-axis are too few, and, so far as noted, have been so rapidly fatal that it is not possible to derive from them any facts bearing on the physiological reactions of the respiratory centre to high-graded anæmia. One of the curiosities of medicine appertaining to this subject is the observation recorded in *Virchow's Archiv*, lxi. p. 93, of the case of a man who had fractured the base of the skull in its posterior fossa, and, the basilar artery becoming caught and pinched in the crack, death occurred rapidly with all the signs of cerebral anæmia, verified by the post-mortem appearances.

tile period. The occasional symmetry of the deformity is in favor of this view. That there are other conditions of cerebral malnutrition,¹ masking themselves in defective development and imperfect isolation of the conducting tracts, and that the consequent differing rate of maturation of these tracts has some relation to the absence or presence of a predisposition to chorea and other disturbances of nervous equilibrium so common at this period of life, I regard as at least probable. But it is at the period of puberty that we encounter the most important discrepancies between the requirements of brain-nutrition and the furnished blood-supply. The disposition to uncomplicated cerebral anæmia is greatest at this period of life and in the female sex. Beneke² has shown that as the human being grows the arteries, which in children are very large in proportion to the length of the body, get to be relatively smaller and smaller toward the period of puberty—that after this period they widen to again attain a large circumference at old age. There is thus added to the other and more obscure factors which may determine general anæmia at puberty a diminished calibre of the arteries in both sexes. To some extent the disadvantageous influence of (relatively) narrow vascular channels may be overcome by increased cardiac action, and the almost sudden increase in size of the heart about this period is probably the result of the demand made upon its compensatory power. But, as we learn from the same observer that the female heart remains relatively as well as absolutely smaller than that of the male, we can understand why the female should be less able to overcome the pubescent disposition to cerebral (and general) anæmia than the male. Menstruation, which in a certain proportion of girls scarcely maintains the semblance of a physiological process, acting rather as a drain than a functional discharge, is added to the anæmia-producing factors. It is among those who marry in the ensuing condition, who bring forth child after child in rapid succession, perhaps, in addition, flooding considerably at each confinement, that we find the classical symptoms of chronic cerebral anæmia developed.

In the male sex the period of adolescence has not the same profound influence in producing cerebral anæmia that it has in females. To some extent, however, habitual self-abuse and early sexual excess of the former produce results similar to those occurring in consequence of perverted physiological processes in the latter. Many of the symptoms presented by the inveterate masturbator are probably due to cerebral anæmia; there

¹ I have found in three children under fourteen months of age, who died with symptoms not unlike those of slowly-developed tubercular meningitis, including convulsions, strabismus, temperature disturbance (slight), and terminal coma, without nuchal contraction or pupillary anomalies, a remarkably anæmic brain. The sulci gaped; there were few or no puncta vasculosa; the cortex extremely pale, and the white substance almost bluish-white. On attempting to harden the brain of the youngest of these children, using every precaution and a sufficient number of sets of hardening fluids, including the chromic salts and alcohol, I found that small cavities formed in the cortex, varying from the scarcely visible to two-thirds of a millimeter in diameter. Their existence were demonstrable the day after the death and almost immediate autopsy performed in this case. There had been no antecedent disease in any one of these cases; the children had been lethargic, inactive, and the oldest had made no attempt to walk or talk. There was no morphological or quantitative defect in cerebral or cranial development, and microscopic examination showed that the cavities were not perivascular. In all these cases the patients belonged to the tenement-house population.

² An excellent abstract of Beneke's original monograph, by N. A. P. Bowditch, will be found in volume i. *Transactions of the Massachusetts Medico-Legal Society*.

are, however, in his case and in that of the early libertine certain vaso-motor complications frequently present which render the clinical picture a mixed one.¹ In addition, abuse of the sexual apparatus has a direct—probably dynamic and impalpable—exhausting effect on the central nervous apparatus.

In the vast majority of cases anæmia of the brain is but a part of general anæmia, and all conditions which tend to impoverish the character of the blood and to reduce the rapidity of movement and fulness of the cerebral blood-column are apt to be associated with signs of cerebral malnutrition. As early an observer as Addison noticed the wandering of the mind in pernicious anæmia, in which disorder anæmia and wasting of the brain have been found post-mortem. In two cases of extreme chlorosis I heard the sound known as the cephalic soufflé with great distinctness;² this sound, when the other morbid conditions that may lead to it can be excluded, indicates a high degree of anæmia. Both patients were somnolent and subject to fainting-spells. In leucocythæmia a rambling delirium is not infrequently noted toward the close of the patient's life, and the habitual sadness and depression of many leukæmic patients is due, as are also certain phases of melancholia, to cerebral malnutrition. In some stages of most, and in all stages of some, forms of renal disease the conditions of cerebral anæmia are present; and it is reasonable to attribute to it some share in the production of the head symptoms of Bright's disease; but here, as in cases of cardiac disease, symptoms due to other influences—uræmia in the former, and insufficient oxygenation of the blood in the latter instance—obscure or conceal those due to the anæmia strictly speaking.

All exhausting diseases, many febrile affections, notably typhoid, starvation from any cause, and exhausting discharges, may produce cerebral anæmia. Under the latter head belong the diarrhœal affections of childhood, which not infrequently lead to an aggravated form of anæmia of the brain known as hydrocephaloid. In addition to the provoking causes of cerebral anæmia there are certain accessory ones: prominent among these is the upright position and sudden rising. The reason of this influence is self-evident, as is also the fact that it is most apt to manifest

¹ Kiernan of Chicago has described peculiar trophic disturbances—dermato-neuroses, color-changes of the hair, etc.—in a case of masturbatory mental trouble associated with marked anæmia. The patient whenever he flushed up heard a noise as of a pistol snapped near the mastoid region. In the case of a young man of eighteen who—the pampered son of wealthy parents—became his own master at fifteen, and had at that age indulged in sexual orgies which were continued to an almost incredible extent, it was found that he gradually lost his memory, and on one occasion had a violent epileptiform attack. During his convalescence from the stuporous state which followed it was noted that the patient was quite bright in the morning, but that after he had been up a while he relapsed into a state of apathy, with amnesia, which, decreasing in intensity from week to week, was eventually only noted toward evening, and finally disappeared, the case terminating in complete recovery.

² When an anæmic murmur at the base of the heart coexists with the cephalic soufflé, the latter may be regarded as an evidence of anæmia; but where the former is absent—that is, when the cephalic soufflé is an isolated, independent symptom—there is reason to suspect the existence of a tumor or some other cause of compression of the carotid artery at or after its entry into the cranium. In one of the cases referred to in the text, pressing on one or the other carotid produced numbness and tingling in the opposite arm, leg, and cheek. Similar observations were made by Tripiér (*Revue de Médecine*, March, 1881), who strenuously maintains the existence of the cephalic soufflé in the adult, against Henry Roger, and in consonance with the observations of Fisher and Whitney. In the last-mentioned case of mine the sound could be heard a distance from the head.

itself in cases of cardiac enfeeblement. Many a convalescent from an exhausting fever or other disease has on rising from bed fainted; some have fallen dead from cerebral anæmia already existing, but fatally intensified by this sudden change of position. A number of cases are on record by Abercrombie, Forbes Winslow, J. G. Kiernan, and others where persons manifested the symptoms of cerebral anæmia only when in the upright position and even in lying on one side or the other; these are, however, far rarer than is claimed by some later writers.

The purest form of acute cerebral anæmia, aside from that produced by surgical interference with the cerebral circulation or extensive hemorrhages, is that induced by mental influences, such as fright, a disagreeable odor, or a disgusting or harrowing spectacle. Some persons, not suffering from general anæmia or any diseased condition thus far mentioned, on experiencing the emotional influences named will be observed to turn pale, to breathe heavily, and either sink into a chair or fall on the floor partly or entirely unconscious. They are then suffering from a spasm of the cerebral arteries resulting in acute and high-graded cerebral anæmia or syncope. This condition is marked by some of the symptoms previously mentioned as occurring with bilateral ligature of the carotids: thus, the feeling of oppression on the chest, vertigo, heaviness of the limbs, nausea, and vomiting are characteristic; a cold sweat breaks out on the forehead; the visual field becomes darkened; and hearing is rendered difficult by the tinnitus.¹ The pulse is small and of low tension, but regular.

As a rule, the subjects of simple syncope recover, the horizontal position, which is assumed perforce in most cases, carrying with it the chief remedial influence—namely, the facilitating of the access of a fuller blood-supply to the brain. While, as stated, the tendency to syncope may exist in healthy non-anæmic individuals, it is far more common with those who suffer either from chronic cerebral anæmia or from many of its predisposing conditions. The arterial spasm which causes syncope is an exaggeration of what occurs within physiological limits² in all persons

¹ Most authors claim that the sense of hearing is blunted, as that of vision is. This is so in some, but certainly not in a large number of other cases. I have now under observation a girl whose physical conformation—her neck is very long and her shoulders tapering—and extreme susceptibility combine to favor the occurrence of syncope. She faints in my office whenever an examination is made, even though it be entirely verbal; and after recovering frequently lies down to answer by deputy, as experience has shown her that she is less likely to faint in this position. I have repeatedly satisfied myself from her subsequent statements that she heard what was said, while she appeared to be quite unconscious and “saw everything black or through a cloud.” It is not improbable that the impressions which most writers on the subject convey were derived from the experience of novices in fainting; these, in the alarm and anxiety of their condition, and confused by the tinnitus, might well fail to hear what the bystanders said, particularly as on many such occasions the fainting person is apt to be surrounded by a confused Babel of tongues. While the auditory nerve is as sensitive to the irritative influence of anæmia as any, and there is a case of a boy on record (Abercrombie) who could only hear well when lying down, and was deaf when he stood up, yet the conclusions of other authorities who have studied the subject would lead one to think that there are individual differences in this respect. How often does not the dying person, after feeling for the hands of a relative whom he cannot see, converse with him responsively! And how much need is there not of the humane physician to remember that the sense of hearing is the last intellectual sense to die, lest he speak unguardedly at the bedside!

² It has been experimentally determined by Istomanow (*St. Petersburg Dissertation*, 1885) in persons whose brain-surface had become partially accessible to observation through traumatic causes that pain, warmth, pleasant smells, and sweet tastes cause a

when subjected to emotional or violent external impressions of any kind.

MORBID ANATOMY.—In those severe cases of cerebral anæmia which terminate fatally the entire brain appears bloodless. Since the color of this organ under ordinary circumstances is in great part due to the vascular injection, it appears very different when this admixture is lessened or removed. Then the gray substance, instead of presenting a reddish-gray tint, is of a pale buff color in infants, and a pale gray in adults who have died of acute or intense cerebral anæmia. The white substance exhibits few or no puncta vasculosa, and there is no indication of the faint rosy tinge which even the white substance has in the normal brain. All these appearances can be imitated in the brain of an animal that is bled to death; they are also met with in those who have died of inanition, particularly in cases of melancholia attonita, the subjects of which had long refused food. Most writers state that the ventricular and subarachnoid fluids are increased in amount,¹ and that the sulci appear wider in anæmic than in normal brains. That these fluids must be increased to compensate for the diminished blood-amount is evident. But it is not unlikely that exaggerated estimates of the increase have been made; and for this reason: Since the meninges and choroid plexuses are comparatively bloodless, the cerebro-spinal fluids are more likely to present themselves free from that admixture of blood which renders the obtaining and measuring of their quantity so difficult under ordinary circumstances. The gaping of the sulci has not been verified by me either in animals that had been bled to death or in cases of cerebral anæmia in rapidly-fatal atonic and phthisical melancholia. In protracted cases of this nature I frequently found gaping of the sulci: here, from the nature of the cases, the patients dying either from self-starvation, imperfect assimilation, or wasting diseases, the occurrence of a certain amount of atrophy of the brain-substance proper could not be excluded.²

With protracted fevers accompanied by inanition—and this applies particularly to the later period of typhoid fever—a condition of cerebral anæmia is found which is of the greatest interest to the clinician. The brain as a whole is bloodless; there may or may not be apparently hyperæmic districts, but the injection is altogether on the surface; the consistency of the brain is considerably diminished, and this organ is often

contraction of the cerebral vessels and a sinking in of the brain-surface, while tickling, unpleasant odors, bitter and sour tastes, produce the reverse condition; that is, bulging of the brain-surface and increased injection of the vessels. Istomanow's results are verified by other observations, particularly by the fact that with the latter class of impressions there is an increase in the general blood-pressure, with sinking of the surface-temperature, and, as measured by Mosso's method, decrease in the volume of the extremities. While there is a general correspondence between these observations and clinical experience, there are a few unexplained discrepancies.

¹ Hammond, on the other hand (*Diseases of the Nervous System*, p. 77), has the ventricles generally empty.

² Up to within a very short time ago it would have appeared heretical to claim that any considerable amount of brain-wasting could ensue from starvation alone, as the oft-cited experiments of Chossat seemed to show that mammals, birds, reptiles, and amphibians lose in body-weight while being starved, but that the brain-weight is not disturbed to any appreciable extent. Six years ago I examined the brain of a tortoise (*Cestudo Virginica*) which had starved fully a year through ignorance of the keeper of an aquarium. The atrophy of the brain was so marked that it had undergone demonstrable changes of contour. Since then Rosenbach (*Archiv für Psychiatric*, xvi. p. 276) has demonstrated that brain-wasting and other changes do occur in starved rabbits.

distinctly œdematous. In exceptional cases the œdema is so great that softening results, the white substance becoming fluidified at the cortical limit near the base of the sulci and at the ventricular walls. This is due perhaps as much to post-mortem maceration as to pre-mortem œdema, but that the latter condition exists is shown by the condition of the brain as a whole. The loss of memory, the difficulty of correlating the past and present, the rambling, incoherent conversation, and anenergetic stupor observed in the decline of typhoid and other exhausting fevers, especially in older subjects, may be properly attributed to the injurious effects of post-febrile anæmia and anæmic œdema of the brain. Aside from fevers, œdema is apt to be associated with anæmia where venous stagnation is a complicating feature; consequently, it is not uncommon with certain uncompensated valvular lesions, emphysema, and other chronic pulmonic troubles.

Positive observations of tissue-changes from simple cerebral anæmia have not been recorded. Even in extreme cases the essential nervous structures, the ganglionic bodies, the nerve-fibres, their sheaths, and the neuroglia, appear healthy. The adventitial and pericellular spaces are sometimes enlarged, and variations in the number and distribution of the free nuclei of the neuroglia and the border bodies of the periadventitial districts have been observed by me, but not with such constancy as to justify more than this mere mention. In his researches on starvation Rosenbach found the brain œdematous and the ventricles dilated; there were also microscopical changes which indicated a profound disturbance of nutrition; the large cells of the anterior spinal horn and cerebellum had lost their transparency, being in a condition resembling cloudy swelling. The neuroglia appeared to be in a similar condition as that of nerve-cells. Singular as it may appear on first sight, the capillaries were found crowded with blood-corpuscles, and there were many evidences of diapedesis of such. This may indicate a passive accumulation due to deficient cardiac and vascular contractility. The changes, as a whole, were not unlike those found in myelitis,¹ except in so far as no actual inflammatory signs were present.

SYMPTOMS.—The clinical phenomena of acute cerebral anæmia have been in the main related in connection with the etiology of this disorder. We shall now proceed to detail those which occur with cases more likely to engage the attention of the practitioner either on account of their gravity or protracted duration.

Uncomplicated Chronic Cerebral Anæmia of Adolescents and Adults.—This condition is one of the common manifestations of general anæmia. Most anæmic persons are languid, drowsy, suffer from insomnia, tinnitus aurium, and other signs of imperfect cerebral irrigation. In some these troubles become alarmingly prominent and may approach the confines of mental derangement. This is particularly apt to occur with women who have borne and nursed a large number of children. In addition to the typical signs of cerebral anæmia, they exhibit depression, may suffer from hallucinations, and even become afflicted with lachrymose or suicidal melancholia (insanity of lactation of the somato-etiological school).

¹ Several distinguished neurologists, notably Westphal, who were present when Rosenbach presented his conclusions, were unable to recognize so profound a deviation from the normal structural conditions as he claimed (*Archiv für Psychiatrie*, xvi. p. 279).

Depression of the mental functions is the most constant symptom of cerebral anæmia, and the one which most frequently directs the physician's attention to its existence; its subjects appear mentally blunted, the apprehensive powers are diminished, and it is difficult for the patient to interest himself in anything, or when interested to keep up a mental effort—that is, his attention—any length of time. In more severe grades of the trouble the patients become somnolent in the daytime. Contrary to what those who regard sleep as essentially due to cerebral anæmia might expect, sleep is disturbed, and the patient is wakeful or suffers from vivid and frightful dreams, or even deliria. Others pass a quiet night, but are rather in a trance-like condition than a healthy sleep. Lethargic as the cerebral anemic person is on the whole, and unable as he feels himself to exert his will-power (aboulia), yet he is often irritable, perverse, and petulant in consequence of that morbid excitability which is a universal attribute of the overworked or imperfectly nourished nerve-element. The younger the patient the more likely is the condition apt to impress one as a stupor, while with older patients irritability is more prominent. In the former the obtuseness is often rapidly overcome when the patient assumes the horizontal position.

It was supposed by Abercrombie that an acute exacerbation of cerebral anæmia of this form in weakly and aged individuals might terminate in death. This condition corresponded to the so-called serous apoplexy of the old writers. With increasing accuracy in our autopsies this condition is more and more rarely recorded, although the possibility of its occurrence as a pathological rarity cannot be denied. As a rule, the chronic form of cerebral anæmia when it terminates fatally, which is exceptional, is marked by a deepening coma and gradual extinction of the vital processes, the Cheyne-Stokes phenomenon preceding this.

Patients suffering from chronic cerebral anæmia are afflicted with morbid irritability of the optic and auditory nerves. Loud sounds and bright lights are very annoying to them. Roaring, buzzing, and beating sounds in the ear are common, and scintillations, *muscæ volitantes*, and temporary darkening of the visual field—particularly noticed when the head is suddenly raised—are complained of in all cases. It is often found that the tinnitus disappears and the hearing power improves on assuming the horizontal position.

Headache of greater or less severity is found in the majority of cases: it is more severe in the rapidly-developed forms, and I have found it to be complained of in agonizing intensity by women who had risen from childbed and who had flooded considerably. As a rule, the headache, whether severe or mild, is symmetrical and verticalar, in some cases associated with an ache subjectively appearing as if it extended to the back of the orbit. It is remarkable for its constancy, and its exacerbations are often complicated with vertigo and nausea, so that it is not infrequently interpreted as a reflex evidence of gastric disorder. A stitch-like feeling, located in both temples, is often associated with it.

Occasionally sufferers from chronic cerebral anæmia experience seizures, or rather exacerbations, of their disorder which approach in character, while not equalling in degree, an attack of syncope. Whether in bed or in a chair, they then feel as if their limbs were of lead; they deem that they cannot stir hand or foot; the other symptoms related are aggra-

vated; they yawn and breathe deeply, but hear all that is said by those near them, and do not lose consciousness. They express themselves as feeling as if everything around them were about to pass away. One of my patients would frequently find that if this condition overtook her while lying on one side, that side would remain numb for some time and be the seat of a tingling sensation which disappeared on the parts being rubbed. The same was noticed when she awoke in the morning in a similar position. To what extent these features were due to the general anæmia is doubtful. As previously stated, true syncope occurs in chronic cerebral anæmia, but much less frequently in those subjects of this disorder who have reached middle life than in adolescents.

The radial pulse in cerebral anæmia does not necessarily show the anæmic character; not infrequently the general blood-pressure is increased at the onset of the acute form, and if long continued this may be followed by a decrease of the same. The pulse-character may therefore vary greatly in frequency, resistance, and fulness. In protracted cases it is soft, easily compressible, and rapid.

It is not uncommon to find indications of a slight unilateral preponderance of the signs of cerebral anæmia. In one case which terminated in recovery, and was otherwise pure, vertigo was not produced on turning from the left to the right, but it was produced to a distressing degree on turning in the opposite direction; in a second, equally typical, there was for a long time a subjective sensation of falling over toward the right side.

There appears to be much less constancy in the relationship of the deficient blood-supply to the severity of the symptoms than is usually supposed. Much depends upon the time of life at which the disorder develops: a brain that has acquired stability through education and exercise is less vulnerable to the influence of general anæmia than one that has not. The nerve-centres appear, to some extent at least, to regulate their own blood-supply; and whether it be through a change in the blood-current rapidity or some other factor neutralizing the evil effects of the intrinsically inferior quality of the blood, we must attribute to the self-regulating nutrition power of the brain the not uncommon phenomena of an active mind in an anæmic body. And where the general anæmia reaches so high a degree as to involve the brain, under such circumstances we find that irritability to sensory impressions and fretfulness are more prominent than the lethargy and indifference which characterize the juvenile chlorotic form. Although this distinction is less marked between these two classes in regard to acutely-produced anæmia, yet it is observable even there. If in a youth or girl while undergoing phlebotomy cerebral anæmia were to reach such a degree as to cause subjective sounds, they would either approach or fall into a faint; but Leuret, the distinguished cerebral anatomist, while being subjected to the same procedure, hearing a hissing sound, did not lose consciousness, but complained that some one must have upset a bottle of acid on a marble table in the same room, as he supposed he was hearing the sound of effervescence thus produced.

Much, too, appears to depend on dynamic and other thus far undiscovered intrinsic conditions of the brain-tissue itself, irrespective of the mere amount and rapidity of the blood-current. If the subject be exposed to wasting diseases, to blood-poisons, or to vicissitudes of temperature and

to physical exhaustion in addition to the causes producing cerebral malnutrition, deliria of a cortical nature are more apt to characterize the case than in simple anæmia. These are known as the deliria of inanition, and present themselves under two forms. The first has been frequently observed in sailors, travellers, and others who have undergone starvation in exposed situations, and is tinged by the psychical influences incident to such a condition. Just as the Greeley survivors at Cape Sabine, when reduced to their miserable rations of seal-skin boot-leather and shrimps, entertained each other with the enumeration of imaginary culinary luxuries, so others who have suffered in the same way declaim about gorgeous banquets in the midst of a howling wilderness, or, as occurred to a miner who lost his way in Idaho a few winters ago, experienced hallucinatory visions of houses, kitchen utensils, and persons with baskets of provisions. In others the terror of the situation leads to the development of rambling and incoherent delusions of persecution.

The second form, regarded as a variety of starvation delirium, is found in the post-febrile periods of typhoid and other exhausting fevers. In aged persons it may even develop shortly after the onset of the disease. It is usually unsystematized, of a depressive cast, and may be associated with a condition resembling melancholia agitata. In a small proportion of cases insanity of the ordinary types, but more commonly of the special kinds comprised in the group of post-febrile insanity, develops from the anæmic fever delirium as its starting-point.

The spurious hydrocephalus (hydrocephaloid, hydrencephaloid) of Marshall Hall and Abercrombie, referred to in the section on Etiology, is an important condition for the diagnostician to recognize. A child suffering from this disorder presents many symptoms which are customarily regarded as characteristic of tubercular meningitis or of chronic hydrocephalus; thus the pupils are narrow—sometimes unequal;¹ there is strabismus, and there may be even nuchal opisthotonos, while the somnolent state in which the little patient usually lies may deepen into a true coma, in which the pupils are dilated, do not react to light, nor do the eyelids close when the cornea is touched. Ominous as this state appears, it may be completely recovered from under stimulating and restorative treatment. On inquiry it is found that the symptoms above mentioned were preceded by cholera infantum or some other exhausting complaint, such as a dysentery or diarrhœa, and that the somnolent condition in which infants are often found toward the close of such complaints passed gradually into the more serious condition described.² The infants thus affected do not, however, sleep as healthy children do, but moan and cry, while apparently unconscious of their surroundings. The surface of the body is cool and pale; the pulse and respiration are normal, except in the comatose period, but the former is easily compressible. The chief points distinguishing hydrocephaloid from true hydrocephalus and other diseases associated with similar symptoms are the following: 1st, There is no rise of temperature; 2d, the pupils are equal; 3d, the fontanelle is sunken in; 4th, the pulse and respiration, with the exception stated, are natural; 5th, there is an ante-

¹ This is not admitted by most writers, but does occur exceptionally.

² It should not be forgotten, however, that very similar symptoms occur after cholera infantum, with a much graver pathological condition—namely, marantic thrombosis of the sinuses.

cedent history of an exhausting abdominal disorder; 6th, also a facial appearance characteristic of the latter.

One of the gravest and rarest forms of cerebral anæmia is one which occurs as a result of extreme general anæmia in very young infants. In a remarkable case which I have had an opportunity of studying, the abolition of certain cerebral functions reached such a degree that the opinion of a number of physicians was in favor of tubercular meningitis.¹ There was at the time of my examination complete extremity hemiplegia, and there had been conjugated deviation, restlessness in sleep, and dulness in the waking hours: all these symptoms except the hemiplegia disappeared whenever a more assimilable and nutritious food was used than the one previously employed. On one occasion there were evidences of disturbed vaso-motor innervation; on several, convulsive movements. This history, associated with ordinary evidences of general anæmia, covered a period of eighteen months, without the slightest abnormality of temperature being noted or discoverable during that period. The mucous surfaces of this child were almost colorless, certainly without any indication of the normal tinge; the mother had nursed it, and her milk had been found to possess scarcely any nutritive value. The case terminated fatally at the age of twenty months.

Partial Cerebral Anæmia.—Most writers on cerebral anæmia discuss a number of varieties of partial cerebral anæmia as distinguished from the acute and chronic general forms. Some of the conditions thus described properly appertain to the angio-spastic form of hemicrania, others to epilepsy, and the majority to circulatory disturbances dependent on arterial disease. Aside from the partial cerebral anæmia resulting from surgical causes, I am acquainted with but one evidence of limited cerebral anæmia which can be regarded as independent of the neuroses or of organic disease, and that is the scintillating scotoma. This symptom, in the only case in which I observed it, occurred in a medical student, accompanied by pallor and nausea in consequence of the disgust produced in him by the combined odors of a dissecting-room and of a neighboring varnish-factory. The totally blind area of the visual field was strictly hemianopsic in distribution and bounded by a colored zone scintillating, to use the sufferer's words, like an aurora borealis. The attack, probably protracted by his great alarm at being blind in one-half of the visual field, lasted three hours. As the cause in this case was a psychical impression and accompanied by the ordinary signs of that fainting which is not an uncommon occurrence in the dissecting-room; as, furthermore, the individual in question never had a headache except in connection with febrile affections, and then in the lightest form, and is neither neurotic himself nor has a neurotic ancestry or relatives,—I regard it as the result of a simple arterial spasm intensified in the visual field of

¹ It was stated by an experienced practitioner that death occurred with unmistakable symptoms of tubercular meningitis. Certainly, the absence of temperature disturbance at the time of the hemiplegic and other exacerbations, as well as other important features for a period exceeding a year, shows that whatever favorable soil the earlier condition may have furnished for the secondary development of such or other gross structural disease, tubercular meningitis did not exist at the time; while the absence of pupillary and optic-nerve symptoms, as well as the rapid changes from day to day or week to week under dietetic treatment, militate against the assumption of any other organic affection incident to childhood.

one hemisphere, analogous to the more general spasm of ordinary syncope.¹

DIAGNOSIS.—There is so little difficulty in recognizing the nature of those cases of acute cerebral anæmia which depend on recognizable anæmia-producing causes that it is unnecessary to point out their special diagnostic features. With regard to chronic cerebral anæmia, and its differentiation from other circulatory brain disorders, I refer to the last article. In this place it will be necessary only to point to some of the symptoms which, individually considered, are found in other disorders, and may therefore be misinterpreted. The chief of these is vertigo, which, as already stated, being associated with nausea, and even vomiting, is not infrequently confounded with stomachic vertigo, while the opposite error is also, though less frequently, fallen into. The chief differential points are—that stomachic vertigo is relieved by vomiting, and anæmic vertigo is not; that the former is rather episodic, the latter more continuous; that in the free intervals of the former, while there may be some dulness, there is not the lethargy found with anæmia; that the headache with the former is either over the eyes or occipital, and most intense after the passage of a vertiginous seizure, while anæmic headache is verticalar or general, and not subject to marked momentary changes. It is unnecessary to indicate here the positive evidences of gastric disorder which are always discoverable in persons suffering from stomachic vertigo; but it is also to be borne in mind that such disorder is frequently associated with the conditions underlying general and cerebral anæmia, particularly in the prodromal period of some pulmonary troubles.

There are a number of organic affections of the brain which are in their early periods associated with symptoms which are in a superficial way like those of cerebral anæmia. As a rule, focal or other pathognomonic signs are present which render the exclusion of a purely nutritive disorder easy; but with some tumors, as is generally admitted, these signs may be absent. It is not difficult to understand why a tumor not destructive to important brain-centres, nor growing sufficiently rapid to produce brain-pressure, yet rapidly enough to compress the blood-channels, may produce symptoms like those of simple cerebral anæmia. It is claimed that with such a tumor the symptoms are aggravated on the patient's lying down, while in simple anæmia they are ameliorated.² The latter proposition holds good as a general rule; as to the former, I have some doubts. Not even the ophthalmoscope, although of unquestionable value in ascertaining the nature of so many organic conditions of the brain and its appendages, can be absolutely relied on in this field. Until quite recently, optic neuritis, if associated with cerebral symptoms, was regarded as satisfactory proof that the latter depended on organic disease; but within the year it has been shown by Juler³ that it may occur in simple

¹ It may be remembered that Wollaston had scintillating scotomata, and that after his death a small focus of softening was found in the one visual field. Ordinarily, this disturbance is associated with hemicrania.

² The increased flow of blood to the brain in anæmia is not always momentarily remedial: if, for example, the patient stoop down, he flushes more easily than a normal person, and suffers more than the latter. The same is observed with regard to stimulants.

³ *British Medical Journal*, Jan. 30, 1886. In the case reported suppression of the catamenia is spoken of, as well as the fact that treatment was directed to the menstrual disturbance. It is not evident from the brief report at my disposal whether the suspension of the menstrual flow was symptomatic of general anæmia or of a local disturbance. Optic

cerebral anæmia, and both the latter and the associated condition of the optic nerve be recovered from.

The claim of Hammond and Vance that ordinary anæmia of the brain may be recognized through the ophthalmoscope is almost unanimously disputed by experienced ophthalmoscopists, nor is it unreservedly endorsed by any authority of weight among neurologists. That there may be color-differences to indicate anæmia is, however, not impossible; and the fact that a concentric limitation of the visual field sometimes occurs should not be forgotten. It is distinguished from that found with organic diseases by its variability through the day and in different positions of the body.

TREATMENT.—Chronic as well as acute cerebral anæmia, dependent on general anæmia, usually requires no other medicinal treatment than that rendered necessary by the general anæmic state of which it is a part. This has been discussed at length in the third volume of this work: it remains to speak of certain special precautions and procedures rendered necessary by the nervous symptoms predominating in such cases. As the insufficiently nourished brain is not capable of exertion, mental as well as physical rest is naturally indicated. And this not only for the reason that it is necessary to avoid functional exhaustion, but also because the anæmic brain when overstrained furnishes a favorable soil for the development of morbid fears, imperative impulses, and imperative conceptions. This fact does not seem to have been noticed by most writers. The mind of the anæmic person is as peculiarly sensitive to psychical influences as the anæmic visual and auditory centres are to light and sound; and in a considerable proportion of cases of this kind the origin of the morbid idea has been traced to the period of convalescence from exhausting diseases. The prominent position which masturbation occupies among the causes of cerebral anæmia perhaps explains its frequent etiological relationship to imperative conceptions and impulsive insanity.

Although the radical and rational treatment of cerebral anæmia is covered by the treatment of the general anæmia, there are certain special symptoms which call for palliative measures. Most of these, such as the vertigo, the optic and aural phenomena, improve, as stated, on assuming the horizontal position. The headache if very intense will yield to one of three drugs: nitrite of amyl, cannabis indica, or morphine. I am not able to furnish other than approximative indications for the use of remedies differing so widely in their physiological action. Where the cerebral anæmia and facial pallor are disproportionately great in relation to the general anæmia, and we have reason to suppose the existence of irritative spasm of the cerebral blood-vessels—a condition with which the cephalalgia is often of great severity—nitrite of amyl acts as wonderfully as it does in the analogous condition of syncope.¹ Where palpitations are complained of, and exist to such a degree as to produce or aggravate existing insomnia, small doses of morphine will act very well, due

neuritis has been recorded as having been present in a large number of cases with no other assignable cause than a uterine disorder. As previously stated, Hirschberg and Litten found choked disc under like circumstances.

¹ There are disturbances in the early phases of cerebral syphilis, whose exact pathological character is not yet ascertained, which so closely resemble the condition here described that without a knowledge of the syphilitic history, and misled by the frequently coexisting general anæmia, it is regarded as simple cerebral anæmia. Under such circumstances, as also with the cerebral anæmia of old age, amyl nitrite should not be employed.

precautions being taken to reduce the disturbance of the visceral functions to a minimum, and to prevent the formation of a drug habit by keeping the patient in ignorance of the nature of the remedy. When trance-like conditions and melancholic depression are in the foreground, cannabis indica with or without morphia will have the best temporary effect: it is often directly remedial to the cephalalgia. Chloral and the bromides are positively contraindicated, and untold harm is done by their routine administration in nervous headache and insomnia, irrespective of their origin. Nor are hypnotics, aside from those previously mentioned, to be recommended; the disadvantages of their administration are not counterbalanced by the advantages.¹ Frequently, in constitutional syphilis, insomnia resembling and probably identical with the insomnia of cerebral anæmia will call for special treatment. In such cases the iodides, if then being administered, should be suspended, and if the luetic manifestations urgently require active measures, they should be restricted to the use of mercury in small and frequent dosage, while the vegetable alteratives may be administered if the state of the stomach permit.

Among the measures applicable to the treatment of general anæmia there are three which require special consideration when the cerebral symptoms are in the foreground: these are alcoholic stimulants, the cold pack, and massage. It is a remarkable and characteristic feature of cerebral anæmia that alcoholic stimulants, although indicated, are not well borne²—at least not in such quantities as healthy persons can and do take without any appreciable effect. I therefore order them—usually in the shape of Hungarian extract wines,³ South Side madeira, or California angelica—to be given at first in such small quantities as cannot affect the cerebral circulation unpleasantly, and then gradually have the quantity increased as tolerated. In fact, both with regard to the solid nourishment and the stimulating or nourishing fluids and restorative drugs the division-of-labor principle is well worth following. The cerebral anæmic is not in a position to take much exercise, his somatic functions are more or less stagnant, and bulky meals are therefore not well borne. Small quantities of food, pleasingly varied in character and frequently administered, will accomplish the purpose of the physician much better.

The cold pack, strongly recommended by some in general anæmia, is not, in my opinion, beneficial in cases where the nervous phenomena are in the foreground, particularly in elderly persons. Gentle massage, on the other hand, has the happiest effects in this very class of cases.

Of late years my attention has been repeatedly directed to cerebral anæmia of peculiar localization due to malarial poisoning. It has been

¹ Urethran and paraldehyde have failed in my hands with anæmic persons.

² Hammond, who classes many disorders under the head of cerebral anæmia which the majority of neurologists regard as of a different character, has offered a very happy explanation. He says, "Now, it must be recollected that the brains of anæmic persons are in very much the same condition as the eyes of those who have for a long time been shut out from their natural stimulus, light. When the full blaze of day is allowed to fall upon them retinal pain is produced, the pupils are contracted, and the lids close involuntarily. The light must be admitted in a diffused form, and gradually, till the eye becomes accustomed to the excitation. So it is with the use of alcohol in some cases of cerebral anæmia. The quantity must be small at first and administered in a highly diluted form, though it may be frequently repeated."

³ Such as Meneszer Aszu; there is no genuine tokay wine imported to this country, as far as I am able to learn.

noted by others that temporary aphasia and other evidences of spasm of the cortical arteries may occur as equivalents or sequelæ of a malarial attack. I have seen an analogous case in which hemianopsia and hemianæsthesia occurred under like circumstances, and were recovered from. Whether more permanent lesions, in the way of pigmentary embolism or progressing vascular disease, causing thrombotic or other forms of softening, may develop after such focal symptoms is a matter of conjecture, but I have observed two fatal cases in which the premonitory symptoms resembled those of one which recovered, and in which these were preceded by signs of a more general cerebral anæmia, and in one case had been mistaken for the uncomplicated form of that disorder. Where a type is observable in the exacerbation of the vertigo, headache, tinnitus, and lethargy of cerebral anæmia, particularly if numbness, tingling, or other signs of cortical malnutrition are noted in focal distribution, a careful search for evidences of malarial poisoning should be made; and if such be discovered the most energetic antimalarial treatment instituted. It is in such cases that arsenic is of special benefit.

The treatment of syncope properly belongs to this article. Where the signs of returning animation do not immediately follow the assumption of the recumbent position, the nitrite of amyl, ammonia, or small quantities of ether should be exhibited for inhalation. The action of the former is peculiarly rapid and gratifying, though the patient on recovery may suffer from fulness and pain in the head as after-effects of its administration. The customary giving of stimulants by the mouth is to be deprecated. Even when the patient is sufficiently conscious to be able to swallow, he is usually nauseated, and, as he is extremely susceptible to strong odors or tastes in his then condition, this nausea is aggravated by them. By far the greater number of fainting persons recover spontaneously or have their recovery accelerated by such simple measures as cold affusion, which, by causing a reflex inspiration, excites the circulatory forces to a more normal action. Rarely will the electric brush be necessary, but in all cases where surgical operations of such a nature as to render the development of a grave form of cerebral anæmia a possibility are to be performed, a powerful battery and clysters of hot vinegar, as well as the apparatus for transfusion, should be provided, so as to be within reach at a moment's notice.

Inflammation of the Brain.

Before the introduction of accurate methods of examining the diseased brain the term inflammatory softening was used in a much wider sense than it is to-day. Most of the disorders ascribed to inflammatory irritation by writers of the period of Andral and Rush are to-day recognized as regressive, and in great part passive, results of necrotic destruction through embolic or thrombic closure of afferent blood-channels. Two forms of inflammation are universally recognized. One manifests itself in slow vascular and connective-tissue changes and in an indurating inflammation. There are two varieties of it: the first of these, which is associated with furibund vaso-motor explosions and regressive metamorphosis of the functional brain-elements, is known from its typical

association with grave motor and mental enfeeblement as parietic dementia or dementia paralytica. The second, which is focal in the distribution of the affected brain-areas, is known as sclerosis. The former is treated of in a separate article; the latter is considered in connection with the spinal affections which either resemble it in histological character or complicate its course. The second form of cerebral inflammation is marked by the formation of the ordinary fluid products of acute inflammation in other organs of the body; this is the suppurative form, usually spoken of as abscess of the brain.

In addition to these two generally recognized inflammatory affections there are a number of rare diseases which are regarded by excellent authority as also of that character. The vaguely-used term acute encephalitis has been recently reapplied with distinct limitations to an acute affection of children by Strümpell. This disease is usually of acute onset, infants under the sixth year of age being suddenly, and in the midst of apparently previous good health sometimes, attacked by fever, vomiting, and convulsions.¹ Occasionally coma follows, which may last for several days, perhaps interrupted from time to time by recurring convulsions or delirium. The convalescence from this condition is rapid, and in some cases is complete; in others paralysis remains behind in the hemiplegic form. The paralysis is usually greater in the arm than in the leg; in extreme cases it involves the corresponding side of the face, and, as the paralyzed parts are arrested or perverted in growth, considerable deformity, even extending to asymmetry of the skull, may ensue. The deformity is aggravated by contractures. Usually there is some atrophy of the muscles, but in one case I found actual hypertrophy² of some groups, probably in association with the hemiathetoid movements.

The sequelæ of acute infantile encephalitis present us with the most interesting forms of post-paralytic disturbances of muscular equilibrium. Hemichorea and hemiathetosis, as well as peculiar associated movements and hemicontracture, are found in their highest development with this class of cases. Occasionally epileptiform symptoms are noted,³ and in others true epilepsy is developed. It is under such circumstances that imbecility is apt to be a companion symptom or result; and this imbecility is prominently noted in the moral sphere.

The grave set of symptoms briefly detailed here are attributed by Strümpell⁴ to an acute encephalitis, analogous, in his opinion, to the acute poliomyelitis of children. Its frequent occurrence after measles and scarlatina, as well as the fact that Ross⁵ in a carefully-studied case arrived at the opinion that the disease was an embolo-necrotic result of endocarditis, would lead to the conclusion that it is a focal affection, probably due to the transportation of infectious elements to the brain through the blood-vessels. Its occurrence in children in the midst of apparent health⁶

¹ As in my case of infantile encephalitis followed by athetoid symptoms (*Journal of Nervous and Mental Diseases*).

² This was followed by atrophy. There are never any qualitative electrical changes.

³ Which in one case of my own disappeared spontaneously.

⁴ As a surmise, for up to his writing no reliable autopsies had been made.

⁵ *Brain*, October, 1883.

⁶ McNutt (*American Journal of Medical Sciences*, January, 1885) cites Strümpell as attributing the theory of an inflammatory affection, which is analogous to poliomyelitis in its suddenness and nature, to Benedict, and refers to p. 349 of Strümpell's textbook under the erroneous date of 1864. This work was published in 1883-84, and the theory is

is consistent with the fact that rheumatism and an attendant slight endocarditis frequently pass unrecognized in infancy. It is supposed that a diffuse form of inflammatory non-suppurative softening exists by some of the Germans, but the proof advanced in favor of this view is not conclusive.

A number of rare forms of interstitial encephalitis have been described. In one, elaborately studied by Danillo, an inflammatory hypertrophy of the cortex, involving the parenchyma as well as the connective and vascular structures, was found in a limited area of the motor province of the right hemisphere. There had been crossed epileptiform convulsions during life.¹

There is some question among pathologists as to the recognition of Virchow's encephalitis of the new-born. Certainly a part of Virchow's material was derived from the imperfect study of a condition of infantile brain-development which, as Jastrowitz showed, is physiological, and on which Flechsig based his important researches of tract-development. More recent studies, however, demonstrate that there is a form of miliary encephalitis in new-born children due to septic causes, such as, for example, suppuration of the umbilical cord. The demonstration by Zenker of the occurrence of metastatic parasitic emboli in cases of aphthous stomatitis, and by Letzerich of a diphtheritic micrococcus invasion in the brain of his own child, show that the subject of early infantile encephalitis merits renewed consideration.²

Strictly speaking, the reactive changes which occur in the brain-substance bordering on tumors, hemorrhagic and softened foci, belong to the domain of encephalitis; but as they are considered in conjunction with the graver lesions to which they are secondary both in occurrence and importance, it is not necessary to more than refer to them here.

Abscess of the Brain.

As indicated in the last article, there formerly existed much confusion in the minds of pathologists regarding the terms softening and abscess of the brain. As long as softening was regarded as an inflammation, so long was abscess of the brain regarded as a suppurative form of softening. Aside from the fact that there is some resemblance in mechanical consistency between a spot of ordinary softening and one of inflammatory softening, there is no essential similarity of the two conditions. True softening is to-day regarded as the result of a death of brain-tissue produced by interference with the blood-supply; it is therefore a passive process. Inflammatory softening, of which abscess is a form, is due to an irritant, usually of an infectious nature. It is to the results of such irritation that the term suppurative encephalitis should be limited.

MORBID ANATOMY.—In all well-established inflammatory brain trou-

advanced by Strümpell as his own. It is only a synonym, hemiplegia spastica infantile, that is attributed to Benedict.

¹ *Bulletin de la Société de Biologie*, 1883, p. 238.

² The attempt of Jacusiel to revive Virchow's encephalitis of the new-born (*Berliner klinische Wochenschrift*, 1883, No. 7) under the title of interstitial encephalitis does not seem to have met with encouragement, for, besides Jastrowitz, Henoch and Hirschberg opposed this view in the discussion.

bles the active part is taken by the blood-vessels and connective tissue; the ganglionic elements undergo secondary, usually regressive or necrotic, changes. The brain, considered as a parenchymatous organ, is not disposed to react readily in the way of suppurative inflammation unless some septic elements are added to the inflammatory irritant. Foreign bodies, such as knitting-needles, bullets, and slate-pencils, have been found encapsulated in this organ or projecting into it from the surrounding bony shell without encapsulation and without any evidences of inflammatory change. As a rule, a foreign body which enters the brain under aseptic conditions will, if the subject survive sufficiently long, be found to have made its way to the deepest part of the brain, in obedience to the law of gravity, and through an area of so-called inflammatory red softening which appears to precede it and facilitate the movement downward. This form of softening derives its color from the colored elements of the blood, which either escape from the vessels in consequence of the direct action of the traumatic agent; secondly, in consequence of vascular rupture from the reduced resistance of the perivascular tissue in consequence of inflammatory oedema and infiltration; or, thirdly, in obedience to the general laws governing simple inflammation.

A cerebral abscess may present itself to the pathological anatomist in one of three phases—the formative, the crude, and the encapsulated. In the first it is not dissimilar to a focus of yellow softening, being, like the latter, a diffuse softened area varying from almost microscopical dimensions to the size of a walnut, and of a distinctly yellow tinge. Microscopic examination, however, shows a profound difference. In pure yellow softening there are no pus-cells; in the suppurative encephalitic foci they are very numerous, and congregated around the vessels and in the parenchyma in groups. The crude abscess is the form usually found in cases rapidly running to a fatal termination. Here there is an irregular cavity in the brain, usually the white central substance of the cerebrum or cerebellum, formed by its eroded and pulpy tissue; it is filled with yellow, greenish, and more rarely brownish pus. In the most furibund cases broken-down brain-detritus may be found in the shape of whitish or reddish flocculi, but in slowly-formed abscesses the contents are free from such admixture, and thus the third phase is produced, known as the encapsulated abscess. The cavity of the abscess becomes more regular, usually spheroid or ovoid; the pus is less fluid, more tenacious, and slightly transparent; and the walls are formed by a pseudo-membrane¹ which is contributed by the sclerosing brain-substance, which merges gradually into the outlying normal tissue. I have seen one acute cerebral abscess from ear disease which might be appropriately designated as hemorrhagic; the contents were almost chocolate-colored; on closer inspection it was found that they were true pus, mingled with a large number of red blood-discs and some small flocculi of softened brain-substance. This hemorrhagic admixture was not due to the erosion of any

¹ There is considerable dispute as to the real nature of the tissue encapsulating cerebral abscesses. It is known, through the careful observations of R. Meyer, Goll, Lebert, Schott, and Huguenin, that the capsule may form in from seven to ten weeks in the majority of cases, about eight weeks being the presumable time, and that at first the so-called capsule of Lallemand does not deserve the name, being a mucoid lining of the wall. At about the fiftieth day, according to Huguenin, this lining becomes a delicate membrane composed of young cells and a layer of spindle-shaped connective elements.

large vessel, for the abscess had ruptured into the lateral ventricle at that part where it was most purely purulent. In a case of tubercular meningitis, Mollenhauer in my laboratory found an abscess in the white axis of the precentral gyrus, with a distinct purulent infiltration following the line of one of the long cortical vessels. The abscess was not encapsulated, the surrounding white substance exhibited an injected halo, and the consistency of the contents was that of mucoid material.

In cases where the symptoms accompanying the abscess during life had been very severe it is not rare to find intense vascular injection of the parts near the abscess, and it is not unlikely that the reddish or chocolate color of the contents of some acutely developed abscesses is due to blood admixture derived from the rupture of vessels in this congested vicinity. Sometimes the entire segment of the brain in which the abscess is situated, or the whole brain, is congested or œdematous. In a few cases meningitis with lymphoid and purulent exudation has been found to accompany abscesses that had not ruptured. It is impossible to say whether in this case there was any relation between the focal and the meningeal inflammation, as both may have been due to a common primary cause.¹ In such cases, usually secondary to ear disease, thrombosis of the lateral sinus may be found on the same side. Where rupture of an abscess occurs, if the patient have survived this accident long enough—for it is usually fatal in a few minutes or hours—meningitis will be found in its most malignant form. A rupture into the lateral and other ventricles has been noted in a few cases.²

Some rare forms of abscess have been related in the various journals and archives which have less interest as objects of clinical study than as curiosities of medical literature. Thus, Chiari³ found the cavity of a cerebral abscess filled with air, a communication with the nose having become established by its rupture and discharge.

The contents of a cerebral abscess usually develop a peculiarly fetid odor. It has been claimed that this odor is particularly marked in cases where the abscess was due to some necrotic process in the neighborhood of the brain-cavity. The only special odor developed by cerebral abscesses, as a rule, is identical with that of putrid brain-substance, and it must therefore depend upon the presence of brain-detritus in the contents of the abscess or upon the rapid post-mortem decomposition of the neighboring brain-substance.

In two cases of miliary abscess which, as far as an imperfect examination showed, depended on an invasion of micro-organisms, an odor was noticed by me which was of so specific a character that on cutting open the second brain it instantly suggested that of the first case, examined six years previous, although up to that moment I had not yet determined the nature of the lesion.⁴

¹ Otitis media purulenta in the two cases of this kind I examined.

² In one, observed together with E. G. Messemer, intense injection of the endymal lining, with capillary extravasations, demonstrated the irritant properties of the discharged contents.

³ *Zeitschrift für Heilkunde*, 1884, v. p. 383. In this remarkable case the abscess, situated in the frontal lobe, had perforated in two directions—one outward into the ethmoidal cells, the other inward into the ventricles, so that the ventricles had also become filled with air. This event precipitated a fatal apoplectic seizure.

⁴ Owing to the lack of proper methods of demonstrating micro-organisms, the first case

That form of abscess which, from its situation in or immediately beneath the surface, has latterly aroused so much interest from its important relations to localizations is usually metastatic, and directly connected with disease of the overlying structures, notably the cranial walls. In this case the membranes are nearly always involved. The dura shows a necrotic perforation resembling that found with internal perforation of a mastoid or tympanic abscess. The pia is thickened and covered with a tough fibro-purulent exudation; occasionally the dura and leptomeninges are fused into a continuous mass of the consistency of leather through the agglutinating exudation. The abscess is usually found open, and it is not yet determined whether it begins as a surface erosion, and, bursting through the cortex, spreads rapidly on reaching the white substance, or not. The white substance is much more vulnerable to the assault of suppurative inflammation than the gray, and not infrequently the superficial part of the cortex may appear in its normal contiguity with the pia, but undermined by the cavity of the abscess, which has destroyed the subcortical tissue. Possibly the infecting agent, as in some cases of ear disease, makes its way to the brain-tissue through the vascular connections, which, however sparse at the convexity of the brain, still exist.

CLINICAL HISTORY.—The symptoms of a cerebral abscess depend on its location, size, and rapidity of formation. There are certain parts of the brain, particularly near the apex of the temporal lobe and in the centre of the cerebellar hemisphere, where a moderately large abscess may produce no special symptoms leading us to suspect its presence. There are other localities where the suppurative focus¹ indicates its presence, and nearly its precise location and extent, by the irritative focal symptoms which mark its development and by the elimination of important functions which follows its maturation. It is also in accordance with the general law governing the influence of new formations on the cerebral functions that an acutely produced abscess will mark its presence by more pronounced symptoms than one of slow, insidious development. Indeed, there are found abscesses in the brain, even of fair dimensions, that are called latent because their existence could not have been suspected from any indication during life, while many others of equal size are latent at some time in their history.

An acute cerebral abscess is ushered in by severe, deep, and dull headache, which is rarely piercing, but often of a pulsating character. The pain is sometimes localized, but the subjective localization does not correspond to the actual site of the morbid focus.² It is often accompanied

whose clinical history was known was imperfectly studied; of the second case, accidentally found in a brain obtained for anatomical purposes, the examination is not yet completed.

¹ Practically, our knowledge of localization of functions in the human brain begins with the observation by Hitzig of a traumatic abscess in a wounded French prisoner at Nancy named Joseph Masseau. The year of the publication of this interesting case constitutes an epoch in advancing biological knowledge, which will be remembered when even the mighty historical events in which Hitzig's patient played the part of an insignificant unit shall have become obsolete. This, the first case in the human subject where a reliable observation was made was an unusually pure one; the abscess involved the facial-hypoglossal cortical field (*Archiv für Psychiatrie*, iii. p. 231).

² Although Ross seems to be of a contrary opinion, it is the exception for the pain to correspond in location to the abscess.

by vertigo or by a tendency to dig the head into the pillow or to grind it against the wall. With this there is more or less delirium, usually of the same character as that which accompanies acute simple meningitis. As the delirium increases the slight rise in temperature which often occurs in the beginning undergoes an increase; finally coma develops, and the patient dies either in this state or in violent convulsions. The case may run its course in this way in a few days, but usually one to three weeks intervene between the initial symptoms and death.

Between the rapid and violent course of acute cerebral abscess detailed, and the insidious course of those which as latent abscesses may exist for many years without producing any noticeable symptoms whatever, there is every connecting link as to suddenness and slowness of onset, severity and mildness of symptoms, and rapidity and slowness of development and progress. It is the encapsulated abscesses which are properly spoken of as chronic, and which may even constitute an exception to the almost uniform fatality of the suppurative affections of the brain. Thus, the symptoms marking their development may correspond to those of an acute abscess, but coma does not supervene, temporary recovery ensues, and the patient leaves the hospital or returns to his vocation. But all this time he appears cachectic, and there will be found, on accurate observation, pathological variations of the temperature and pulse. The appetite is poor; the bowels are usually constipated; there are frequent chilly sensations and horripilations, and a general malaise. This condition slowly passes away in the few cases which recover; in others relapses occur, usually of progressing severity, and terminate life. The period during which the symptoms of the abscess are latent may be regarded as corresponding to the latent period which sometimes intervenes between an injury and the development of the symptoms of acute abscess, and which, according to Lebert, may comprise several weeks or months. In other words, the morbid process may be regarded all this time as progressing under the mask of a remission. It is this latent period which it is of the highest importance for the diagnostician to recognize. There is usually headache, which is continuous and does not change in character, though it may be aggravated in paroxysms. Usually the temperature rises with these paroxysms, and if they continue increasing in severity they may culminate in epileptic convulsions.

Many of the symptoms of cerebral abscess—prominently those attending the rapidly-developed forms and the exacerbations of the chronic form—are due to cerebral compression. It is the pulse and pupils, above all, that are influenced by this factor.

In an affection having so many different modes of origin as cerebral abscess, and occupying such a wide range of possible relations to the cerebral mechanism, it is natural that there should exist many different clinical types. So far as the question of the diagnosis of localized cerebral abscesses is concerned, I would refer to the article dealing with cerebral localization, in order to avoid repetition. With regard to the etiological types, they will be discussed with the respective causal factors.

ETIOLOGY.—Abscess of the brain is so frequently found to be due to metastatic or other infectious causes that it is to be regarded as highly improbable that it is ever of idiopathic occurrence. The most frequent

associated conditions are—suppurative inflammation in neighboring structures, such as the tympanic cavity, the mastoid cells, the nasal cavity, or inflammation or injury of any part of the cranium and scalp. The connection of these structures with the brain through lymphatic and vascular channels is so intimate that the transmission of a pyogenic inflammatory process from the former to the latter is not difficult to understand. But disease of far distant organs, such as gangrene of the lung, and general affections, such as typhoid fever, occasionally figure among the causes of cerebral abscess, particularly of the miliary variety.

Among the commonest causes of cerebral abscesses are those which the surgeon encounters. The injury may be apparently slight and limited to the soft parts, or the bone may be merely grazed. Gunshot wounds are particularly apt to be followed by a cerebral abscess; and it has been noted that those which granulate feebly, whose base is formed by a grayish, dirty, and fetid material, are most apt to lead to this ominous complication. The symptoms do not usually develop immediately, and after the surgeon is led to indulge in the hope that danger is past, proper reaction sets in, healthy granulations develop—nay, the wound may close and be undergoing cicatrization—then the patient complains of feeling faint or drowsy, and with or without this premonition he has convulsive movements of one side, sometimes involving both extremities and the corresponding side of the face. Consciousness is usually preserved, but the spells recur, and the patient is noted to be absent-minded during and after the convulsive seizure. On some later day he is noticed to become pale, as in the initial stage of a true epileptic seizure; total abolition of consciousness follows, and the clonic spasms, affecting the same limbs and muscles involved in the first seizures, now recur with redoubled violence. After such an attack more or less paresis is observed in the muscles previously convulsed. A number of such seizures may occur, or a fatal issue terminate any one of them. Not infrequently the field of the involved muscles increases with each fit. Thus the thumb or a few fingers may be the first to show clonic spasm; in the next fits, the entire arm; in succeeding ones, the leg and face may follow suit. In such a case the periphery first to be convulsed is the first to become paralyzed, thus showing that where the disease began as an irritative lesion the cortex is now destroyed, and that around the destructive focus as a centre the zone of irritation is spreading excentrically, first to irritate and then to destroy seriatim the functions of the various cortical fields in their order. According to the teachings laid down in the article on *Localization*, the order of invasion and extension, as well as the nature, of the focal symptoms will vary. Finally, the attacks become more severe and of longer duration; the patient does not recover in the intervals, but complains of nausea, pain, confusion, and head-pressure. He is noted to be dull, his temperature is slightly raised (100° F.), and the speech may be affected. Several attacks may occur in a day, each leaving the patient more and more crippled as to motility and mind. He is delirious and drowsy at intervals; his temperature may rise after an attack from one to four degrees, usually remaining near 103° – 104° F. in the evening; and, coma developing, death occurs, the convulsion or paralytic phenomena continuing at intervals during the moribund period, and the temperature and pulse sometimes running up rapidly toward the last. On examining

the parts, it is found that the bone is necrotic at the point of injury, usually only in its outer table, but sometimes in its entire thickness. In exceptional cases the normal continuity of the entire table is not interrupted to all appearances, and a small eroded spot on the inner table is found bathed in pus, or a detached necrotic fragment may be found in the latter. Corresponding to the purulent focus on the inner table the dura mater is detached, discolored, and perforated in one or more places with irregular rents or holes which have a greenish or blackish border. An abscess is found in that part of the brain which corresponds to this opening. There is no question that it was caused by direct infection from the necrotic spot.

Cases have been noted,¹ apparently of idiopathic origin, in which a sudden paralysis of a few fingers was the first symptom produced by the development of a cerebral abscess. In a few days such a paralysis extends to the other fingers and to the forearm. Occasionally no convulsive phenomena are noted, or choreic movements indicate, in their place, that the cortical field is irritated. Such cases usually run a rapidly fatal course.

The most frequent cause of cerebral abscess in civil practice is suppurative inflammation of the middle ear. It may be safely asserted that the person suffering from this affection is at no time free from the danger of a cerebral abscess, a purulent meningitis, or a phlebitic thrombosis of the sinuses. Cases are on record where the aural trouble had become chronic, and even quiescent, for a period of thirty years, and at that late date led to abscess with a fatal termination. Of 6 cases of this character in my experience, 4 of which were verified by anatomical examination, not one but had occurred at least four years after the commencement of the ear trouble, and 1 happened in a man aged fifty-four who had contracted the latter affection in childhood. In 2 there was in addition diffuse purulent meningitis, limited on the convexity to the side where the abscess was situated.² In 4 the abscess was in the temporal lobe, 1 of them having in addition an abscess in the cerebellar hemisphere of the same side; in a fifth the abscess was in the deep white substance of the cerebral hemisphere, opening into the lateral ventricle, and in the sixth it was in one cerebellar hemisphere alone.

The course of this class of abscesses is usually obscure: focal symptoms are not commonly present, and the constitutional and local symptoms usually appear as a gradual outgrowth from the aural troubles. Thus there is at first usually little fever, vertigo, and chilliness, but considerable tinnitus, and sometimes pain in the ear. Occasionally local signs of a septic metastasis of the otitis, such as œdema over the mastoid or painful tumefaction of the cervical glands, are visible. The pain previously referred to the region of the ear now becomes general; commonly—even where the abscess is in the temporal lobe—it becomes progressively aggravated in the frontal and sometimes in the nuchal region, and under an increase of the febrile phenomena death may exceptionally occur without further complication. Even large abscesses in one half of the cerebellum occur without producing Ménière's symptom—a fact

¹ Arthur E. W. Fox, *Brain*, July, 1885.

² One of these was seen during life by J. R. Pooley; the other was a paretic dement at the New York City Pauper Asylum.

which leads to the suspicion that the purulent deposit must have been of slow and gradual development. In one case distinct symptoms indicating an affection of the subcortical auditory tract were observed. As a rule, this class of abscesses are accompanied toward the close by active general symptoms—convulsions, coma, narrowing and impaired light-reaction of the pupils. Delirium, when a prominent symptom from the beginning, indicates the probable association of meningitis with the abscess.¹ Occasionally severe pain, rigor, high temperature, and paralysis may be absent even with rapidly-developed abscess from otitis.²

Ulcerative endocarditis, infectious osteomyelitis, pulmonary gangrene, general pyæmia, and, as is claimed by a few authors, typhoid fever, are often accompanied by multiple abscesses in the brain-substance. Usually the foci are small, as may be readily inferred from the fact that they are of embolic origin, the emboli being usually so small as to lodge in very small vessels, and that the fatality of the primary disease is so great as to cut short life before the abscess can reach larger dimensions. For the same reasons the symptoms they produce are rarely distinctive. In chronic lung affections accompanied by putrescence in bronchiectatic or other cavities cerebral abscesses are not uncommon occurrences. Under these circumstances, although we must assume an embolic origin, the abscess is rarely multiple, and the symptoms are as marked as in the ordinary varieties. Thus a patient suffering from chronic phthisis, with or without prodromal malaise or somnolence, experiences formications and pain in his right leg; he then notices a slight halt in walking; twitches appear in the affected extremity; it becomes distinctly paretic. The arm then becomes affected in like manner; the pupils become unequal; a severe chill occurs, followed by delirium, convulsions, coma, and death.

DIAGNOSIS.—There is little difficulty in recognizing the existence of a cerebral abscess in which well-marked focal and constitutional symptoms coincide, or where a distinct abscess-producing cause, such as an ear trouble, a head injury, or a putrid bronchiectasis, coexists.³ But there are a number of cases, varying from the latent form to forms with obscure general symptoms, whose recognition is impossible or at best a matter of conjecture. Such cases may be readily confounded with certain tumors. The existence of febrile symptoms, although not excluding tumor, as some tumors are accompanied by such, is greatly in favor of abscess. On the other hand, choked disc, which is rare with abscess and found only with the very largest, is in favor of tumor.

PROGNOSIS AND TREATMENT.—The majority of cerebral abscesses must, from the nature of the case, be regarded as not influenceable by medicinal measures or surgical treatment. The miliary and other abscesses due to general septic causes or to mycotic invasion, being in the nature of

¹ The same is probably true of oculo-motor paralysis, which Ross (*loc. cit.*, vol. ii. p. 735) refers to uncomplicated abscess.

² This was the case with an abscess containing five ounces of pus recorded by C. S. Kilham at the Sheffield Medical Society (*British Medical Journal*, February 13, 1886). As illustrating what was stated about the non-correspondence of the pain and the location of the abscess, it may be stated that notwithstanding this large abscess was in the temporal lobe, what pain was present was in the forehead.

³ Yet a leading and careful authority was misled into making the diagnosis of abscess in a case of ear disease complicated by a cerebral tumor.

the case but features of intrinsically dangerous or fatal primary diseases, do not call for special measures. It is different with those due to local trouble about the head and to surgical causes. Remarkable advances have been made in the operative treatment of cerebral abscesses, chiefly owing to the increasing accuracy of the localization of the affected areas through the disturbance of their function, and to the perfection of surgical methods. A number of cases by Gussenbauer, Wernicke, and others have shown that some abscesses may be accurately located during life by the focal symptoms produced by their presence. Wernicke's observation of a large abscess in the occipital lobe showed two facts. First, it permitted the study of the effect of large abscesses on the cerebral movements, as it was found after trephining that the pulsation movement of the brain was lost and the dura tensely bulging, thus indicating a high degree of cerebral pressure. Secondly, the operation showed that an abscess can be emptied of its contents, under moderate aseptic precautions, without provoking contiguous inflammatory reaction or infecting the meninges. Notwithstanding these favorable local conditions, the patient died. Gussenbauer¹ was more fortunate. He surmised from the fluctuation of some symptoms and the predominance of others that his patient had an abscess in the frontal lobe. The suspicion was verified: an abscess of the size of an apple was found, opened, and emptied of its contents. The patient recovered without any immediate untoward symptom.²

The uncertainties of localization in some districts of the brain are so great that a number of attempts to repeat the explorations and aspiration of Wernicke and Gussenbauer have failed. In one case recently operated on in New York City the aspirating-needle was run into the brain-substance in several different directions without striking the pus. It is a question under such circumstances whether the chances of an abscess becoming latent, minimal though they be in cases with pronounced signs, are not to be preferred to those which an uncertain operation can give. The superficial encephalitic foci offer far better opportunities for surgical triumphs. Here not only the symptoms are much more constant, and point more unerringly to the site of the morbid spot, but there are often other signs, such as the evidences of impaction of a foreign body, local tenderness on percussion, or bone disease, which aid in determining the proper spot for the application of the trephine. Several operations where traumatic encephalitis existed with or without leptomeningitis of the convexity, followed by complete recovery, were performed by Macewen.³

The medicinal treatment of abscess of the brain is limited to derivative methods, whose aim is the relief of pressure—an aim whose fulfilment is more frequently illusory than otherwise.

Benefit has been claimed from the energetic use of mercury, chiefly in the form of calomel, by older writers; and recently Handfield Jones has endorsed its administration, attributing to it a remission in a case in which it was employed. It must be remembered, however, that remissions occur spontaneously in this disease, and that the purgative action of calomel may act well for the time being in an affection so apt to be associ-

¹ *Prager medizinische Wochenschrift*, 1885, Nos. 1, 2, and 3.

² Epileptic and focal spasms subsequently developed, which shows that a new inflammatory or other destructive process may have set in in the vicinity of the emptied sac.

³ *The Lancet*, 1885, vol. i. p. 881.

ated with hyperæmia and increased cerebral pressure as is an abscess of the brain.¹ In the nature of the case, even this latter momentarily beneficial effect is at the best temporary.

The prophylaxis of cerebral abscess can be carried out only in cases due to cranial and aural affections. The importance of treating all scalp and cranial injuries under aseptic² precautions is recognized by all surgeons. It is generally admitted that the trephining of a bone suspected to be the site of an otitic or necrotic process involves fewer risks than the allowing it to remain. Similar principles govern the treatment of the inflammatory involvement of the mastoid cells often complicating otitis media. If trephined at all, these should be trephined at the earliest moment. It was a belief among the older aurists that the sudden cessation of an aural discharge was of evil augury, and that cerebral complications were more apt to follow under such circumstances than when the ear discharged freely. Von Trötsch, Politzer, Gruber, and Toynbee have opposed the exclusive application of the old dogma. In so far as the older ear-surgeons regarded a profuse aural discharge as an encouraging sign, in this respect they were of course wrong. But their observation of the frequent concurrence of cerebral sequelæ with suppression of discharge is, I think, borne out by a large number of cases. It does not apply, however, to the suppression of discharge by the rational employment of aseptic injections.

Spinal Hyperæmia.

The spinal cord is found to vary considerably in color in different individuals. To some extent this difference is influenced by the position occupied by the body after death, but not as markedly as in the case of the brain. Thus it will be paler in a body which has been kept in the prone than in one which has been kept in the supine position.³ It is usually found more injected in persons who have died of febrile affection than in those who have died of exhausting diseases; notably is this the case with typhus fever and with subjects who die with congestive malarial chill. But the most intense congestion, where the gray substance instead of having the normal rosy hue appears like a blood-soaked sponge, and the white substance instead of the tint to which it owes its name has a pink shade, is found in subjects dying in convulsive disorders complicated by asphyxia, such as epileptic status, tetanus, and certain toxic disorders.

In attempting to apply the fact that varying degrees of vascular injection are found on post-mortem examinations of the spinal cord to the elucidation of certain clinical phenomena, we encounter the same difficulties and sources of error that confronted us in the study of nutritive

¹ *Brain*, October, 1884, p. 398.

² This term is used in its widest sense here.

³ I have not seen it noticed anywhere, but it is a fact readily demonstrable in any autopsy made in a well-preserved body that when a short segment of cord is observed at the moment of section the section surface appears pale; but if it be again examined after a few moments, it will show a reddish tinge, marked as a faint injection would be; this tinge distinctly deepens under the eye. I have observed this in specimens which were not held in the hand, so that the influence of pressure can be excluded. Nor do I believe that the elasticity of the tissues is such as to account for the phenomenon.

brain disorders. The majority of writers have therefore contented themselves with making a careful clinical study of the mostly subjective signs of disorders which, once designated as spinal anæmia and hyperæmia, are now classified under the non-committal titles of spinal irritation and exhaustion (neurasthenia), as in this volume. A number of these disorders, like the so-called anæmic paralysis of Bouchut, Leroy d'Étiolles, Beroliet, Baimier, and Brandis, would to-day be considered as hysterical or reflex; and a few of the instances cited by their contemporaries as cases of spinal hyperæmia have been since demonstrated to resemble the initial phases of organic diseases of the cord.

The causes of active spinal hyperæmia are either direct, as when the spinal centres are overtaken by muscular strain either through over-exertion or through toxic convulsions, surprised by violent shocks, such as concussion accidents, or collateral, as when a physiological discharge (menstruation) or a pathological one (hemorrhoidal flux) is suddenly checked. A few cases are reported where carbonic-oxide-gas poisoning provoked spinal hyperæmia. But, like the alleged cases of spinal hyperæmia after continued and exanthematic fevers, they were probably cases of incipient or established myelitis. Hammond claims that surface chilling exerts the same congesting influence on the cord which he claims for the brain; but no definite observations have been made in this direction.

Passive spinal hyperæmia has been attributed to obstructive cardiac and chronic pulmonary affections. In such cases, as with most causes acting on the circulation of blood in the nerve-centres, the coexisting cerebral congestion usually masks the spinal. It is a question how far the intense hyperæmia of the cord found in some cases of tetanus, strychnia-poisoning, and the condition called hydrophobia¹ is primary and an indication of neural hyperexcitability, and how far it is secondary to the asphyxia attending the last phases of these convulsive states. The weight of opinion is in favor of an acceptance of the latter as the chief or only factor.

Over-exertion and sexual excesses are frequently followed by a sensation of fulness and tension in the sacral and lumbar regions, which may be relieved by lying prone, while it is aggravated while lying supine.² From the location of this pain it is evident that it is not due to congestion of the cord or its membranes, but to fulness of the vertebral and spinal veins of the lower segment of the vertebral column. A similar sensation, which may be relieved by the same change in position or by a hemorrhoidal flux, is complained of by patients suffering from portal obstruction. The veritable symptoms of hyperæmia manifest themselves in the parts which receive their nervous supply from the affected districts. The reflexes are usually more active; paræsthesias of different kinds, such as formication, tingling, and creeping sensations, are common; and

¹ In a case of hydrophobia clinically as well marked as has been recorded, which I had the privilege of examining through the courtesy of Kretschmar, both brain and cord were found remarkably anæmic.

² Although this fact has been questioned, I have no doubt whatever that it is true, from a large number of observations. In many subjects suffering from the results of excessive venery or masturbation, an intolerable, sometimes pulsating, feeling in the lumbosacral region is only relieved by raising the lower end of the trunk with the back up. This condition is influenced by a change of residence to a district having a different level above the sea, and consequently a different barometric condition.

there is more or less motor weakness, the limbs feeling heavy and sometimes being the seat of an acute pain. As a rule, these symptoms are limited to the lower half of the body

There is very little question when these symptoms exist for any length of time, and become aggravated, that more subtle nutritive changes than are covered by the single term hyperæmia become responsible for them. In a pure hyperæmia the position-test of Brown-Séquard, which shows relief when the patient is upright or prone and aggravation when he is supine, particularly if the gravitation of blood to the cord be facilitated by raising the head and extremities, ought to yield constant results. But in some cases, particularly those of long-standing, the very opposite is noted: the patient's symptoms are aggravated by standing or sitting up, and relieved by lying down. Here there is probably exhaustion or malnutrition of the nerve-elements, rendering them abnormally sensitive to exertion. This view is supported by the fact that molecular disturbances, such as those which probably accompany simple concussion, predispose the patient to the development of the symptoms of spinal hyperæmia, and aggravate them if established previous to such accident.

Hammond,¹ who in his chapter on Spinal Congestion and Anæmia follows rather the older authors, such as Ollivier, than the newer and either more cautious or more sceptical writers on the subject, describes the symptoms of congestion as comprising belt sensations, paraplegia, erections of the penis, muscular twitches, loss of expulsive power, and incontinence of the bladder, paralysis of the abdominal muscles, paralysis of the anal sphincter, loss or abolition of reflex excitability, diminution of electro-muscular contractility, and occasionally hyperæsthesia and shooting pains. It is not doubtful for a moment that if such a case were to occur in hospital experience it would be regarded as one of organic disease, and not incipient, but well-established organic disease of the cord. Those making the diagnosis would have their opinion strengthened if, as Hammond states, the process took place with great rapidity and had a tendency to extend itself and eventually involve the whole cord, or if, as Brown-Séquard is by him cited as stating, bed-sores occurred in addition. Although Hammond describes certain anatomical changes, such as increased development of blood-vessels and distension and injection of them, I am unable to find any cases recorded as spinal congestion during life, and carefully examined with a due regard to sources of error after death, in which such changes were found. It is true that after strychnine- and cocaine-poisoning an intense hyperæmia² of the cord is found. In mammals it is of a far more pronounced character than in reptiles, and usually more marked in proportion to the existing asphyxia. That the characteristic toxic effects of these drugs is not to be sought for in their direct or indirect congesting influence is shown by the fact that exsanguinated frogs can be made to undergo strychnine tetanus when their blood is replaced by a saline solution according to the method of Salkowski. Little support, therefore, could be derived from a pretended analogy between toxic and

¹ *Diseases of the Nervous System*, 7th ed., p. 392.

² It is true that in animals which are so organized that the congestion cannot be attributed to asphyxia, as I showed (*Hammond Prize Essay of the American Neurological Association*, 1878) in some experiments on strychnine, arterial congestion and small foci of hemorrhage were found in the upper cervical cord of frogs who had been kept in continuous strychnine tetanus for over seventy days.

pathological hyperæmias, even if the phenomena of both were similar; which is not the case.

The introduction of subaqueous caissons for workmen engaged in the building of bridges, in which those employed labor under abnormal atmospheric pressure, has led to the development of a previously-unknown cerebro-spinal affection known as the caisson disease, and in which, it is generally supposed, either congestion or hemorrhage of the spinal cord occurs in consequence of sudden changes of vascular pressure resulting from sudden diminution of the barometric pressure. Clinically, this affection has been studied in England, France, and above all in America in connection with the building of the East River Bridge and the one over the Mississippi at St. Louis.¹ Experiments by Hoppe-Seyler, Bert, and I. Rosenthal have shown that a sudden diminution of pressure leads to hemorrhages in various tissues, and, according to the two first-named, a development of gas occurs in the vascular and other fluids of the body. A number of peculiar symptoms which do not specially interest us here occur in conjunction with the so-called caisson disease: these are—pain in the ear, with or without otitis sicca; peculiar pains in the joints, which occur on leaving the caisson, and are probably due to hyperæmia of the joint-surfaces and sudden increase of the intra-articular fluid; and retardation of the pulse-rate. In some cases cerebral hyperæmia is added, the patients tottering about as if drunk. The spinal symptoms consist of a paraplegiform affection. The paralysis is usually sudden; in some cases the patient a few minutes after stepping from the air-chamber falls down perfectly helpless as far as the lower half of the body is concerned. The expulsive power of the bladder is usually weakened, and there is anæsthesia to all forms of sensation in the affected limbs, as well as diminished electro-cutaneous sensibility. The patient often complains of a strange feeling, as if the lower half of his body were a foreign substance. With this the electro-muscular reactions are normal. In the majority of cases these symptoms disappear entirely in from three to ten days, but occasionally they remain longer; imperfect recovery of motion and sensation occurs, or, as happened in a few cases, one of which was carefully examined during life by Lehewess and after death by Leyden, death occurs as in myelitis. In the only case where an autopsy and careful microscopical examination were made under these circumstances² peculiar fissures were found in the substance of the spinal cord, surrounded by areas of reactive myelitis and filled with granule-cells. The absence of any pigmentary relics of a hemorrhage induced Leyden to assume that the lacunæ were not of hemorrhagic origin. He inclines to the view that they were due to the escape of gas from the blood-plasma, and consequent multilocular inflation of the tissue. If his observation be confirmed, it constitutes a strong objection to the hyperæmic theory of the caisson disease. There is neither permanent hyperæmia nor congestive or hemorrhagic myelitis developed, as far as the limited material thus far studied permits a conclusion.

Pure spinal hyperæmia rarely presents itself for treatment. The form due to over-exertion is recovered from by rest in a very short time; that due to suppressed discharges, by the re-establishment of the latter or by

¹ Clark, *St. Louis Med. and Surg. Journ.*, cited from Hammond, *loc. cit.*

² E. Leyden, *Archiv für Psychiatrie*, ix. p. 316.

the application of leeches to the lumbo-sacral and iliac region. Ergotin is recommended by Hammond in very large doses. It is a question whether this drug may not exert a bad effect in protracted cases where its use has to be continued for a long time.¹ In using it, it is well to bear in mind that imperfect nutrition of nerve-elements is perfectly compatible with an increased blood-amount.

Strychnia has been given with benefit in the caisson disease—another evidence, as this drug is theoretically contraindicated in true hyperæmia, that this disease is not, as Hammond and the majority of authors with him regard it, essentially a congestive affection. The treatment of those numerous cases in which signs of venous fulness accompany spinal exhaustion and irritation is detailed in the articles dealing with those affections.

Spinal Anæmia.

Anæmia of the cord-substance proper, like hyperæmia, is practically inseparable from the corresponding condition of the membranes. The influence of a reduced blood-amount on the functional activity of the spinal cord is more susceptible of exact demonstration than the corresponding nutritive disturbance of the brain. As the functions of this segment of the nervous axis are far simpler than those of the higher organ, there is more unanimity among observers as to the interpretation of their disordered states. In Stenon's experiment, and the more elaborate modifications made by those who have followed his method, it is found that interference with the supply of arterial blood to the spinal cord is followed by abolition of the function of the gray matter; if the supply be still further diminished, the functions of the white tracts become eliminated; next the peripheral nerves, and ultimately the muscles themselves, lose their normal excitability. On the re-establishment of the circulation these various parts regain their functional capacity in the inverse order of its suspension—the muscles first, next the nerves, then the white substance, and last the gray substance of the cord. The initial symptoms of some cases of myelitis from refrigeration correspond more nearly to such a result of artificial anæmia of the cord than they do to anything that is customarily regarded as hyperæmia.²

No one has gone farther than Hammond in erecting a theoretical anatomical framework which elaborately provides for the accommodation of various symptoms of spinal anæmia. He describes anæmia of the posterior columns, and sharply discriminates between it and anæmia of the antero-lateral columns. It is a question whether the conducting tracts of these columns are seriously affected in their functions by anæmia as long as the centres of innervation are well nourished. Undoubtedly, it is the gray substance of the cord which is most vulnerable to the influence of

¹ A young physician, who for a long period took ergotin in twelve-grain doses for the relief of symptoms regarded as congestive, acquired a tolerance of the drug such as I have not seen recorded anywhere, and in addition presents some obscure signs of cerebellar disease and initial optic-nerve atrophy.

² I have seen distinct pallor of the spinal meninges on dipping the posterior extremities of a dog, whose cord had been exposed, into water. It is to be remarked, however, that other observers, notably Hammond, have either obtained different results or interpreted the consequences of refrigeration differently.

disturbed circulation and nutrition, as Stenon's experiment has shown; and a glance at the distribution of the blood-vessels will show that a partial anæmia or hyperæmia, limited to special cornua in any considerable length of the cord, is an exceedingly improbable occurrence. With regard to isolated anæmia of the white columns, it is to be admitted that the posterior are most vulnerable to malnutrition. But it is doubtful whether this vulnerability is so great as to allow of an exclusively posterior anæmia, or whether a protracted anæmia of this kind could exist for years as a purely symptomatic—or, as some designate it, functional—disorder.

Hammond candidly states that in specifically locating the lesions in these affections he is aware that post-mortem examinations are wanting to support them, and admits that what he calls anæmia of special parts of the cord is the spinal irritation of most authors, and in part the reflex paraplegia of others.

The most clearly-established form of cerebral anæmia is the one which is indicated by the ischæmic paraplegia of Jaccoud and the paraplegia following profuse hemorrhages. The former is produced by all causes which, by obstructing the flow of arterial blood in the abdominal or thoracic aorta, cut off the proper blood-supply to the cord, which the latter receives through the intercostal and upper lumbar arteries. Aneurism, compression by tumors, and embolism of the aorta produce this result. The consequence is paraplegia corresponding in all features of its development to the phenomena observed in Stenon's experiment. These features, already detailed, suffice to show that it is not the anæmia of the peripheral nerves and muscles that is chiefly responsible for the paraplegia, but the insufficient irrigation of the gray and white substance of the cord itself. The same is true of the paraplegia following hemorrhage which has been noted after uterine, renal, and enteric hemorrhages. Both affections are exceedingly rare.

The influence of general anæmia on the functions of the spinal cord is not susceptible of accurate study. The cerebral enlargement of the nervous axis is so much more unfavorably situated than the cord that it suffers first and most when general anæmia is present. The consequence is that the signs of cerebral anæmia mask those of spinal anæmia. It is supposed, however, by many authorities that the effect of anæmia on the cord may be regarded as an auxiliary factor in the production of hysterical and neurasthenic symptoms.

How far the spinal cord is liable to suffer from arterial spasm is as yet a matter of conjecture. It is supposable that just as a powerful psychical impression provokes a sudden spasm of the cerebral arteries, so a peripheral irritation may provoke a spasm of the spinal arteries. In this way the reflex paralyses, motor and vaso-motor, are explained by many writers.

The subject of reflex palsy has been so much confused by improper cataloguing—if it can be so called—that some of the best authorities have become sceptical as to its occurrence. Among the chief sources of error has been the attributing to irritation of the genital organs various convulsive, psychical, and paralytic disorders. Adherence of the prepuce and its excessive length were charged with being responsible for idiocy, imbecility, epilepsy, and every form of paraplegia and pnaplegia. It was further claimed that instances of complete cure of each of these

affections had followed the removal of the exuberant or adherent prepuce. I cannot find a single instance recorded where such a cure was effected in any of our large medical centres, so as to prove convincing to critical colleagues. On the contrary, L. C. Gray¹ has shown that various surgical procedures have been needlessly resorted to on this erroneous theory in cases of organic diseases of the spinal cord. I have seen two unfortunate children suffering from the worst forms of anterior poliomyelitis, one afflicted with pseudo-hypertrophic paralysis, and several hydrocephalous and microcephalous idiots, whose prepuces had been sacrificed to the theory alluded to—it is needless to add without any result, good or bad.

The possibility of a reflex paralysis occurring from genital irritation in the male cannot be denied; among the lower animals a ligature around the spermatic cords sometimes produces paraparesis, and paraplegia is a common complication of renal and vesical troubles in others. But analogous observations in man are rare, and becoming rarer with our increasing acumen in diagnosis. In females peculiar reflex disturbances are found associated with uterine and ovarian derangements. In one case of retroflexion, with possible dislocation of the ovary, referred to me by H. J. Boldt, there is a remarkable vaso-motor paralysis of the right arm during each menstrual period: this member becomes greatly enlarged, of a purplish-blue color, and cold. Equally remarkable are the reflex disturbances resulting from the presence of worms in the intestinal canal. Every form of spinal and cerebral paralysis, even aphasia, has been observed in connection with helminthiasis. Such disorders yield as rapidly as they are developed to the exhibition of vermifuges.

Special interest has been aroused by the discovery laid down in the joint treatise of J. W. Mitchell, Morehouse, and Keen of reflex paralysis following injuries, observed in the War of the Rebellion. The cases cited by them appear singular on first sight. The paralysis is often observed in parts of the body which are not only remote from the seat of injury, but have no direct connection, physiologically or otherwise, with it. The hand may be injured and the opposite leg paralyzed.

Since Mitchell, Morehouse, and Keen first announced the existence of this peculiar form of reflex paralysis a careful search has been made by military surgeons engaged in other campaigns for like results. Notably was this done in the Franco-Prussian War. A number of confirmatory instances have been collected, some of which rival in singularity those related by the discoverers of the affection. In one case a unilateral paralysis agitans followed a punctured wound of the opposite shoulder, and in another reflex aphasia followed a gunshot wound of the lumbar region.² A discrimination is to be made between such cases where the paralysis, anaesthesia, or neuralgia is an immediate result of the injury, and those where they follow after weeks or months. In the latter instance we have not true reflex disorders to deal with, an ascending

¹ *Reflex Irritation from Genital Irritation.* In this paper written communications from all or nearly all neurologists in the United States—certainly including all those of national fame and large experience—are cited, in which they testify to never having seen a case of this character cured by operations on the penis (*Annals of Anatomy and Surgery*, Jan. and Feb., 1882.)

² *Staats-Bericht über die deutschen Heere im Krieg gegen Frankreich*, 1870-71, vol. vii.—abstracted in *Neurologisches Centralblatt*, 1886, p. 207.

neuritis having been found in the few cases which could be carefully followed up.¹

The theory that the reflex paralysis from utero-ovarian, intestinal, and surgical affections, when acutely produced, is due to central anæmia, is as acceptable as any other would be in the absence of decisive observations.

Spinal anæmia will but rarely present itself as a subject for special and separate treatment. When not associated with an intrinsically grave condition, such as aortic obstruction, dysentery, fatal hemorrhage, or typhoid fever, it is an exceedingly benign affection, rapidly yielding to tonic and restorative measures combined with rest.

Embolism, Thrombosis, Hemorrhage, and Abscess of the Spinal Cord.

Although the spinal cord is a segment of the same central organ as the brain, nourished in a similar way, and subject to the same physiological and pathological laws, lesions of the vascular apparatus, which play so important a part in brain pathology, play a comparatively insignificant one in that of the spinal cord. Embolic, thrombic, and primary hemorrhagic lesions of the cord are so rare that their possible existence has even been denied. A primary thrombosis of the cord has not yet been satisfactorily demonstrated to occur independently of syphilitic lesions; and when it occurs the ensuing tissue-changes, as described by Heubner, Julliard, and Greiff, are usually in the background as compared to the gummatous, sclerotic, or meningitic changes which coexist. The clinical as well as the anatomical picture is accordingly either one of a myelitis or meningitis, as the cases of Charcot-Gombault, Heubner, McDowell, Wilks, Wagner, Zambaco, Homolle, Winge, Moxon, Schultze, Westphal, Julliard, and Greiff show. (See Myelitis and Spinal Meningitis.)

With regard to the occurrence of hemorrhage into the substance of the spinal cord (hæmato-myelia), it is so rare an occurrence that I can recall but a single case in which I entertained the diagnosis of this lesion; and in that very case I am unable to declare that it was not a hemorrhagic myelitis. Aneurismal changes of the spinal arteries are comparatively of rare occurrence, and as other predisposing causes to primary vascular rupture are rare in the cord, the probability of its occurrence is very much diminished. Hebold,² in a young girl who had developed severe cerebro-spinal symptoms during a period of nine months following an erysipelatous disorder, found the upper dorsal cord, on section, dotted with numerous reddish and round points. These points corresponded to

¹ In a case of Mollenhauer's, vesical paralysis and paresis of the right leg occurred six years ago (1880) in a veteran of our civil war who had a gunshot wound of the right hand, with signs which are still present, of occasional exacerbation of brachial neuritis. Prodromal signs of paresis were noticed at intervals since his return from the campaign. The bladder trouble and paresis are now apparently stationary. Such a case can be accounted for only on the assumption of an organic cord-change secondary to a neuritis.

² *Archiv für Psychiatrie*, xvi. 3. Rupture of miliary and other aneurisms in the meninges has been reported by Astley Cooper, Traube, and others. It is remarkable that such cases are more and more rarely recorded from year to year in inverse ratio to the accuracy of our spinal autopsies. I have never found a miliary aneurism below the uppermost cervical level of the cord. On the other hand, I have found extensive spinal hemorrhage in cases where the vessels of the cord proper were fairly healthy.

aneurismal dilatations of the vessels. As there were other inflammatory and vascular lesions in the same subject, the author referred their causation to a general constitutional vice, the result either of the phlegmonous or of a tuberculous disorder.

It is claimed that suppression of the menses, over-exertion, lifting heavy weights, and concussion are causes of spinal hemorrhage. The same causes are also mentioned for acute hemorrhagic myelitis; and it is a question whether the supposed hemorrhage is an initial lesion or secondary to congestive or anæmic softening.¹

The symptoms attributed to spinal hemorrhage are the same, taking the same locality of the cord, as those of a very rapidly-developed transverse myelitis. It is unnecessary to enumerate these here in anticipation of the next section. They are described as being much more sudden. This suddenness is the only diagnostic aid on which we can rely.² The fate of the patient is said by Erb to be decided within a few days. If he survive the immediate consequences of the hemorrhage, he is apt to recover, as to life, altogether, with such permanent atrophies, paralyses, and anæsthesias as are entailed by the destruction of the tracts and gray substance involved in the hemorrhage. The treatment recommended for this condition consists of rest, either in the lateral or prone position, local depletion and derivation to the intestinal canal, as well as the internal use of ergotin. The local application of ice, which is also advised, is probably based on illusory views.³ After the immediate danger is past the case is to be treated as one of myelitis—a very safe recommendation in view of the probability that it was a case of myelitis from the beginning.

The descriptions given of the hemorrhagic foci as observed after death strengthen the view that they were in the majority of cases of myelitic origin. Usually, they are stated to extend up and down the cord in the direction of least resistance—that is, in the gray substance—resembling an ordinary apoplectic clot. But in their neighborhood there was usually considerable softening, and, to judge by the descriptions given, this softening differed in no wise from that which is the characteristic feature of acute myelitis;⁴ and often the transition from a peripheral zone of white

¹ I have never found vascular ruptures, although carefully searching for them, in the spinal cord of persons dying instantly after falls from a great height, or, as in one case which I was fortunately able to secure the cord of, where the subject had been violently thrown down. Where hemorrhages have been found under these circumstances they were, as far as I am able to learn from the cases recorded, meningeal.

² And even this sign is unavailable as a distinguishing feature in supposed hemorrhage from concussion, as sudden paraplegias of motion and sensation are found in some cases of railway spine, and, although a number of cases terminating fatally have been examined, there was not always hemorrhage even in the meninges.

³ Until authorities shall have agreed as to what effect the exposure of the bodily periphery to certain temperatures has on the circulation of the cord, it would be premature to make any special recommendations as to the temperature at which they should be kept. I am inclined to believe that while, as is universally accepted, a general cooling of the bodily surface tends to increase vascular fulness in the cord, as in all other internal organs, a partial cooling, as of the feet, produces local anæmia at the level of origin of the nerves supplying the cooled part. Certainly, the bilateral neural effects of unilateral cooling are in favor of this view.

⁴ In the latest treatise on nervous diseases published in our language (Ross, *loc. cit.*, vol. ii. p. 325) the insufficient foundation on which a whole chapter has been built up is illustrated by the admission that the usual evidence of acute central myelitis may be observed far beyond the limits of the hemorrhagic infiltration. If a large area of softening in the brain were found to contain a central or peripheral clot of blood, and histologically resem-

softening, through an intermediate zone of red softening, to a central compact clot, is so gradual as to leave it unquestionable that the softening pre-existed, and that a vessel had broken down in the midst of the myelitic detritus. Many ancient foci of myelitis betray the hemorrhagic complication of their initial period by the presence of pigmented residue of the absorbed clot.

Embolisms and embolic softenings of that part of the spinal cord which is supplied by the small spinal vessels are so rarely observed in the dead-house that our knowledge of their possible occurrence and character is almost entirely the result of experimental observations or based on analogy. The situation of these vessels, the angle at which their supply-tubes are given off from the aorta, all act as protectors of the cord against what is one of the chief dangers to which the brain is exposed. No definite symptoms have been attributed to the few doubtful cases of simple embolic occlusion of the spinal arteries found accidentally in human subjects. Even those emboli which, when once let loose in the circulation, are found distributed in nearly every organ of the body, those derived from ulcerative endocarditis and those due to the invasion of micrococci, are comparatively rare in the cord. Leyden found multiple capillary emboli in the spinal cord from the former cause.¹ Small grayish white foci in a similar distribution were found to be due to an invasion of coco-bacteria from a decubitus by Rovigli.¹ In this latter case an increase of pain and muscular spasm in the history of the case of sclerosis which was thus complicated was attributed to the parasitic affection.

Just as simple and infectious embolic lesions are frequent in the brain and rare in the cord, so purulent inflammation or abscess is an exceptional occurrence in spinal as compared with cerebral pathology, and probably for the same reasons.

Simple Acute Myelitis.

SYNONYMS.—Spontane (primäre) acute Rückenmarkserweichung, Softening of the spinal cord, Ramollissement blanc de la moelle, Myélite aiguë.

As Leyden, whose treatise² may be regarded as the foundation of our knowledge on this subject, correctly avers, it is to Abercrombie and Ollivier that we owe the determination of the existence of that acute structural disease of the spinal cord, now termed myelitis, as an affection independent of meningeal changes. The anatomical descriptions given by these older writers may be accepted at the present day as models of accurate observation by the naked eye. Their statement that in acute myelitis the substance of the spinal cord is softened and changed into a puriform, yellowish, diffuent mass; that while the disorganization is sometimes more marked in the posterior, at others in the anterior, and occasionally in the lateral half, it is most pronounced in the axis of the cord, because the central gray substance is the favorite starting-point

bling a typical embolic or thrombic softening, no one would be in doubt as to which of the two was the primary lesion.

of the morbid process,—requires no modification to-day. Considerable doubt existed in the minds of the contemporaries of Ollivier and Abercrombie as to whether this change was the result of a true inflammation; and one of the clearest thinkers of the day, Recamier,¹ regarded myelitic softening as a lesion peculiar to the nervous apparatus, and different from ordinary inflammation. I believe that the most profound investigators of the present day have not been able to rid themselves of a similar doubt. The discovery of Gluge's so-called inflammatory corpuscles, which was regarded as settling the question, only served to confuse the student by the confidence with which it was urged that they were infallible criteria of the inflammatory process. Under the non-committal designation of granule-cells these bodies still flourish in the annals of cerebro-spinal pathology. As we shall see, a number of products of real disease, of artifice, and of cadaverous change have passed and do pass muster under this name. The first substantial progress in our knowledge of the minute processes underlying inflammation of the spinal cord was made by Frommann and Maunkopf, but it applied altogether to the chronic inflammatory or cirrhotic affections of the cord. The difference between acute and chronic myelitis is greater than is the difference between acute and chronic inflammation in any other organ; and it must be admitted that if Recamier is to be regarded as having erred in asserting that acute myelitis is not a true inflammation, he is justified in so far as he asserted many features of the process to be altogether peculiar to the organ affected. Leyden himself attempted to throw light on the subject by provoking myelitis experimentally in dogs. He injected Fowler's solution into the spinal cords of three dogs, and in each instance produced changes which he interpreted as comparable to the myelitis of human pathology. But the inflammation thus provoked was not of the cord-substance alone; it also involved the membranes, and the inflammatory foci were in several instances purulent. Now, pus never² forms in ordinary myelitis. An abscess of the cord never occurs where a septic agency can be excluded. In six dogs whose spinal cords I wounded in the dorsal and lumbar regions by aseptic methods, and who survived from two to seven days, I never found purulent or indeed any active inflammatory process, as that term is ordinarily understood, but exactly such passive and necrotic or reactive changes as occur in the acute myelitis of human pathology.

Owing to the advance of clinical and anatomical knowledge made within the past fifteen years many forms of spinal disease classed with the inflammations have been recognized as distinct pathological entities, no longer to be confounded with simple acute myelitis, ordinarily so called. Special forms of acute spinal paralysis, notably acute poliomyelitis anterior of children and the corresponding chronic affection among adults, have become separated in this way, and are accordingly treated of in separate parts of this volume.³

¹ Cited by Leyden.

² In the textbooks and encyclopædias, without an exception, the statement that pus may be a product of myelitis is made. This is true of traumatic cases and of such depending on septic and zymotic causes alone. I am unable to find a single carefully observed case of the occurrence of pus in simple myelitis in the literature.

³ For other and practical reasons the traumatic and compression forms of myelitis are also assigned a separate place.

Some dispute exists as to the propriety of making a distinction between acute and chronic myelitis, since an acute myelitis, if the initial attack be recovered from with life, presents a similar condition clinically as chronic myelitis; and this quiescent or slowly-progressing condition may extend over many years. The term acute with reference to inflammation of the spinal cord refers only to the active period of the disease. Just as an embolic softening of the brain is an acute affection, but may be followed by a chronic paralysis or aphasia, so the acute myelitic process may be followed by a chronic paraplegia. It is improper to call the latter a chronic myelitis. It is merely a protracted symptomatic sequel of the acute process. The latter is distinguished from chronic myelitis both clinically (by the rapidity of its onset) and anatomically (by the early dissolution of nerve-elements in the focus of disease). Limited in this sense, acute myelitis, excluding the special clinical forms already adverted to, is rather a rare disease.

MORBID ANATOMY.—The most recognizable change noted in an acute myelitic focus is one of consistency: the spinal substance is softened. In some cases the softening is so slight that the observer may doubt whether he has a pathological or cadaveric softening to deal with, the dorsal cord, which is most apt to be the site of an acute transverse myelitis, being precisely the part which is most apt to show the latter change even in fairly well-preserved bodies. In extreme cases the softening may be so intense that the cord-substance, completely fluidified, runs out of the meningeal sac, leaving the latter a collapsed membranous cylinder to mark the place where the cord once was. Where the cord-substance is sufficiently firm to permit of sections being made through it, the normal outline of the gray and white substance is found obliterated, either presenting the appearance as if the gray and white matter had been stirred up together or of a more uniform color-change. The color may be either white, reddish, yellowish, or chocolate-like. It depends upon the participation of the blood-vessels in the change. If there be much hyperæmia, there will be developed what is known as red softening; if there be much extravasation and commingling of blood with the diffuent cord-tissue, a chocolate color will mark the diseased area; and similarly one and the same focus may present different tints in different parts according to the age and intensity of the process and the more or less advanced retrogressive metamorphosis of the extravasated fluid. As already stated, the purulent form of softening or abscess does not occur in ordinary myelitis.

There is considerable variation in the extent of the affected areas of acute myelitis. In the typical and severe transverse form the whole thickness of the cord may be disorganized, and the disorganization may extend in the length of the cord, so as to involve the level of exit of from two to five pairs of nerves. In less furibund cases the area of absolute softening is confined to the gray substance and its immediate neighborhood, the submeningeal white substance being but slightly affected or escaping. Sometimes several foci of intense softening are scattered through a short length of the cord and connected by less severely involved areas of softening or œdema. Leyden distinguishes three types of distribution—the transverse, the longitudinal, and the disseminated insular or multiple form. He includes under the longi-

tudinal type the so-called central softening of Albert, but undoubtedly many cases of syringo-myelia have passed under this designation. The submeningeal form of softening which, with Ollivier, he states to occur in association with spinal meningitis, must be a very rare affection, as it is difficult to find a well-established case recorded. The longitudinal form shows the same predilection for the gray substance which the acute myelitic process generally does, but I have seen a finely demarcated fascicular myelitis limited to the lateral column in a paretic negro. In this case the pyramid tract and the contiguous area in front of it were so intensely softened that for a length of twelve centimeters a hollow canal ran through the cord in the place previously occupied by the diseased substance. In recent cases of myelitis the diseased area is usually found surrounded by a transition zone in which, the morbid change gradually becoming less intense, the consistency is firmer, and which merges into that of the normal cord. In cases where death occurs after a few weeks a more abrupt demarcation is usually found; this is due to the reactive changes occurring in the neighborhood. The connective tissue becomes firmer, and thus the softening centre becomes surrounded by a sclerosing capsule. Ultimately, the centre undergoes complete disintegration and absorption, and a cavity is left behind filled with a clear fluid; in short, a cyst surrounded by a firm capsule represents the residua of disease. In cases where the softening at the centre of the focus does not proceed so rapidly nor reach so high a degree as to result in liquefaction, the less vulnerable elements, the blood-vessels and supporting tissues, survive the death of the ganglionic and conducting substance; the connective elements hypertrophy, and thus a firm sclerotic patch is formed, indicating the location of the previously softened field.

It seems to be generally admitted, with Hayem, that the blood found exuded in the hemorrhagic form of myelitis does not necessarily indicate an active determination, but is rather, like some forms of so-called red softening of the brain, the result of capillary rupture or necrosis in the midst of the disintegrated tissue, now rendered incapable of supporting the vessels. The existence of a purely white form of myelitic softening shows that a textural change is the primary occurrence, and that the participation of hyperæmia or congestion is not an essential feature of myelitis. The assumption of an initial inflammatory congestion is made rather on theoretical grounds than on the basis of observation. It is simply incredible that, as Ross¹ claims, white softening should be a third stage, preceded by red and yellow softening as a first and a second stage! How the extravasated blood, which pathologists generally allow to leave long-lasting traces, manages to disappear, and how blood-vessels in the midst of necrotic or oedematous surroundings suddenly acquire such contractile energy as to produce a total emptying of their contents while the perishable nerve-elements remain behind, are problems which should be solved before attempting to assign to a condition which is often found to be a primary phase of myelitis the position of a late and regressive stage. Erb admits that red softening, to which he also assigns the position of a first stage, is very rarely seen, only traumatic and rapidly fatal cases of central myelitis offering opportunities of examining it. None of the

¹ *A Treatise on Diseases of the Nervous System*, 1882, vol. ii. p. 280. The author states no authority, nor does he advance his own observations in support of this statement.

various forms of exudation claimed to occur at this period under the names of vitreous, colloid, or hyaline deposit have been confirmed in any recently well-studied case.¹ The great mass of authorities, however, still agree in regarding the minute changes of the initial stage of myelitis to correspond to those of ordinary inflammation. The vessels are described as injected, the adventitial spaces as crowded with the formed elements of the blood, and the vascular walls and the neuroglia infiltrated with granule-cells and fatty granular matter. By some, inflammatory changes of the neuroglia are described, but I am unable to find a single case in which these were determined in early fatal cases. As far as our observation goes, the hypertrophy of the neuroglia is a later occurrence.

As to the nervous elements themselves, they are always found affected. The nerve-cells appear inflated, their processes fragile, sometimes suddenly swollen in their course, at others very thin and brittle. Multiplication of the nuclei of the large multipolar cells has been described. It must be an unusual occurrence, as it has been confirmed by but a few of the numerous observers who have examined into this question. The protoplasm of the nervous elements loses its normal striation and fine molecular granulation; it becomes either coarsely granular or hyaline. The axis-cylinders, both in their intracineal and their intramyelinic course, show changes similar to those of the cell-processes in the gray matter. Particularly frequent are swellings in their course, the diameter of the cylinder being so much increased as to almost equal that of the myelin tube. This increase in diameter is regarded as an inflammatory swelling by some, as secondary to disturbed nutrition by others; it precedes disintegration: the substance becomes granular, fragile, and in the end dissolves. In the mean time the myelin loses its continuity, irregular segments of it fusing into round and oval masses.²

The period now reached by the morbid process may be regarded as a sort of interregnum. The necrotic tissues have not yet disappeared on the one hand, the products of inflammation have not yet organized themselves on the other. It is in this period that the ganglionic elements are described as undergoing certain changes in outline and in appearance. Above all, one change has interested observers, which, consisting in the development of what appear to be spherical vacuoles in the interior of the cell, is termed vacuolization. I can compare it to nothing so nearly as to

¹ Baumgarten's case of hyaline exudation, *Archiv der Heilkunde*, vol. xvii. 276, was an infectious myelitis and associated with anthrax.

² Many of the bodies represented as granule and colloidal cells are in reality round spheres of myelin, whose resemblance to a nucleated cell is sometimes heightened by their occasional inclusion of a fragment of an axis-cylinder which has not yet lost its power of imbibing carmine and other dyes. Where softening has proceeded farthest, there the spherical and other forms of myelin are found crowding the field, and mingled with them are blood-corpuscles, fragments of blood-pigment, granular detritus, and bodies known as fatty granular cells. A number of bodies of very different origin have received this name, some of them, like the fragments of myelin alluded to, not even meriting the name of cells. Others, however, are veritable formed histological elements, either leucocytes or cellular ingredients of the neuroglia, which, having fed on the products of myelin disintegration, have become enlarged and coarsely granular. The longer the duration of the process the more numerous are these bodies, showing that they are not the coarse and essential factor of the inflammation, but an accompaniment, subserving some conservative process, inasmuch as they either remove effete material or contribute to the permanent organization of the cicatricial or atrophic tissue.

the appearance which is produced by the formation of gas-bubbles in a putrefying albumen or other semifluid substance.

This vacuolization of ganglion-cells is now regarded as a cadaveric change. It is not agreed, as yet, whether its occurrence in myelitis is so frequent as to suggest its ante-mortem occurrence as a veritable feature of the disease. I have been struck by this change in the neighborhood of wounds artificially produced in dogs, even in the fresh specimen. It must be remembered, however, that under these circumstances, the nutrition of the cell being destroyed and exposure to the macerating effect of the cerebro-spinal and pathologically exuded fluids occurring, a cadaveric change may take place *intra vitam*.

The influence of phosphorus and alkaloid as well as metallic poisons on the cord has been experimentally studied by a number of observers. Unfortunately, Popow, Tschisch, and Danillo—who described as characteristic a resulting change in the staining reaction of the cells, the development of vacuoli in them, and an atrophy of their processes—had not made a sufficient number of examinations of normal cords under like methods of preparation to recognize which of these deviations is without the physiological confines. Kreyssig¹ demonstrated the existence of all these conditions in the cords of perfectly healthy animals preserved in chromic acid;² and Schultz confirms him, and expresses a surprise, which must be shared by all reflecting investigators, that poisons of so widely different a character should have an identical effect on the cord-substance, as is claimed by the writers named.

If life be prolonged and the conservative processes assert themselves, the disintegrated material disappears, and as the white color of the greater area of the cord was due to the myelin, and the latter has now become destroyed within the diseased area, the latter presents a grayish color. This phase is often termed gray softening. The consistency is, however, much firmer than in the previous stage. Trabeculæ of connective tissue form, enclosing in their meshes a large number of neuroglia-nuclei and sometimes spaces filled with fluid. According as condensation and retraction or rarefaction preponderate the process will terminate either in the formation of a sclerotic focus or of a cyst. Occasionally an irregular spongy tissue containing several small cysts results.

Charcot claims that a restitution of anatomical continuity, and therefore of physiological potentiality, may occur in a myelitic cicatrix. But the experiments of Kahler³ and Homén⁴ prove that when a nerve-tract

¹ *Virchow's Archiv*, cii.

² He attributes the remarkable difference in staining of nerve-cells of the same ganglionic group and in the same section to the sudden transferral of the hardened specimens to strong alcohol, which seems to be the custom in some German laboratories. He claims that uniformity in staining is effected if the specimen be transferred from the chromic preparation to weak alcohol, then to stronger, and thus by gradual increase of the strength to strong spirit. Possibly, instead of approximating the real structural indications by this method, Kreyssig may obliterate them. In specimens which alcohol is not permitted to touch before staining is completed, very deeply and very lightly stained cells will be found almost side by side. The shorter the hardening process, the more perfect the staining method, the more likely are these differences to be found. It is reasonable to assume that the difference in dye-absorbing power indicates slight differences in the cell-protoplasm, marking the nutritive state of the latter and occurring within physiological limits.

is once destroyed within the spinal cord all hope of restoring that tract in structure, and thus to restore its functions, is at an end. Unlike the fibres of the peripheral nerves, those of the spinal cord and brain do not seem capable of regeneration.¹ If a restoration of function is to occur at all, it must occur through other channels than those destroyed—in other words, by vicarious action.

In a large number of cases myelitis is a limited affection; that is, its ravages remain confined to the area originally involved. But occasionally the morbid process involves the next segments above or below, extending with specially great rapidity through the anterior gray horns. Exceptionally, the entire cord may thus become the site of a generalized myelitis. There is one segment of the cord which may be regarded as possessing an acquired vulnerability when a myelitic focus is in its neighborhood, and that is the lower end. It seems that while the results of a transverse myelitis in the middle dorsal cord may remain stationary for ten or more years, those of a transverse myelitis at the upper lumbar level do not; on the contrary, the entire cord below the lesion appears to be doomed to undergo the same degeneration by contiguity. This is the only occurrence which seems to deserve the name of a descending myelitis: an ascending extension is more frequently noted in other parts of the cord, but the frequency of both the so-called ascending and descending types has been unduly magnified by the inclusion of the secondary degenerations, which are constant sequelæ of all complete destructive transverse lesions of the cord, but which are rather passive phenomena, and probably influence the clinical progress of the case but little, except under such conditions as are potent in that chronic form of myelitis which underlies *tabes dorsalis*.

CLINICAL HISTORY.—The symptoms of acute myelitis usually correspond to those of any more or less completely transverse lesion of the cord, and accordingly vary with the altitude of the upper level of the lesion. In a general way, they may be stated as consisting of—

First, paralysis of movement in the parts supplied from the nerves given off below the level of the lesion. The reason for this can be easily recognized in those cases where the pyramid tract, which conveys voluntary impulses centrifugally, is interrupted by the softening.

Second, paralysis of sensation in the parts supplied by the same nerves. This is equally explained by the pathological interruption of the centripetal impressions normally conveyed brainward.

Third, alterations in the nutrition of the parts supplied by the nerves arising in the affected level.

Fourth, abolition of those reflexes which are translated in the level of the lesion.

Speaking crudely, then, the symptoms of a transverse myelitis fall into two natural groups. The one which includes the first and second categories enumerated are symptoms due to interruption of cerebral functions; the other, which comprises the last two categories, being due to abolition or perversion of spinal functions. There is a third group comprising certain constitutional symptoms.

¹ According to the first observer, this is probably due to structural differences. The extramedullary fibres have a sheath and annular constrictions which are absent in the intramedullary.

Aside from those variations due to the distribution, extent, and intensity of the lesion there are others which depend on the rapidity of its invasion. There are three types in this respect—the apoplectiform, the ordinary acute, and the subacute. The term apoplectiform has been used in two different senses, one being clinical, and referring to the rapidity of onset of the symptoms; the other anatomical, and referring to the nature of the lesion. It is, however, doubtful if a distinction in the latter sense is practically valuable. The presence of a blood-clot in a myelitic focus is itself secondary to the softening, and the intensity and rapidity of the process must have shown itself in the development of the latter.¹ The term ought, therefore, to be used in a clinical sense only.

The constitutional symptoms of acute myelitis—which, however, are often absent—are its most distinctive features in one sense. Disorders of motion and sensation and perversions of nutrition are signs common to all destructive affections of the cord, whether of a traumatic, neoplastic, or a chronic inflammatory character. But fever, headache, and delirium,² associated with gastric and visceral disturbances of acute development, are not found to be initial and intrinsic symptoms with them as with acute myelitis. In their absence the mode of onset is characteristic. A high degree of paralysis, motor or sensory, is developed with a rapidity unequalled in any chronic affection of the cord. Sometimes there is a prodromal period in which formication, numbness, and disorders of movement are observed in the same part of the body which are destined to become paralyzed at a later stage of the malady. Within a few hours, days, or at most weeks, complete paraplegia may become developed. The prodromal symptoms may include any form of disturbed sensation. Lancinating pains, tingling, a feeling of the limbs falling asleep, peculiar and indescribable sensations attending the acts of micturition and defecation or of placing the feet violently on the ground, are common. Occasionally they are found in one limb only, although motor and sensory paralysis may ultimately occupy the symmetrical member as completely as the one first involved. In some cases it has been noted that the patient is unable to lie down, or, if lying, to occupy the dorsal recumbent position. This feature has been utilized to support the theory of an initial congestion, which is supposed to be relieved or aggravated according as the cord is kept elevated or depressed.

In most cases of transverse myelitis, when the anterior cornua are destructively involved, we possess in the electrical tests valuable and unerring means of determining the altitude and extent of the lesion. Whenever we find the atrophy of a paralyzed muscle accompanied by qualitative electrical changes in myelitis, we must conclude that the cell-group from which that muscle receives its nerve-supply is destructively involved.³ These changes are particularly well demonstrable when the

¹ I am able to recall but a single case in which, even clinically speaking, a primary hemorrhage into the cord-substance was plausible. In this instance a sudden arrest of menstruation had occurred nearly simultaneously with a combined strain and exposure in a young girl.

² These symptoms are to be regarded as actual parts of the myelitic symptoms only when they accompany the prodromal or initial periods. The later complications, uræmia and septicæmia, the latter arising from pyelitis, cystitis, or decubitus, often lead to constitutional disturbance which is not due to the myelitis as such.

³ The proposition, originally, I believe, made by myself, that there are distinct cell-groups in the spinal cord which are constant with certain animal species, and correspond

cervical or lumbar enlargements are affected. They are not as readily ascertainable in the case of a transverse myelitis in the upper dorsal region, on account of the situation of the muscles supplied by the upper dorsal nerves, and the consequent difficulty of application of the necessary tests.

The disturbance of the deep reflexes with very few exceptions affects the same peripheries as are represented in the destroyed and impaired gray nuclei. Thus, if the lower part of the lumbar enlargement be affected, the reflexes of the Achilles tendon and the gluteal muscles will disappear; if the upper lumbar enlargement, the knee-jerk disappears.¹ Disease of the lower part of the cervical enlargement is in like manner associated with absence of the wrist-tendon reflexes, while the disappearance of the elbow-tendon reflex suggests a higher involvement at the levels of the fifth and sixth cervical nerve-roots.

In complete transverse acute myelitis of the cervical region high fever is a constant symptom. In unilateral myelitis of this region flushing of the face and unilateral sweating are produced, together with iridoplegia, sometimes preceded by dilatation, owing to initial irritation and succeeding paralysis of the sympathetic branches originating at this level of the cord.

Just as the disturbed reflexes and the belt sensations enable us to distinguish at what levels of the cord the myelitis is situated, so the distribution of the motor and sensory paralysis affords corroborative evidence of such location and additional proof of its extent and intensity.

Transverse myelitis at and above the level of origin of the phrenic nerve is almost immediately fatal, through its interference with the innervations required in respiration. In the upper part of the cervical enlargement it produces complete paraplegia of motion and sensation in the trunk and all four extremities. In the lowest part of the cervical enlargement it produces paralysis of the same parts, but the serratus magnus and scapular muscles escape. The nuclei of origin of the muscles moving the upper extremity are situated so that those which are farthest removed from the axis of the body when the arms are extended are situated lowest in the cord. The sensory paralysis is distributed in harmony with the motor paralysis; that is, when there is paralysis of motion in the hand

in relative development to ventral, dorsal, and appendicular muscular groups ("Architecture and Mechanism of the Brain," *Journal of Nervous and Mental Diseases*, April, 1880), appears to be confirmed in a general way by the researches and cases of Edinger, Kahler-Pick, Dejerine-Major, Genzmer, Von Monakow, Sahli, Prévost-David, F. Schultze, Remak, and Parrot-Joffroy; for the knowledge of the first and last of which I am indebted to the review of the subject by Starr ("Localization of the Functions of the Spinal Cord," *American Journal of Neurology and Psychiatry*, August, 1883).

¹ The disappearance of the knee-jerk and similar reflexes was originally supposed to be a phenomenon exclusively pertaining to spinal disease and to a destructive lesion anywhere in the track of the centripetal and centrifugal nerves connected with that segment of the cord in which the reflex is supposed to be translated. But aside from a number of physiological observations* which prove that cerebral conditions may influence the intensity of the jerk, there are pathological ones which show that it may be permanently abolished in disease of the pons and cerebellum, and temporarily abolished or diminished immediately after capsular and ventricular hemorrhage. The associated symptoms in the former case, and the history of the onset and total hemiplegia in the latter, serve to distinguish them from destructive spinal lesions should the occasion for discriminating between them ever arise; which is not likely.

* S. Weir Mitchell and M. J. Lewis found that voluntary effort increases the jerk at first, but if continued diminishes its excursive force (*The Medical News*, 1886, Feb. 13th and 20th).

and forearm the anæsthesia or subjective numbness is also in the hand and forearm. The same correspondence is not found in affections of the lumbar enlargement, for anæsthesia of the gluteal region accompanies paralysis of the crural muscles when the lesion is low down at the level of the lower lumbar and upper sacral nerves. The distribution of the anæsthesia, in other words, is not by segments of the limb, but by surfaces. The gluteal, posterior femoral, gastrocnemial, and outer pedal surfaces are affected together with the muscles moving the foot, while the thigh and inner side of the leg and foot become anæsthetic, with lesion of the upper part of the lumbar enlargement accompanying paralysis of the quadriceps and deep muscles. It is not difficult to understand this discrepancy when we bear in mind the different plan of distribution followed by the brachial plexus as compared with the lumbar and sacral plexuses. It is not, in my experience, found that the anæsthesia affects that surface which covers the part moved by the paralyzed muscle; which is characteristic of associated paralysis and anæsthesia from cortical disease.

One of the most dreaded occurrences in acute myelitis is the malignant bed-sore. The ordinary decubitus which results from the protracted sojourn of the patient in bed, coupled with the prominence of his trochanters and sacrum resulting from general or atrophic emaciation, is also common, but is comparatively benign and easy to prevent or to manage when established. The malignant bed-sore, on the other hand, is a spontaneous occurrence, due to the same obscure but undeniable trophic influences exerted for good by the normal and for evil by the diseased nerve-centres, which play so large a part in the symptomatology of *tabes dorsalis*. It cannot be avoided; it is not due to pressure alone, or, as some have claimed, to the macerating influence of the dribbling and decomposing urine. The development of this lesion is exceedingly rapid, and it may be regarded as a sort of local gangrene. The skin shows a livid color; vesicles appear, then burst; the part becomes denuded; and within a few days a deep ulcer with a dark border and base appears, discharging a sanious fluid. The subsequent history is that of a rapid extension and destruction of the neighboring tissues, even down to the bone, and if situated over the sacrum opening into the spinal canal through the necrotic arches of the sacral vertebra, thus leading either to general septicæmia or to putrid infection of the spinal meningeal sac. Occasionally, gangrenous spots coexist on other parts of the body, notably the lower extremities, where neither pressure nor maceration can be accused of playing a part, proving that the process is primarily due to the spinal affection.

Acute central myelitis, as described by Dujardin-Beaumetz, Hayem, Hallopeau, and Erb, usually runs its course very rapidly. Indeed, all of these observers speak of it as the most violent and quickly fatal variety of spinal inflammation. I have, however, seen one case with T. A. McBride at the Presbyterian Hospital in which all the characteristic symptoms of acute central myelitis were markedly developed and present in their characteristic groupings, and yet the patient had been suffering from progressing symptoms of myelitis for one year and a half before that time.¹

¹ At the time the patient had undergone such a profound change in appearance that I failed to remember him, and it was only by accident I learned that I had seen him in

Usually, complete anæsthesia and paralysis of the lower half of the body occur in this form. But the most characteristic feature is a rapidly progressive atrophy not only of the paralyzed muscles, but also of some which are still partially under the dominion of the will. With this there is extreme vesical and rectal trouble, the sphincters being paralyzed. As a rule, the deep and superficial reflexes are destroyed—they are always diminished—and trophic disturbances of a malignant type, such as acute decubitus, joint-changes, and œdema, are common. The paraplegia is characterized by the flaccid condition of the limbs; the contractures and spastic symptoms found with other forms of myelitis are entirely absent, and qualitative electrical changes, beginning with disappearance of farado-muscular contractility, are found in the atrophying muscles. There are marked constitutional symptoms with this form; the tendency to an ascent of the process and successive involvement of one segment after another of the gray matter is great, and a fatal issue, as far as known, is inevitable.

DIAGNOSIS.—The principles governing the determination of the affected region of the cord in acute myelitis are exactly the same as those detailed in the later sections on Chronic Myelitis or Sclerosis, the acuteness of the onset, and the relapses which sometimes occur, and the predominance of irritative spasms—which, however, is an inconstant criterion—serving to distinguish between the acute and chronic form of spinal inflammation. In the present state of our knowledge it is impossible to always differentiate between acute central myelitis and syringo-myelus—a condition in which the formation of a perieudynal neoplasm, and its subsequent breaking down in the axis of the cord, lead to the formation of a tubular cavity.¹ The neoplasm in this instance is classified among the gliomatous new formations. The symptoms depend, exactly as do those of myelitis, on the distribution of the destructive lesion. In some cases the posterior cornua and columns are chiefly involved, and extreme anæsthesia is found; in others the anterior columns are affected, and the symptoms of a poliomyelitis or an imperfect transverse myelitis may be imitated.²

As a rule, the sensory disturbance in syringo-myelus is out of proportion to the muscular atrophy developed; that is, it involves a far more extensive province. It is usually of a peculiar character: some forms of sensation are involved but slightly, or even escape, and others may be nearly destroyed. Commonly, it is the pain and temperature-sense which suffer most, while the cutaneous space and pressure, as well as the muscular sense, are not materially disturbed. These peculiarities are not commonly found in cases of myelitis, and when present, and particularly when the paralytic or sensory affections involve all four extremities

private consultation with his family attendant, F. A. McGuire, a year previous. On the latter occasion I had made the diagnosis of subacute myelitis chiefly limited to the posterior columns; there were ataxia, both static and locomotor, slight incontinence, belt sensation, and ocular symptoms, with abolition of the deep reflexes in the lower limbs.

¹ This cavity, unlike that of hydro-myelus, is not a dilatation of the central canal, but, lying to one side of it, is excavated in the cord-substance.

² Repeated fractures have been noted in cases marked by profound analgesia. It is believed that they are not always due to trophic changes, but may be the result of muscular action, exaggerated on account of the patient's inability to gauge his efforts. Still, in the majority of cases the presence of positive trophic disturbances of the skin seems to indicate the probability of some textural change facilitating the fracture.

alike, they suggest the existence of syringo-myelus. As yet we are unable to make more than a probable diagnosis between the two diseases.

DURATION AND PROGNOSIS.—The duration of the disease varies. Cases of the apoplectiform variety are mentioned, in which the process reached its height in a few minutes, or where the patient, having retired in good health the night before, awoke finding himself paralyzed in the lower half of his body. Death may terminate such a case in a few days or weeks. In another class of cases, complicated by serious involvement of the bladder, the fatal termination is often precipitated by putrid cystitis, pyelitis, or uræmic poisoning, and even in cases which have passed the dangers of the early period in safety these ominous complications may develop with the usual result many years after the beginning of the illness. In a number of cases the first period, that in which the morbid process becomes developed, is followed by one of comparative quiescence, in which the paralyses of sensation and motion then established remain stationary for months and years. A number of authors, Erb, Leyden, Strümpell, and Ross, speak of such a case as one in which chronic myelitis has followed an acute myelitis. It seems improper to use the terms acute or chronic in this way. As it is generally understood that the term acute applies to myelitis in which disintegration of the nerve-elements predominates over interstitial proliferation, and in which the secondary sclerosis is rather like the cicatrix of an acute inflammation and necrosis, it should not be confounded at any period, no matter how similar the clinical signs may be, with a process which is essentially an interstitial one from the start. If chronic amaurosis results from an acute glaucoma, we do not change the latter designation to chronic glaucoma.

In cases where the symptoms at the acme indicate rather an involvement of the peripheral than the central paths of the cord, and in which an incomplete motor and sensory paralysis develops, the patients often regain a considerable amount of motor power and sensation, so that they may reach a good age, suffering at most from a paresis of some one muscle or muscular group, occasional bladder trouble, and pains. It has been laid down as a rule that where paraplegia and other signs remain stationary for years, there is no hope of even partial recovery. The following remarkable and well-attested case proves that this rule is not without exceptions:

Isidor K——, æt. forty-four years, worker in tobacco. After over-exertion in the fall of the year 1879 he had numbness, tingling, dorsal pain, and paresis rapidly developed, which induced him to consult the physicians at the clinic of the University of the City of New York. After some slight improvement a relapse occurred, and several others followed, usually provoked by over-exertion, till he became completely paraplegic. He was, according to his account, several times exhibited to a medical class by Willam A. Hammond, and remembers that this authority spoke of a possible ascent of the affection and ensuing involvement of the arms. His bladder was at no time seriously disturbed. For four years and three months he was totally paraplegic; his lower extremities were without life; and for the greater part of the time he could not move his toes. The limbs were cold and pale, but underwent little atrophy. The only exercise obtained during this time was in a roller carriage. His sexual power was abolished throughout the whole

four years and over. Nothing can be learned as to his reflexes in this period.¹ The paralysis of sensation was as complete as that of motion, and the lower limbs never perspired. The arms remained free. There was a dorsal belt sensation.

On July 23, 1884, shortly before mid-day, while lying on the bed, in which he had lain a helpless cripple for over four years, except when lifted into the roller carriage, he felt a sudden rush of warmth. Surprised at this first sensation he had felt for years in limbs which had been quasi-foreign appendages, he raised up the bed-clothes and saw that they changed color. There was some tingling for about three minutes, and a perspiration broke out in the affected members. With this he found he could move his feet: half alarmed, half exulting, he sent for his physician, L. Weiss, who found that the patient could stand and walk with considerable freedom. I was then consulted, and found the patient presenting a picture of incomplete transverse myelitis. He could walk, turn about, stand with closed eyes with slight swaying, and his knee-phenomenon was of short excursiveness, but exceedingly spasmodic, and this symmetrically so. He was carefully watched, and against the advice of his physician engaged in peddling cigars, and subsequently took a position as attendant at the pauper asylum on Ward's Island. Here he was on his feet fully twelve hours a day, and his motion, which had continued improving until it was to all practical intents and purposes normal, aside from a slight stiffness, again became impaired, and a joint trouble in the metacarpo-phalangeal articulation of the right little toe, which had troubled him a week after his partial recovery, recurred.² On January 15th of the present year I again examined him. His knee-phenomenon was greatly exaggerated, cutaneous sensations scarcely impaired, gait paraparetic, but he could walk great distances, and claimed to suffer less from the exertion than from the tenderness accompanying the joint trouble referred to. There had, therefore, occurred, without any assignable cause—for the patient was not under treatment for a year or more before the event—an almost instantaneous restoration of sensation, locomotion, and sexual power; all of which faculties, notwithstanding the infraction of every medical direction given, remained established for two years, with prospects of so continuing a longer period.

TREATMENT.—Most of the therapeutic propositions relating to the treatment of the acute myelitic process are based on the theory that it is of a congestive character or associated with congestion. Accordingly, the internal administration of such drugs as ergotin, which diminish the calibre of the blood-vessels, and local measures, such as depletion, wet cupping, and counter-irritation, intended to act in the same way by derivation, are unanimously recommended by authorities. The suggestion of Hammond, that the patient occupy a ventral or lateral, and not the dorsal, position, is based on, and entirely consistent with, this same view. It is difficult to say what effect is attributable to these measures. Remarkable spontaneous changes—retrogressions as well as advances of the morbid process—occur equally under expectant as under active treatment. I have never seen any improvement in the active phase of simple myelitis which

¹ Hammond has no notes of the case, having discontinued the clinic, and Ludwig Weiss, the physician in charge, saw him only occasionally in behalf of a benefit society.

² This was a trochic joint trouble.

I felt confident I could attribute to any special remedy employed with a view of acting directly on the morbid process. Indeed, improvement has been claimed by Jewell as a result of the use of strychnia—a drug which under the very dogmas governing the orthodox treatment of the disease might be expected to do positive damage.¹

In relapses of acute myelitis which had been brought on by chilling of the feet I have obtained good results by derivation to the lower extremities, and on many grounds think that the morbid process in the cord, if it can be affected at all, can be affected by treating the periphery where the symptoms are noted more readily than by applying the cautery or bleeding over the proven site of the disease. Exposure of the dorsal region to cold has not yet been noted as a cause of acute myelitis, whereas such exposure of the lower extremities is a frequent one. This seems to show that the spinal cord is more vulnerable to influences affecting its nervous distribution than to those which are topographically nearer. If this is true as regards morbid influences, it may be urged that it is plausible as regards remedial influences if these are to drive out the disease tendency by the same door it entered.

Rest is imperative during the active progress of the disease. It may be stated as a canon that the earlier the patient takes to his bed, and the more thoroughly he obeys the injunction to attempt no motion of the affected members, the better, *cæteris paribus*, will the result obtained be. Countless cases are on record where a relapse was directly traceable to a walk undertaken prematurely or carried farther than was wise. As convalescence or partial restitution advances, gradually increasing exercise is to be attempted, not waiting for the danger-signal of a tired feeling to discontinue it; for that feeling, developed, means positive harm already done. It is therefore necessary to allow the returning function to be utilized only within small limits at first, and extending them slowly.

In all cases of severe myelitis where the formation of bed-sores is to be apprehended the water-bed should be employed. Owing to the low temperature which the rubber sac constituting it has, it is necessary to cover it with some well-warmed and non-conducting material and to have the room well warmed. If bed-sores are already formed, they are to be treated according to ordinary surgical principles. Antiseptic means should be in the foreground in the case of the malignant bed-sore. It is to be remembered that the latter is a gangrenous process, and, in so far as the formation of a line of demarcation between the necrotic and the conserved tissue is concerned, the ordinary expectant rules of surgery govern the case: the water-bath appears to yield the best results. Ordinary bed-sores yield readily to mechanical protection and stimulating ointments or the balsam of Peru. Iodoform is recommended, but it produces granulations of an indolent character as compared with those obtained through the use of resinous ointments.

The warm bath is probably the most useful measure in acute myelitis.

¹ Jewell gives very large doses of this alkaloid. L. C. Gray, in a discussion held before the American Neurological Association, cited numerous observations directly conflicting with those of Jewell. I cannot, in view of a recent observation in a typical case of acute anterior poliomyelitis, in which by accident the toxic effects of strychnia were obtained, consider this dispute as at all settled. In direct connection with the toxic symptoms the abolished patellar jerk returned in an exaggerated form; motion also returned, and rapid improvement ensued.

In cases due to exposure I do not believe it can be applied too soon. Its temperature should, in the beginning at least, not be higher than about 88° F., and the duration about seven minutes. The continued administration will depend on the immediate effect on the patient, and the sittings can be ultimately prolonged to half an hour or even longer. It should be administered once daily, and, when the patient is not disturbed by the manipulation connected with its use, even oftener. Cold baths are recommended by the Germans, but it seems rather in the passive period of the disease than during its active phase.

The management of the bladder trouble is one of the most critical points in the treatment of most cases. The results of retention of urine are more frequently the cause of a fatal issue than any other single complication. Where there is complete retention continuous catheterization is to be employed, as recommended by Strümpell.¹ In other cases the bladder should be emptied thrice in the twenty-four hours. The catheter is to be thoroughly disinfected, and if the slightest sign of cystitis is noted the bladder should be washed out with astringent and disinfectant solutions. The continuous irrigation with a solution of corrosive sublimate, 1 : 2000, appears to give the best results.

If there be a syphilitic taint present—and more particularly is this true of cases where no other cause can be assigned—large doses of iodide of potassium² should be administered, and mercurial ointment energetically applied, even to the point of salivation.

I am unable to say anything with regard to the local use of electricity in the active period of the disease. Ascending currents are recommended by Erb, weak currents of about five minutes' duration being employed over the part supposed to be affected. In order to secure sufficiently deep deflection of the current large electrodes are applied. The use of galvanism and faradism on the affected periphery, the former being preferred where atrophic, the latter where anæsthetic conditions preponderate, is to be instituted early and continued through the duration of the disease. The rules stated in the section devoted to electro-therapeutics are to be followed. In cases where the bladder or rectum are paralytic, these organs should have galvanism applied to them by means of electrodes shaped like catheters or sounds.

After the acute phase of myelitis is passed, the secondary period is to be managed according to the principles laid down in the section on the Treatment of the Sclerotic Processes.

¹ A. Nelaton's catheter is introduced into the bladder, and kept in place by strips of adhesive plaster fixed to the inner aspect of the thighs. A perforated condom fixed to the catheter, and then fastened to the inguinal region, is in my opinion a better measure, especially in patients who have some motor power left. The catheter is connected with a rubber tube, which should run on a decline in order to effect complete drainage.

² Here, if anywhere, the so-called heroic doses are applicable.

THE CHRONIC INFLAMMATORY AND DEGENERATIVE AFFECTIONS OF THE SPINAL CORD.

By E. C. SPITZKA, M. D.

THE intimate dovetailing of parenchymatous and connective substance in the spinal cord renders the determination of the precise origin of a morbid process often difficult if not impossible. Whatever the mode of origin, the typical termination of inflammatory and degenerative spinal disorders is sclerosis—a condition in which the essential nervous elements suffer diminution or destruction, while the connective substance is either absolutely or relatively in preponderance. The clinical result is nearly the same in all cases, and with few exceptions depends less upon the histological character than on the topographical distribution of the lesion. It is for this reason that we shall follow rather the topographical than the morbid histological principle in classification.

The chronic disorders of the spinal cord here considered have as a common character the slow and progressive displacement of the normal conducting nerve-tubes by a grayish, reddish, or otherwise discolored tissue, which is firmer in texture than normal nerve-substance. Minute examination shows that it is above all the myelin of the nerve-tubes that is wasted or destroyed, while the axis-cylinders may share in this dissolution, or, as in one form of sclerosis, they may persist and even continue in their conducting function. This increased consistency is found to be due to the increase of connective-tissue trabeculæ and of the neuroglia. In some cases this increase is active and absolute, like the increase in certain phases of hepatic cirrhosis; in others it is rather relative and passive, being merely a condensation of the connective framework after the intervening elements have wasted away, just as the texture of a compressed sponge is more compact than that of an expanded one.

Crudely, the affections of the cord characterized by this change may be divided into two great groups—the regular and the irregular. The former are characterized by their limitation to special nerve-tracts. Thus, in primary lateral sclerosis we find a special tract in the posterior part of the lateral columns occupied by the lesion. A number of spinal diseases with well-defined symptoms are due to active morbid processes which similarly follow the normal distribution of the great nerve-tracts of the cord, with the same, almost mathematical, regularity with which the medullary white develops in the foetal and infantile cord. In another class of cases we find that the same tracts are involved in like manner—not in the way

of primary disease, but through the interruption of the physiological continuity of the nerve-tract by some other disease, to which the sclerosis is therefore secondary. These are the so-called secondary degenerations.

The irregular affections of the cord comprise cases in which the sclerotic foci are either disseminated through the cerebro-spinal axis in numerous foci, or diffusely involve a greater or lesser length and thickness of the medullary cylinder, or, finally, extend in the transverse plane completely or nearly so across the section area of the cord at a definite level.

As the symptoms of the regular affections of the cord are by far the most readily recognizable, and a preliminary knowledge of them will facilitate the better understanding of the irregular forms, we shall consider the former first. They may be subdivided into two groups. The largest, longest known, and best studied consists of acquired, the other, containing less numerous cases and varieties, and rendered familiar to the profession only within the last decade, comprises the spinal disorders due to defective development of the cerebro-spinal and spinal-fibro systems.

Tabes Dorsalis.

SYNONYMS.—Locomotor ataxia and ataxy, Posterior spinal sclerosis; Graue degeneration der Hinterstränge (Leyden), Rückenmarksdarre (popular), Rückenmarksschwindsucht; Tabes dorsualis (Romberg); Ataxie locomotrice progressive (Duchenne).

HISTORY.—Undoubtedly, this disease must have been observed by the ancient masters of medicine, but their descriptions group together so many symptoms of other organic as well as functional diseases of the cord that it is impossible to obtain a clear idea as to what special form they had in view when they spoke of tabes dorsualis. This term was adopted by the German writers of the last and the earlier part of this century as designating all wasting affections of the cord; and it was not till Romberg in 1853 and Duchenne in 1858 differentiated the characteristic clinical signs, and Cruveilhier and Todd (1847) determined the distribution of the lesion in the posterior columns, that the medical profession began to recognize the distinctness of this the most common form of organic spinal ailment.

At this time, when tabes dorsalis became recognized as a clinical entity depending on sclerotic degeneration of the posterior segment of the cord, the inco-ordination or ataxia manifested in the peculiar gait of the patient was regarded as the most characteristic, essential, and constant symptom of the disease. It was regarded as an axiom in physiology that the posterior segment of the cord was subservient to centripetal and sensory conduction, and nothing appeared to follow more naturally than the conclusion that the patient exhibited inco-ordination because, his sensory conduction being interrupted or destroyed, he had lost the necessary gauge for judging of the required extent and force of a given movement. Since then both spinal physiology and pathology have undergone a profound revolution. So far are we to-day from regarding anterior and motor or posterior and sensory as convertible terms that we locate the

most important centrifugal tract of the cord behind the plane which divides it into anterior and posterior halves, while the most recently differentiated centripetal tract is represented by Gowers as lying in front of it. It has been determined, through Türek, Bouchard, and Flechsig and his pupils, that the posterior white columns of the cord contain several systems of fibres, whose functions—where determinable—are of an exceedingly complex nature. The elaborate investigations of Charcot, Schultze, and Strümpell, made during the past decade, have shown that the distribution of the diseased field in the posterior segment is not uniform, but is most intense in special areas. These were found to be affected with a remarkable constancy and regularity. Almost coeval with this discovery came the recognition of symptoms found in the earliest phases of the disorder by Westphal, which, attributable as they were found to be to the involvement of the special reflex mechanisms of the cord, enable us to demonstrate the existence and extent of the disease at periods which previously were not within the ken of the clinician. The reproach which Leyden was justified in making, that most tabic patients pass through the pre-ataxic phase of their disorder under the diagnosis of rheumatism or some similar affection, can now no longer be made. Our ability to recognize the advent of this disease has reached such a degree of refinement that the question arises whether we are always justified in alarming a patient who has a prospect of remaining free from invalidating complications for many years with the announcement of a disease which, above all other spinal affections, is looked upon with dread as equally hopeless, insidious, and distressing.

CLINICAL HISTORY.—The development of tabes dorsalis is typically slow and its precise commencement usually not determinable. In some cases this or that one of the characteristic symptoms of the disease preponderates from the beginning, and continues throughout the illness as a prominent feature; in others distinct stages can be recognized, each marked by one or several symptoms which were absent or slight in the other stages. In some cases the progress of the affection is marked by episodes which are absent or rare in other cases. As a rule, however, it may be stated that tabes is a progressive affection, marked by pronounced temporary changes for better or worse, which are often developed with astonishing rapidity, and subside as quickly, terminating fatally unless its progress be arrested by treatment or interrupted by some other fatal affection. The latter is by far the more frequent termination in the well-to-do class of sufferers.

For purposes of convenience we may consider the symptoms of the earlier period of the illness as pre-ataxic, and those of the later as the ataxic. It is to be remembered, however, that in the strictest sense of the term there is usually some disturbance of co-ordination even in the early period, while the symptoms of the pre-ataxic period continue over the ataxic period, and may even become aggravated with it. Often the patient does not himself suspect a spinal, or indeed any nervous, disorder, and consults the physician either on account of rheumatic pains, double sciatic neuralgia, bladder disturbance, diminished sexual power, amaurosis, diplopia, or even gastric symptoms, which on closer examination are revealed to be evidences of tabes. The determination of the initial symptoms is retrospective as a rule.

Of the subjective signs, one of the commonest, if indeed it be ever entirely absent, is a tired feeling, particularly noted in the knees and ankles. This sensation is compared to ordinary muscle-tire, but is provoked by slight exertion, and not as easily remedied by rest. Often a numb feeling is associated with it, although no objective diminution of cutaneous sensation be determinable. This combined feeling of tire and numbness, described as a going-to-sleep feeling in the ankle, has indeed been claimed by one observer¹ to be pathognomonic of early tabes. Next in frequency, and almost as universal, are peculiar pains: these are manifold in character and distribution, but so distinctive as to alone suggest the existence of the disease from the manner in which the patient describes them. One variety, the lightning-like, is compared to a sudden twinge of great intensity shooting through the limb. The sciatic and anterior crural branches are the lines usually followed by this pain, but there are cases where perineal and abdominal regions are affected. Often the pain is so severe that the patient cries out or the limb is violently contracted under its influence. It differs from rheumatic pain in the fact that it is distinctly paroxysmal and that the intermissions are complete; that it is not greatly aggravated by motion nor relieved by rest, while the rheumatic pain is; that tabic pain is usually relieved, and rheumatic pain aggravated, by pressure, while hyperæsthesia is present with the former, and either absent or barely indicated with the latter. The lightning-like pains are sometimes combined with another form, which is even more distinctive in character. This form does not affect the distribution of special nerves, but is found limited to a small area which the patient is able to localize definitely: it may not exceed a centimeter or two in diameter, and within this area the pain is excruciating. It is either of a burning character or compared to the firm pressure of a vise or heavy weight, or to the tearing, boring, and jumping of a violent toothache.

While some patients escape these pains almost entirely,² others are tormented with them at intervals for years, their intensity usually diminishing when the ataxic period is reached. There is little question among those who have watched patients in this condition that their pains are probably the most agonizing which the human frame is ever compelled to endure. That some of the greatest sufferers survive their martyrdom appears almost miraculous to themselves. Thus, in one case the patient, who had experienced initial symptoms for a year, woke up at night with a fulminating pain in the heels which recurred with the intensity of a hot spear-thrust and the rapidity of a flash every seven minutes; then it jumped to other spots, none of which seemed larger than a pin's head, till the patient, driven to the verge of despair and utterly beside himself with agony, was in one continued convulsion of pain, and repeatedly—against his conviction—felt for the heated needles that were piercing him. In another case the patient, with the pathetic picturesqueness of invalid misery, compared his fulminating pains to strokes of lightning,

¹ Canfield, *Lancet*, 1885, vol. ii. p. 110.

² I have at present under observation two intelligent patients (one of whom had been hypochondriacally observant of himself for years) who experienced not a single pain, as far as they could remember, and who have developed none while under observation. Seguin mentioned a case at a meeting of the Neurological Society with a record of but a single paroxysm of the fulgurating variety. Bramwell (*Brit. Med. Journ.*, Jan. 2, 1886) relates another in which the pains were entirely absent.

"but not," he added, "as they used to appear, like lightning out of a clear sky, but with the background of a general electrical storm flashing and playing through the limbs."

Either while the pains are first noticed or somewhat later other signs of disturbed sensation are noted. Certain parts of the extremities feel numb or are the site of perverted feelings. The soles of the feet, the extremities of the toes, the region about the knee-pan, and the peroneal distribution, and, more rarely, the perineum and gluteal region, are the localities usually affected.¹ In a considerable percentage of cases the numbness and tingling are noted in the little finger and the ulnar side of the ring finger; that is, in the digital distribution of the ulnar nerve. The early appearance of this symptom indicates an early involvement of the cord at a high level. Some parallelism is usually observable between the distribution of the lightning-like pains when present and the anæsthesia and paræsthesia if they follow them. With these signs there is almost invariably found a form of illusive sensation known as the belt sensation. The patient feels as if a tight band were drawn around his body or as if a pressure were exerted on it at a definite point. This sensation is found in various situations, according as the level of the diseased part of the cord be a low or high one. Thus, when the lower limbs are exclusively affected or nearly so the belt will be in the hypogastric or umbilical region; if the upper limbs be much involved, in the thoracic region; and if occipital pain, anæsthesia of the trigeminus, and laryngeal crises are present, it may even be in the neck. Correspondingly, it is found in the history of one and the same patient: if there be a marked ascent—that is, a successive involvement of higher levels in the cord—the belt will move up with the progressing disease. This occurrence, however, is less frequently witnessed than described. In the majority of cases of tabes disturbances of the bladder function occur very early in the disease. Hammond indeed claims that in the shape of incontinence it may be the only prodromal symptom for a long period.²

I have under observation a patient who has been compelled to use the catheter daily for years, who has gradual disappearance of the knee-jerk and reflex iridoplegia, but who has presented no other evidence of tabes during the year and a half he has been watched. Among the exact signs of tabes, reflex iridoplegia and abolition of the knee-jerk are probably the earliest to appear. It may be assumed with safety that in ninety-nine out of a hundred cases both the inability of the pupil to respond to light and the absence of the knee-jerk will be found long before ataxia is developed. Cases are recorded where no other positive signs were found, and no other signs of the disease developed for a number of years,³ and others where disappearance of the knee-jerk was the very first indication.

The opinion of observers as to the frequency of double vision as an early symptom of tabes is far from being unanimous. The majority of writers speak of it as rare, but it is probable that this usually transient symptom is forgotten by the patient, or because of its apparent triviality

¹ In the exceptional cases where the initial sensory disturbance is marked in the perineal and scrotal region I have found that the antecedent fulminating pains had been attributed to the penis, rectum, and anal region; and in one case the subjective sense of a large body being forcibly pressed through the rectum was a marked early sign.

² *New England Medical Monthly*, 1883.

³ Westphal, also Tuzek, *Archiv für Psychiatrie*, xiii. p. 144.

escapes notice. The patient while looking at an object sees a double image of the latter. This may last for a few seconds, minutes, or hours, and rarely for a day or week.¹ A distinct history of this symptom was given by 58 out of 81 patients in whom I recorded the oculo-motor signs. By far the most important of the exact prodromal signs of tabes are two symptoms—one involving a special faculty of co-ordination, the other the reflex movements of the pupil. One or both of these must be present to justify the diagnosis of incipient tabes.² The disturbance of co-ordination consists in an inability of the patient to stand steadily when his eyes are closed. The majority of healthy persons when tested in this way may show a little swaying in the beginning, but eventually they stand as steadily as they do with open eyes, and there is no subjective feeling of uncertainty as to falling. But the tabic patient exhibits oscillations, and makes efforts to overcome them which, instead of neutralizing, usually aggravate them and betray the great disturbance of his equilibrium. It is not as if he swayed merely because he is uncertain of his upright position, but as if some perverted force were active in throwing him out of it. It is found to be a pronounced feature even in cases where the patient with open eyes is able to walk nearly as well as normal persons, and experiences no trouble in performing intricate evolutions, such as dancing, walking a line, or even walking in the dark—faculties which the patient is destined to lose as his disease progresses.³

In most cases of early tabes it is found that the pupil does not respond to light; it may be contracted or dilated, but it does not become wider in the dark nor narrower under the influence of light. At the same time, it does contract under the influence of the accommodative as well as the converging efforts controlled by the third pair, and in these respects acts like the normal pupil. It is paralyzed only in one sense—namely, in regard to the reflex to light; just as the muscles which extend the leg upon the thigh may be as powerful as in health, but fail to contract in response to the reflex stimulus applied when the ligamentum patellæ is struck. For this reason it is termed reflex iridoplegia.⁴ It is, when once established, the most permanent and unvarying evidence of the disease, and is of great differential diagnostic value, because it is found in comparatively few other conditions.

In a number of cases ptosis of one or both eyelids is noted at an early stage of the disease. It is usually temporary, and coincides as to time with the diplopia, if present.

Patients presenting some or all of the subjective and objective manifes-

¹ It has been asserted that the severer and more persistent diplopias are found with tabes dependent on syphilis.

² Not even the absence of the knee-jerk ranks as high as these two signs. Aside from the fact that this is a negative symptom, it is not even a constant feature in advanced tabes.

³ It does not seem as if the disturbance of static equilibrium were due merely to the removal of the guide afforded by the eyes, for it is noted not alone in patients who are able to carry out the average amount of locomotion in the dark, but also in those who have complete amaurosis. Leyden (*loc. cit.*, p. 334) and Westphal (*Archiv für Psychiatrie*, xv. p. 733) describe such cases. The act of shutting the eyes alone, whether through a psychical or some occult automatic influence, seems to be the main factor.

⁴ It is also known as the Argyll-Robertson pupil. Most of the important symptoms of tabes are known by the names of their discoverers and interpreters. Thus, the swaying with the eyes closed is the Romberg or Brach-Romberg symptom; the absence of the knee-phenomenon, Westphal's or the Westphal-Erb symptom; and the arthropathies are collectively spoken of as Charcot's joint disease.

tations of tabes mentioned may continue in a condition of otherwise comparative health, enabling them to attend to their vocation for from one to twenty years, and it is not improbable that the pre-ataxic period may extend over nearly a lifetime. In a less fortunate minority of cases some of the most distressing evidences usually marking the last stages of the disease are found developed at the onset. Thus, cases are known where optic nerve-atrophy preceded the true tabic period by ten or more years; others in which trophic disturbances, manifested in spontaneous fractures of bones¹ or violent gastric crises, or even mental disturbance, inaugurated tabes dorsalis, instead of closing or accompanying the last chapter of its history, which is the rule.

The disturbance of co-ordination above spoken of as manifested in the inability of the patient to stand well with his eyes closed is the first step in the development of the characteristic ataxia which marks the full-blown affection. The patient finds that he tires more and more on slight exertion—not because his muscles are weak, but because he has to make more voluntary effort than a person in health. He finds that he stumbles easily—is unable to ascend and descend at the curbstone or to walk over an irregular surface with ease. Going down stairs is peculiarly irksome. “I would rather,” aptly said one patient, “troubled as I am in walking, go a mile in the street than walk up three flights of stairs; but I would rather go up six flights of stairs than walk down one.” Soon the patient notices that walking in the dark becomes more a feat of relative skill than the easy, almost automatic, act it was in health. His vocation, if it was one involving the use of the feet, becomes irksome, difficult, and finally impossible, and in a number of cases the upper extremities are also involved.² Delicate motions, such as those required in needle-work, in writing, and by watchmakers, musicians, opticians, and lapidaries, are clumsily performed; even coarser movements, such as buttoning the clothes and carrying a glass filled with water to the mouth, are performed in an uncertain and clumsy manner. Meanwhile, the disturbance of motion in the lower limbs progresses. Difficult as it formerly was for the patient to stand on one foot or with both feet together while the eyes were closed, he is now unable to do either with the eyes open. He straddles in his walk, or, in order to overcome the element of uncertainty involved in moving the knee-joint, keeps this joint fixed and walks with short, stiff steps. If ordered to halt suddenly while thus walking, the patient sways violently, and makes movements with his hands or arms to recover his balance, in some cases staggering and even falling down. He shows a similar unsteadiness when told to rise suddenly from a chair or to mount one, and it becomes impossible for him to walk backward. Later on, it will be found that his feet interfere in walking. He has lost the power of gauging the extent and power of his motions to such a degree that he may actually trip himself up. To neutralize in some way this element of uncertainty of his steps, the patient is compelled to exaggerate all his ambulatory movements, and there results that peculiar gait which was the first symptom directing attention to the dis-

¹ Berger, *Deutsche medizinische Wochenschrift*, 1885, 1 and 2.

² Cases in which the upper extremities are intensely involved in the beginning are uncommon, and those in which they are more intensely involved than the lower, or exclusively involved, may be regarded as pathological curiosities.

ease to which it is due. The feet are thrown outward, and violently strike the ground; the heel touches the latter first, and the patient appears as if he were punishing the ground and stamping along instead of walking. The reason for his adopting these tactics are twofold. In the first place, he has a subjective sense of walking in a yielding substance, as if on a feather bed, air-bladders, cushions, or innumerable layers of carpet, and he therefore makes efforts to touch firm bottom. In the second place, his motor inco-ordination, in so far as it is not the result of anæsthesias, is greatest in those segments of his limbs which are farthest removed from the trunk, and which, enjoying the greatest freedom of combined motion, are also most readily disturbed. His uncertainty is therefore greater in the toes than in the ankle, greater in the ankle than in the knee, and greater in the knee than in the thigh: he prefers to touch the ground with the heel to touching it with the toes, and to move his limb in the hip than in the knee-joint. As the patient advances in life even this limited and clumsy form of locomotion becomes impossible: he takes to his bed, and it is found that he loses all sense of the position of his lower and occasionally of his upper limbs. He is unable to tell which limb overlies the other when his leg is crossed—unable to bring one limb in parallel position with another without the aid of his eyes. If told to touch one knee or ankle with the toes of the other side, his limb oscillates around uncertainly, and makes repeated unskilful dashes at the wrong point, and ultimately all but the very coarsest muscular co-ordination appears to be lost, even when the supplementary aid of the eyes is invoked.

Together with this gradual impairment and abolition of co-ordination, which has given the name of locomotor ataxia to the disease, but not always in that strict parallelism with it on which Leyden¹ based his theory of inco-ordination, the sensory functions proper become perverted and impaired. Usually the determinable anæsthesias are preceded by subjectively perverted sensations, such as the numbness already referred to, or even by hyperæsthesia. Usually, all categories of cutaneous sensation, whether special or pathic, are impaired in advanced tabes; the points of the æsthesiometer are not readily differentiated; the patient is unable to correctly designate the locality which is touched or pinched; the pain-sense is occasionally so much blunted that a needle may be run through the calf of the leg without producing pain, and in some cases without being appreciated in any form. Even if the pain-sense be preserved, it will be found that its appreciation by the patient is delayed as to time. Not infrequently bizarre misinterpretations are made of the impressions acting on the skin. One of these, the feeling as if the patient were standing on carpet, cushions, or furs, whereas he may be standing on stone flagging, has already been mentioned as a factor in the disturbed locomotion of the patient. In the later period, numerous perversions of this kind are noted: to one of these, already mentioned by Leyden, Obersteiner has called renewed attention. It consists in a confusion of sides; the patient when pricked or touched on one foot or leg correctly indicates the spot touched, but attributes it to the wrong side.²

¹ *Klinik der Rückenmarkskrankheiten*, Band ii.

² *Allochiria* is the term applied by Obersteiner. Hammond has offered an explanation, which, as it is based on the assumption of altogether hypothetical nerve-tracts, and not in any sense accords with positively established facts, is more properly a subject for consideration in a theoretical treatise.

While it may be affirmed, as a general proposition, that the tendency of the tabic process is to abolish sensation below the level of the disease, there are noteworthy exceptions, not only in individual cases, but with regard to certain kinds of sensation; nor do the different kinds of sensation always suffer together. Thus, the pain-sense may be blunted and the contact-sense preserved, or, more commonly, the latter blunted and the former exaggerated, so that the unfortunate patient, in addition to being debarred of the useful varieties of sensation, those of pressure and space, has the painful ones exaggerated, as a hyperalgesia. According to Donath,¹ the temperature-sense is usually blunted in tabes, and a greater degree of heat or cold can be borne without discomfort than in health; but in about two-sevenths of the cases studied there was increased sensitiveness to heat, and in one-seventh to cold. One of the commonest manifestations is delayed conduction. This interesting phenomenon has been especially observed in that phase of the disease where tactile perception is beginning to be blunted. If the patient be pricked with a pin, he feels the contact of the latter at the proper moment as a tactile perception, and then after a distinct interval, varying from one to four seconds, his limb is suddenly drawn up and his face contorted under the influence of an exaggerated pain. This fact furnishes one of the chief grounds for the assumption that there are distinct channels for the transmission of pain and tactile perception in the cord, and that they may be involved separately or with different intensity in the disease under consideration. In some advanced cases it is found that not only the transmission of pain-appreciation is delayed, but that there are after-sensations recurring at nearly regular intervals of several seconds, and accurately imitating the first pain-impression.

To what extent the muscular sense is affected in tabes at various stages of the disorder is somewhat in doubt. Strümpell² by implication, and other writers directly, attribute the inco-ordination observed on closing the eyes to the loss of the muscular sense. As this symptom is also observed in patients who when they lie on their backs are able to execute intricate movements notwithstanding the exclusion of the visual sense, and as their uncertainty in an early stage is not always with regard to the position of their limbs nor the innervation of individual or grouped muscles, it seems inadmissible to refer the Romberg symptom³ to the loss of muscular sense alone.

The important part played by eye symptoms in the early stages of tabes has been already referred to. Reflex iridoplegia is one of these early and persisting features; it is sometimes complicated with mydriasis, and occasionally with paralysis of accommodation of one eye. In the majority of my cases there was spinal myosis, often of maximum intensity; in a large number there was in addition irregularity of the outline of the pupil; and where there was mydriasis I found it to be quite symmetrical, in this respect differing from the experience of Müller⁴ and Schmeichler.⁵

¹ *Archiv für Psychiatrie*, xv. p. 707.

² *Lehrbuch der Speciellen Pathologie und Therapie*, p. 193, vol. ii.

³ It should be designated as static ataxia, in distinction from locomotor or motor ataxia, which is manifested in unskilled movements.

⁴ *Centralblatt für die Gesamte Therapie*.

⁵ *Loc. cit.*

Atrophy of the optic nerve is a common and sometimes, as stated, the initial symptom of tabes. It is rarely found in its incipient phase in advanced stages. The patient who escapes involvement of the optic nerve in the pre-ataxic stage is very apt to escape it altogether. It is more frequently found either to precede the pre-ataxic period by months and even years, or to develop during this period, leading to complete atrophy in the ataxic period, and sometimes before. Erb calculates that 12 per cent. of tabic patients have optic-nerve atrophy; he probably includes only such cases in which the atrophy was marked or led to amblyopia. Including the lesser degrees of atrophy, it is found in a larger number of patients. Schmeichler claims as high as 40 per cent.¹ If we regard those cases in which there is noted progressing limitation of the color-field of the retina as beginning optic-nerve atrophy, the majority of tabic patients may be said to have some grade of this disorder. The ophthalmoscopic changes are quite distinctive: at first there is noted a discoloration of the papilla and apparent diminution of the number of arterial vessels; the veins then become dilated; and finally the papilla becomes atrophied, the vessels usually undergoing a narrowing after their previous dilatation. In the first stages of this process visual power is not gravely impaired, but as soon as shrinkage has set in visual power sinks rapidly to a minimum, decreasing till only quantitative light-perception remains. This limited function usually remains throughout, but in a few cases complete amaurosis ensues. As the field of vision becomes diminished, the concentric extinction of quantitative perception is preceded by concentric extinction of color-perception, the color-field for green being the first to suffer; red follows, and blue remains last.

In a large number of cases the only symptoms attributable to a disturbance of the cerebral functions are those connected with the motor relations of the eyeball and pupil, and the function and appearance of the optic nerve. The special senses other than those of sight and touch are rarely affected. Sometimes there is obstinate tinnitus, exceptionally followed by deafness, attributed to atrophy of the auditory nerve. The development of symptoms resembling those named after Ménière is not referable with certainty to a disturbance of the same nerve.

The sexual functions become involved in all cases of tabes sooner or later. In the majority of cases there is a slow, gradual extinction of virile power; in a large minority this extinction is preceded by irritative phenomena on the part of the genital apparatus. Some patients display increased sexual desire and corresponding performing powers, but mostly they suffer from erections of long duration which may be painful, and loss of the normal sensations attending the sexual orgasm. There is no constant relationship between the intensity of the general affection and the diminution of sexual power. It is retained to a limited degree by patients who are barely able to walk, and it may be entirely destroyed in those who have but entered the initial period.

The bladder disturbance,² which in some forms is usually found among the initial symptoms, is always a marked feature in the ataxic period.

¹ *Archives of Ophthalmology and Otology*, 1883.

² Contrary to what might be anticipated from the topographical nearness of the vesical and genital centres in the cord, the disturbances of bladder function and virile power do not go hand in hand.

Usually, there is a frequent desire for micturition, with more or less after-dribbling; sometimes there is retention, alternating with involuntary discharge; complete incontinence may close the scene through the channel of an ensuing cystitis and pyelitis. With the incontinence of urine there is usually found obstinate constipation, which may be varied by occasional spells of incontinence of feces. The crises of tabes often complicate these visceral symptoms.

The reflex disturbances are among the most continuous evidences of the disease. Of two of these, the disappearance of the patellar jerk or knee-phenomenon and the inability of the pupil to react to light, we have already spoken when discussing the initial period. Practically, it may be claimed that both are always found in typical tabes. It has been claimed that the patellar jerk may be exaggerated, or even that its disappearance is preceded by exaggeration. As this disappearance usually occurs extremely early in the pre-ataxic period, it is difficult to follow the deductions of those who claim to have watched an alleged earlier phase of exaggeration. It is more than probable that cases of combined sclerosis, in which the lateral columns were affected together with or earlier than the anterior, have been mistaken for typical tabes. Here, it is true, the jerk is first exaggerated through the disease of the lateral column, and later abolished as the lesion in the posterior reflex arch progresses and becomes absolute.

Other tendinous reflexes¹ suffer with the knee-jerk in the peripheries corresponding to and below the involved level of the cord. The cutaneous reflexes are usually abolished, but may be retained in advanced stages of the disease. The same is true of the cremaster reflex.

Opinion is divided as to the electrical reactions in tabes dorsalis. That qualitative changes never occur in uncomplicated cases all authorities are agreed, but while Strümpell and other modern writers claim there is no change of any kind, a number of careful investigators have found an increased irritability in the initial period, particularly marked in the peroneal group of muscles (Erb). In my own experience this is frequently the case, where lightning-like pains are the only subjectively distressing symptoms complained of.

While the symptoms thus far considered as marking the origin and progress of tabes dorsalis are more or less constant, and although some of them show remarkable remissions and exacerbations, yet may in their entirety be regarded as a continuous condition slowly and surely increasing in severity, there are others which constitute episodes of the disease, appearing only to disappear after a brief duration varying from a few hours to a few days: they have been termed the crises of tabes dorsalis. These crises consist in disturbances of the functions of one or several viscera, and are undoubtedly due to an error in innervation provoked by the progressing affection of the spinal marrow and oblongata. The most frequent and important are the gastric crises. In the midst of apparent somatic health, without any assignable cause, the patient is seized with a terrible distress in the epigastric region, accompanied by pain which may rival in severity the fulgurating pains of another phase

¹ Whether the tendon phenomena are true reflexes or not is a question still agitating physiologists. Opinion inclines in favor of their reflex nature, and, pathologically considered, it is difficult to regard them in any other light.

of the disease, and by uncontrollable vomiting. Usually, these symptoms are accompanied by disturbances of some other of the organs under the influence of the pneumogastric and sympathetic nerves. The heart is agitated by violent palpitations, a cold sweat breaks out, and a vertigo may accompany it, which, but for the fact that it is not relieved by the vomiting and from its other associations, might mislead the physician into regarding it as a reflex symptom. In other cases the symptoms of disturbed cardiac innervation or those of respiration are in the foreground, constituting respectively the cardiac and bronchial crises. Laryngeal crises are marked by a tickling and strangling sensation in the throat, and in their severer form, which is associated with spasm of the glottis, a crowing cough is added.¹ Enteric crises, which sometimes coexist with gastric crises, at others follow them, and occasionally occur independently, consist in sudden diarrhœal movements, with or without pain, and may continue for several days. Renal or nephritic crises are described² as resembling an attack of renal colic. The sudden disturbances of bladder function have been described as vesical crises, and recent French observers have observed so-called *crises clitoridiennes* in female tabic patients which were characterized by voluptuous sensations. All of these symptoms have these in common: that they last but a short time, that their disappearance is as rapid as their advent, and that they depend for their distribution on the attitude of the disease in the cord. The vesical crises are more apt to occur early than late in the disease and where the belt sensation is in the hypogastric region. The gastric and enteric crises are usually found when the belt is in the epigastric level, and the bronchial, cardiac, and laryngeal crises when it is in the thorax and neck. Some connection has been observed between the occurrence of the lightning-like pains and these crises. Thus, a sudden cessation of the former is sometimes the forerunner of the latter. It is also found that one variety of these crises disappears to give way to another: this is particularly noticed with the bronchial crises, which often cease suddenly, to be followed by vomiting.

There is some analogy between the exceptionally-occurring mental disturbance of tabic patients and the crises. Like them, it resembles a disturbance of innervation, in this instance the centres regulating the cerebral circulation appearing to be at fault. It also seems as if in cases of this character the direction of the mental disturbance were determined in some sense by the emotional relations of the oblongata, for the insane outbreak usually consists in a brief but extreme outburst either of a de-

¹ Krause, in a paper read before the Society of Neurologists at Berlin (*Neurologisches Centralblatt*, 1885, p. 543), found either laryngeal crises or other laryngeal symptoms, such as demonstrable ataxia of movement of the vocal cords, in 13 out of 38 cases. This proportion would be far too high for tabes in general; his cases were probably advanced ones. He established the interesting fact that the laryngeal crisis may sometimes be provoked by pressure with a probe on the superior laryngeal nerve at its laryngeal entry-point. Jastrowitz claims to have determined the existence of actual paralysis of the vocal cords with the crises, but Krause concludes from the experimental inductibility of the crisis that it cannot be due to a posticus paralysis. In a discussion on the subject Remak affirms that a unilateral paralysis of the crico-arytenoideus posticus may be an early or the earliest symptom of tabes. It seems, however, that in all cases where he determined such paralysis there had been disturbances of function of other cranial nerves in unusual severity at about the same time.

² They must be extremely rare: they have not occurred in a single one of my 81 private cases, nor do I recall one in clinic or dispensary experience.

pressed and melancholiac or an expansive maniacal or delirious outburst. It is a very rare occurrence, and usually limited to the latest stages. Much more common is the development of paretic dementia, but this is to be regarded rather as a complication than an integral feature of tabes. Most tabic patients retain their mental equilibrium to the last moment; some develop truly heroic resignation to their terrible sufferings and gloomy prospects; and a few, becoming irritable, petulant, and abnormally selfish, show the effect of invalidism manifested equally with other chronic diseases.

In addition to the visceral crises there are other disturbances of innervation of a nutritive or trophic character which are characteristic of tabes. There is scarcely one of the eruptions or other changes which are attributable to central nervous disease which may not occur at some one or other period of this disease. Thus, herpetic eruptions may occur independently or in conjunction with lancinating pains, in one case even corresponding to the area of the belt sensation. Discoloration of the skin or hair, the latter turning gray or white in circular¹ or in irregular patches, spontaneous falling of the nails, spontaneous hemorrhages in the matrix of the nail, ichthyosis,² purpura, diffuse œdemas, localized perspiration sometimes associated with sudamina and accompanied by ecchymoses, muscular atrophies, bullæ, and pemphigus-like eruptions, have been noted by various observers. As yet, they are to be regarded rather as clinical curiosities than as constant features, as diagnostic criteria, or as presenting special indications for treatment. The trophic disturbances affecting the bones and joints and a peculiar ulcerative process known as the perforating ulcer of the foot are better studied, and, ranking among the most formidable and striking manifestations of tabes, merit special consideration. The tabic joint affection, first described by Charcot as a trophic manifestation of tabes, is usually located in the hip or knee, but almost any joint, including the temporo-maxillary articulation, may be its seat. The earlier or lighter forms consist in serous exudations with or without active local manifestations resembling those of synovitis; but the commoner and graver form consists in actual deformity of the articular surfaces, such as enlargement or atrophy, sometimes supplemented by the formation of osteophytes. In addition, spontaneous dislocations occur in a manner which is often quite surprising.³ As a type of such an occurrence the following may serve: A tabic patient presented a synovial swelling of the left knee of truly enormous dimensions; as soon as this became reduced a distinct crepitus was elicited, and both the femoral and tibial articular surfaces found enlarged. The whole process occupied only a few days; the lateral ligaments were then found so relaxed that the leg could be freely moved in every direction.

The connection between the morbid process in the spinal cord and these remarkable arthropathies is as yet unexplained; and as Charcot's original

¹ Rossolymmo, *Archiv für Psychiatrie*, xv. p. 727. I have never observed this symptom as beautifully developed as in a case of spinal irritation, in which the possibility of the existence of any organic disease could be positively excluded. Bulkley has observed albinism.

² In three cases by Ballet et Dutil, *Progrès médicale*, May 19, 1882.

³ Boyer (*Revue de Médecine*, 1884, p. 487) records a case where the hip became luxated spontaneously as an early symptom.

proposition, that they can be always referred to lesions in the anterior horns of the gray matter, has not been sustained, some of the German clinicians, notably Strümpell, are inclined to attribute them, in part at least, to ordinary results and accidents due to the anæsthesia and its disturbing effect on voluntary and automatic joint protection. A controversy arose which was participated in by the Clinical Society of London,¹ and evoked opinions from nearly all the eminent neurologists of Europe. The result of this thorough discussion has been to establish the joint affection as a true tabic symptom due to the same morbid process which underlies the less enigmatical symptoms of the disease. One of the best reasons for regarding these joint lesions as of trophic origin is the fact that they are associated with textural bone-changes by which they become either unduly soft or brittle, and therefore exposed to apparently spontaneous fracture. Cases of fracture of almost every long and some of the short bones are recorded, among the most remarkable being one by Dutil,² where fracture of the radius occurred without adequate cause in the initial period of tabes; and one by Krönig,³ in which the patient, who had been tabic for eight years, broke a lumbar vertebra while catching himself in the act of falling down stairs.

Another reason for considering the arthropathies as of central origin is their chronological association with other signs whose trophic origin cannot be disputed, such as unilateral sweats and œdemas and visceral crises. They are also found to correspond in many cases to the lancinating pains both in location and time.

The feet of an advanced tabic patient usually appear deformed; the extremities of the bones, particularly at the metacarpo-phalangeal articulation, are thickened, and the axis of the foot as a whole is bent. It is a question how far this deformity may be due to persistent faulty innervation of the muscles going to the foot and to ensuing mechanical influences. A most pronounced deformity found in a few cases has been designated by Féré as the tabic foot.⁴ It consists in the thickening of the tissues on the inner side of the foot, obliterating its arch in such a manner that in standing the plantar surface is everywhere in contact with the floor.

¹ The question was formally raised by Morrant Baker at the December meeting in 1884, and the discussion participated in by Charcot himself. Among the opponents of Charcot's theory were Jonathan Hutchinson and Moxon, the latter of whom administered a sound and well-merited criticism regarding some of the premature, if not sensational, announcements of the distinguished French neurologist. He compared the joint lesions of tabes to decubitus: just as the latter can be avoided by a proper protection of the exposed parts, so the former would not occur if the joints could be kept in a, surgically speaking, normal state. Moxon seems to have forgotten, in suggesting this comparison, that there is a form of decubitus which will occur independently of the greatest care and in spite of every measure taken to arrest it, and which can be attributed only to an obscure but active perversion of nervous nutritive control. Barwell, Paget, Herbert Page, Broadbent, and McNamara agreed that the joint lesions are not of surgical or rheumatic origin, but essentially signs of the nervous affection. Although Barwell's claim, that the rheumatic and tabic joint diseases are essentially different, because the former is hyperplastic and the latter is atrophic, is not borne out by all cases of tabic joint disease, some of which are certainly hyperplastic, yet the other reasons advanced for regarding these affections as distinct, and considering the joint affection of Charcot as a trophic disorder, far outweighed those advanced by the opponents of this view. In fact, the only ground the latter had to stand on was the fact that Charcot's asserted anatomical foundation was found to be chimerical.

² *Gazette médicale de Paris*, 1885, No. 25.

³ *Zeitschrift für klinische Medizin*, 1884, vii., Suppl. H.

⁴ Pied tabétique—*Revue de Médecine*, 1884, p. 473.

With this the tarso-metatarsal and the metacarpo-phalangeal joints of the great toes appear greatly swollen.

There is less dispute concerning the nature of the so-called perforating ulcer of the foot. This lesion occurs only in cases where the central or peripheral nervous apparatus is diseased; thus, it may occur with neuritis, and it is therefore unanimously regarded as due to morbid nervous influences. In tabes it may follow an exacerbation of the fulminating pains. It consists in a swelling of the tissues of the foot; the skin becomes firm and thickened; deep sinuous ulcers are then developed, showing but slight if any tendency to granulate, and which extend down to the bone, the latter usually remaining unaffected.¹ In a few cases more remarkable accidents due to disturbed nutrition have been noted. Thus, J. Hoffmann records a subcutaneous rupture of the Achilles tendon, and in another case the spontaneous discharge of all the teeth of the upper jaw within about a week's time.²

COURSE.—Tabes dorsalis is to be regarded as an extremely chronic affection. Its development, as previously stated, is insidious,³ and the symptoms demonstrating the advent of the disease may be so slight for many years that the patient does not regard himself as ill or as likely to become so. In this condition he may remain for ten or more years; and there are cases recorded where the exact signs of the incipient stage were well marked, and yet no ascertainable progress was made in a period of such long duration that the inference naturally follows of a much longer prospective period in which the patient would not have become ataxic. There may be distinguished two forms of invasion: the more frequent is marked by the development of the terebrating, fulgurating, and fulminating pains, to which, sooner or later, the abolition of the pupillary and certain other deep reflexes is added. In the vast majority of cases they are found absent when the physician's attention is directed to the question of the existence of spinal disease. In about one-fifth of the cases pain is at no time a prominent feature of the disease, and may be, as is established by the cases cited, entirely absent. In these patients the first symptoms noted are muscle-tire on slight exertion. Usually, the evidences of disturbed sensation and innervation begin in one extremity or preponderate in it, but symmetry is soon established. The same is noticed in the extension of the morbid process: when the ulnar distribution is involved—which is the first danger-signal on the part of the cervical enlargement of the cord—usually one side is first involved, but the other soon follows, and becomes affected in equal or nearly equal degree. In the overwhelm-

¹ Like most of the manifestations of advanced tabes, the perforating ulcer may occur exceptionally as a pre-ataxic symptom. Thus, Suckling (*British Medical Journal*, 1885, April 4, p. 693) mentions its preceding the development of tabes proper by one year.

² *Berliner klinische Wochenschrift*, 1885, No. 12. In this unique case the loosening and falling out of the teeth preceded the tabes by a year. Demange, who observed the same phenomenon in two cases, found that the ascending root of the fifth pair was involved. The only analogous observation in my experience relates, like the bleaching of the hair in circular patches, to a case of spinal irritation: here the gums and alveolar borders underwent atrophy, exposing the roots of the teeth to beyond the normal alveolar border: first the right upper row, then the right lower row, and finally the teeth on the left side in the same order, showed this condition; only the most posterior fell out.

³ Cases of acute locomotor ataxia have been described. In no instance are they pure or typical, and the last case of the kind published in America, beginning, as it is evident from the account, with signs of general myelitis, illustrates the impropriety of utilizing one or a few symptoms as determining nomenclature.

ing majority of cases the disease manifests itself in the lower extremities first, remaining limited to them for a long period, and if extending to the upper extremities doing so in much slighter intensity than in the lower. Gull, Leyden, and others have observed cases where the arms were first and chiefly involved; but this is extremely rare. Cases of a simultaneous involvement of the upper and lower extremities are more frequently noted. The symptoms detailed above are developed in varying order in different patients, and the line has been already indicated which separates the progressive from the episodial features of the disease. Even in the ataxic period the patients may remain in a comparatively stationary period for many months and years.¹ The general bodily nutrition is usually good, and the muscular strength, as such, rarely affected to any noteworthy extent until the extreme phase of the disease is reached. Even the formidable-appearing crises and trophic disturbances, though occasionally fatal, are not always so. The direct danger from the disease proper, so far as life is concerned, is in the possible development of cystitis and pyelitis, of the malignant bed-sore, and of delirium and coma, the latter of which is occasionally found to be due to cerebral hemorrhage—a lesion which some writers regard as possibly due to some impalpable influence of the spinal disease on the cerebral circulation.²

MORBID ANATOMY AND PHYSIOLOGY.—Our knowledge of the structural disease underlying the symptoms which comprise the clinical picture of *tabes dorsalis* is perhaps the clearest in the domain of spinal pathology. Not alone the commencement of the morbid process and every stage of its subsequent encroachment on the spinal cord, but also its relations to special symptoms, have been demonstrated in numerous cases by some of the most careful German and French investigators.

In advanced cases of *tabes* the disease of the spinal cord is so evident that it was noted even by earlier observers, the region of the cord lying between the posterior nerve-roots being altered in color, consistency, and dimensions. It is gray instead of white, hard instead of soft, and considerably shrunken. The gray discoloration of the surface appears to be complete in the lumbar and lower dorsal region; it is less intense in the upper dorsal and cervical part of the cord; and often shows a division into three streaks, of which one, in the middle line, occupies both columns of Goll, while on either side another extends in the inner side of the posterior root-entry. The posterior roots themselves are frequently atrophied, and exhibit a firmer consistency and darker color than in health. On making cross-sections of the spinal cord it is found that the gray discoloration extends inward, involving more or less of the posterior columns in well-defined areas. Microscopic examination shows that the myelin of the nerve-tubes is either destroyed or atrophied, and the axis-cylinder is found to be affected in the same way, usually presenting alterations in its

¹ Thirteen patients are now under my observation, or I have been able to obtain reliable medical information concerning their condition, who have been in the ataxic period since the date of my first examination, varying from a year to seven years ago. Not one of these patients is materially much worse than at that time. Two only died, both being bedridden at the time they came under observation. Of the first group, three have shown more or less lasting improvement in respect to special symptoms, as will be detailed in connection with the treatment.

² In a case of sudden death, with an asthma-like seizure, of a tabic patient under the charge of T. A. McBride, I found an intense injection of one (the right) vagus nucleus, the color of the *ala cinerea* and of the nucleus on section being almost black.

refraction and diameter where it is not entirely destroyed. In the maximum foci of disease the conducting elements of the cord are nearly destroyed, and their place is occupied by a firm connective substance made up of wavy bundles, enclosing here and there a few atrophied axis-cylinders with wasted myelin-sheaths. The blood-vessels participate in the morbid process, at least as far as the larger vessels are concerned: these are sclerotic, their lumen appears contracted, the adventitial sheath is hypertrophied and occupied by a nucleated, fibrillar connective substance. The capillaries are sometimes normal, or participate in the morbid process to the extent of a thickening of the extra-endothelial sheaths which is either hyaline or fibrillary, and may show inflammatory cell-proliferation. It is evident that the increase of connective tissue in the posterior columns is not merely a relative one, due to the condensation of the normal neuroglia after the disappearance of the normal nerve-tubes, but is the result of actual proliferation. Opinion is somewhat divided as to whether this is to be considered as an inflammatory interstitial proliferation or as a more passive development of tissue compensating for the destroyed conducting elements. My own observations incline me to the belief that in syphilitic tabes the morbid process is essentially interstitial, while in non-syphilitic tabes it is parenchymatous, the disease beginning in the nerve-tubes proper. Perhaps the controversies between pathologists as eminent as Schultze, Tuczek, Rumpf, Zacher, Kahler-Pick, Rosenstein, and Adamkiewicz—who are rather evenly divided into opposing camps, one maintaining the parenchymatous, the other the interstitial, origin of the disease—may be solved when we learn to distinguish between the non-syphilitic and syphilitic cases, which is clinically, as yet, impossible. The difficulty of deciding what is a parenchymatous and what is an interstitial disease of the cord is considerably enhanced by the fact that the neuroglia, which by some at least is regarded as an interstitial connective tissue, is derived, like the nerve-substance proper, from the upper or neuro-epidermic germ-layer of the embryo, and not from the mesoblast, which furnishes all other connective substances in the body.

It is regarded as well established that the sclerosis of the areas of the spinal cord which are affected is preceded by a stage of granular degeneration.¹ This is supported by the facts that the sclerotic areas are surrounded by a zone in which sclerosis has not yet developed, but which is in a state of granular degeneration, and that in more advanced tabes this belt is also found sclerosed. In paretic dementia, a disease whose complicating cord affection closely resembles that of locomotor ataxia, a granular degeneration of the posterior columns is very common in earlier periods, while in later periods a sclerotic tissue is found in the same locality.

I regard these observations as opposed to the assumption of Strümpell that tabes is a system-disease of the cord in the sense in which he employs that term. In his fascinating and suggestive thesis on the systemic affections he cites the observations of Tuczek made on the posterior sclerosis ensuing from ergotism as confirming his view that special systems of nerve-fibres are separately vulnerable to special morbid influences. The remarkable correspondence between the topographical distribution of the lesion of ergotin tabes described by Tuczek and the characteristic areas

¹ Westphal, *Archiv für Psychiatrie*, ix. p. 725.

of sclerosis found in the column of Burdach in ordinary tabes, seems to justify a very different conclusion. Ergot exerts its morbid influence through a disturbance of nutrition. Just as it produces gangrene by constriction of the nutritive vessels of the fingers and of whole extremities, so it produces interference with nutrition of those nerve-elements in the cord which are most liable to suffer from general arterial constriction. These are presumably those portions which are supplied by the longest and narrowest arterial stems—a condition obtaining in precisely those parts of the cord which are affected both in ergotin tabes and in ordinary tabes.

It has also been supposed that the morbid process began in the posterior roots and crept in with these, thence extending upward.¹ This view is opposed by the fact that there is no constant relationship between the root lesion and the cord lesion; the sclerosis of the root-zones within the columns of Burdach I found to be absolute in at least one case where the outer nerve-roots were not distinctly affected.²

In typical tabes the sclerotic process begins in a special triangular field of the posterior column in the lumbar enlargement of the cord. The innermost of the posterior rootlets run through this field, which has been designated by the French school as the posterior root-zones, and the rootlets become exposed to all the vicissitudes which the conducting tracts are destined to undergo in consequence. Throughout the remainder of the cord it is the involvement of the root-zone which indicates the advance of the affection upward. At a time when the lesion is comparatively slight in the cervical level, manifesting itself by a slight grayish or reddish streak to the naked eye, a faint, pale discoloration in chromic-acid specimens, a deeper stain in carminized, and a pallor in sections stained by Weigert's method, the affected part in the lumbar region has undergone great shrinkage; scarcely a single myelin-tube is preserved to receive Weigert's stain within the affected area; the latter involves nearly the entire field between the cornua, and absorbs carmine deeply, so that it is difficult to differentiate the gray and white substance in carminized sections. A small part of the posterior column which most closely adjoins the posterior (gray) commissure remains free in all cases; so also does a small laurel-leaf-shaped field bisected by the posterior median septum. Examination with higher magnifying powers, aided by the modern improved methods of preservation and staining, reveals that the gray substance of the posterior segment of the cord is usually more or less diseased. In advanced cases the gelatinous as well as the spongy part of the posterior gray horn, and even the posterior gray commissure, undergo such considerable atrophy that they may occupy but half the normal area. In some cases the columns of Clarke appear to be involved quite early in the disease.³

¹ Takacs is the most recent defender of this view.

² The root lesion may, like that of the column of Goll, according to a minority of the interpreters, be a secondary process, for in ergotin tabes (Tuczek) both are usually intact.

³ Leyden discovered the degeneration in the fibres which in part make up these columns and correctly traced its origin to the posterior rootlets. Lissauer and Zacher (*Archiv für Psychiatrie*, xv. p. 437) confirmed him, the latter finding, as Leyden was the first to discriminate, that the cells may escape while the fibres are materially diminished. Krause claims that the columns of Clarke are constantly affected, but not necessarily in their entire length, the higher levels appearing quite normal at a time when the lower are severely involved (*Neurologisches Centralblatt*, 1884, p. 50).

The triangular field in the lumbar part of the posterior column, which is one of the typical starting-points of the affection, contains those ascending nerve-bundles which in their cephalic course emancipate themselves from the column of Burdach and constitute the slender columns of Goll. The result is that the degenerative process creeps up these columns at the same time that it ascends in the root-zones and deep portions of Burdach's columns. Some authorities regard this as a mere extension by contiguity;¹ others incline to consider it a secondary degeneration. It may extend to the medulla oblongata, becoming lost in the level where the nucleus of the column of Goll terminates, and is accompanied, at least in those advanced cases in which the upper extremities are involved, by a comma-shaped area of degeneration in the adjoining part of the column of Burdach, which similarly extends into the oblongata and terminates slightly more cephalad. In typical advanced tabes, therefore, the cross-section of the cord exhibits a characteristic distribution of the sclerosis in each level. As this distribution is associated with certain constant symptoms, it is permissible to attempt bringing certain features of the lesion in relation with special features of the disease symptoms. The posterior gray horns and the posterior white columns, together with other fibre-systems connected with them, are much more complicated in structural and physiological relations than the corresponding anterior structures. The relations of the anterior rootlets to the gray substance, and those of the motor ganglionic elements to their controlling tracts, are comparatively simple; those of the posterior roots are very intricate. They run up, in great part, at an angle to the longitudinal tracts; a few pass in directly, and still fewer dip to a lower level. The result is that a section of the cord made in the longitudinal direction through the root-zones, so as to pass from the root-entry to the anterior commissure, shows the column and root-fibres to be woven into each other like a plait. Trabeculæ of connective tissue, dragged in as it were with the posterior roots, fill up the interstices of this labyrinth. They are particularly dense in the lowest part of the lumbar enlargement of the cord, constituting the so-called posterior processu reticulares. It is reasonable to suppose that the overlapping of ascending and descending root-fibres, associated with the presence of an extra amount of connective tissue, imbedded as this fibre-maze is in that part of the cord which is most distant from its lymphatic emunctories, affords a favorable soil for slow inflammatory trouble. This is the primary field of tabic sclerosis, and in it the disease may remain most intense for years, extending but slowly and with diminishing intensity upward, hand over hand, as it were, on the natural ladder which the intertwined fasciculi and their matrix constitute. The longitudinal tracts which lie in and near the root-zones belong to the so-called short fibre systems, uniting the segments of higher and lower levels of

¹ It is held by them that the histological character of the change of the columns of Goll is not different from that in the column of Burdach. Zacher (*Archiv für Psychiatrie*, xv. p. 435) urges that it does not resemble true secondary degeneration, beginning in the vessels and connective substance instead of the nerve-fibres. Schultze (*ibid.*, xiv. p. 386), on the other hand, recognizes a primary involvement of the nerve-fibres in both of the areas of fascicular degeneration in tabes. The observation of intact axis-cylinders by Babinski in the sclerotic fields is in conflict with the latter's claim, and the various differences of observation and interpretation seem to be reconcilable only on the assumption that there are two different modes of origin, both leading to nearly the same results and occasionally combined in one and the same case.

the cord with each other. As the sclerotic process ascends it involves the caudal ends of these systems: they consequently undergo secondary degeneration, and, shrinking in their turn, affect the caudal part of the next system above in the same manner. The morbid process in the column of Burdach may therefore be considered as a combination of inflammatory and degenerative changes, the inflammatory products causing a series of short ascending degenerations, and the vulnerable path thus established being followed by a cirrhotic condition in which the connective and vascular structures participate actively. With regard to the reasons for regarding the degeneration of the column of Goll and that of the comma-shaped field near it as a secondary process due to the cutting off of its apparent nerve-supply at the caudal end, and of the posterior nerve-roots or their provisional terminations, they may be stated in this way: When the lesion of the primary field is limited to the lower lumbar or sacral part of the cord, the degeneration of the column of Goll is limited to its postero-internal part; when the upper lumbar and lower dorsal cord is involved, the entire tract is affected; and when the cervical portion is diseased, the supplementary comma-shaped area degenerates. In other words, the projection tract of the sciatic nerve, as far as it is represented in Goll's column, suffers in the first, that of the crural nerves in the second, and that of the brachial nerves in the third instance. In all advanced cases of tabes the affection of the column of Goll is in direct proportion to the altitude of the lesion in the primary field. Symptomatically, it bears an equally constant relation to the ataxia.¹ No case is on record in which these columns were totally degenerated without some motor inco-ordination of the lower extremity having been observed during life; and no case is recorded in which brachial ataxia had been a marked and persistent feature in which the comma-shaped area—area of the column of Burdach—was healthy.

It is scarcely necessary to seriously consider the suggestion of Strümpell, that the lesion of the column of Goll is in relation with the bladder disturbance.² Cases are on record by Wolff and others where this lesion was intense and there was little or no bladder disturbance.³

If the disease of the column of Goll were a primary systemic affection independent of the disease of the root-field, it would be difficult to understand why it, as well as the likelihood of finding a corresponding degeneration of the direct cerebellar tract, increases with the extent to which this field is involved. This occurrence becomes quite clear when we remember that both the direct cerebellar tract and that of Goll, being centripetal, are under the trophic dominion of the posterior nerve-roots. The opinion is not distinctly expressed, but implied in some writings, that the column of Goll degenerates because of a general transverse cord lesion at a low level; this is not the case in the tabic cord. There is a difference in appearance between that part of the primary field which corresponds to the column of Goll in the lumbar cord and the surrounding sclerosis in early cases: it is more intensely degenerated, more homo-

¹ Krause's case and others show that the ataxia of movement is not influenced by lesion of the column of Clarke; but we are not informed as to the static equilibrium of the patients in whose cords these columns were found intensely affected.

² *Archiv für Psychiatrie*, xii.

³ The column of Goll is not present in those mammals which, like the porpoise, have no developed hind limbs, but these animals have urinary bladders.

geneous in appearance, and more evenly stained. The other part of the triangular field presents a more trabecular appearance. In the specimen represented in the accompanying figure this is easily recognized: the

FIG. 31.

Trans-section of Upper Lumbar Cord of a Patient moderately advanced in Tabes: *f*, ventral or anterior fissure; *g*, caput gelatinosum; *r* *r'*, entry and deep course of the posterior rootlets; *d*, degenerated field, including the origin of the tracts which in higher levels form the columns of Goll; *n*, field near the posterior commissure which remains free from degeneration, both in the lumbar and cervical cord; *s*, sharply marked leaf-shaped field, bisected by posterior septum, which, as claimed by Strümpell and shown in this case, remains free from disease; *z*, zone of nearly normal consistency around it; *a*, diseased field, suspected to be related to the analgesia, not usually affected in early tabes; *r*, fibres running up and down in front of the gelatinous substance; *, region where the tabic process sometimes begins.

darker field corresponds exactly with the ascending degeneration, which follows compression of the cauda equina,¹ and is the sciatic equivalent of the column of Goll.

Among the various constituents of the posterior columns which appear

¹ I have also found that this field corresponds to the column of Goll in its myelinic development: the lumbar part of this column—designated as such by Flechsig—is an entirely different tract, which enjoys a remarkable immunity from disease in tabes.

As illustrating the bearing of the lesion of the column of Goll on the motor ataxia I may refer to two cases which happen to be related side by side by Strümpell (*Archiv für Psychiatrie*, xii. p. 737, Cases 1 and 2). As far as the lumbar segment of the cord is concerned, the distribution of the lesion is similar; but in the one presenting marked motor ataxia the triangular field was slightly diseased, and there was no upward extension of the lesion in the column of Goll. In the other, with marked ataxia, the triangular field was intensely diseased, and ascending degeneration (?) occurred in the sciatic fields of the latter.

In support of the view that the comma-shaped area in Burdach's columns is homologous with the fibres of the column of Goll, it is to be advanced that degeneration of this field bears the same relation to symptoms in the distribution of the ulnar nerve that degeneration of the column of Goll bears to sciatic and crural symptoms. Where the initial pains and subsequent tactile and locomotor disturbance were severe, this field was found affected, and most so in the side where the symptoms had been most intense (Friedreich-Schultze's cured cases, *Archiv für Psychiatrie*, xii. p. 234). This area has no direct connection with the root-fields. Secondly, in a primary system disease of the column of Goll, associated with degeneration of the nucleus of the column of Goll, described by Scoll, an irregular encroachment of the column of Burdach was noted. Third, the innermost fibres of the column of Burdach (those belting the nucleus in the oblongata)

to present a relative immunity to the disease, aside from the area near the posterior commissure and the laurel-leaf-shaped area of the posterior septum, Strümpell noted one which is situated at the periphery of the cord, bordering on the entry-line of the posterior roots and the inner contour of the posterior roots. In the few cases where it was found destroyed there was, what is a comparatively rare thing in moderately severe tabes, complete analgesia. It is not, however, certain that there is a necessary connection between the pathological and clinical fact here. The nerve-roots themselves are involved within the diseased area of the root-zones. The lesion is one of a kind which, affecting a nerve-trunk, would produce first irritation of, then impediment to, and ultimately destruction of, its function. The clinical parallel to this is the occurrence of the lightning-like pains in the earlier phases of the disease, which are followed by delayed pain-conduction, and finally by loss of sensation. Of the rootlets or fibres subservient to the various sensory and reflex functions mediated by the posterior roots, those which convey the centripetal impression normally evoking the patellar jerk appear to be the most vulnerable, or, because of their limited number, the earliest to be destroyed or compressed, with the result of total functional paralysis.¹

With regard to the interpretation of the various tactile sensory disturbances of tabes and the delayed pain-sense conduction little positive advance has been made. That the lesion of the root-zones and gray substance is responsible for them seems to be the general conclusion of French and German observers. Recent researches have shown that disease of the peripheral nerves (multiple neuritis) may produce sensory phenomena which it had previously been customary to regard as pathognomonic of disturbance of their intraspinal terminations and continuations. At the same time, we are confounded by the observation of Erb, that even retardation of conduction of the pain-sense, which the dictum of Schiff taught us to regard as a sign of disturbed function of the spinal gray matter, is also produced by peripheral neuritis.

Immediately adjoining the gelatinous apex of the posterior horn there is a column of vertical fibres which bear a relation to it resembling that have the same relation to the interolivary layer which the column of Goll has through its provisional nucleus of termination.

While the evidence of high lesion of the cerebral continuation of the column of Goll, and, what I regard as its homologue, the comma-shaped area of Burdach, together with the constant association of marked degeneration of these columns with motor ataxia, is strong positive proof of its relation to this symptom, there is equally strong evidence negating its relation to any other of the prominent symptoms of tabes dorsalis. Thus Babesiu (*Virchow's Archiv*, lxxvi, p. 74) found degeneration of the posterior columns limited to the column of Goll, and the patellar reflex was not destroyed; the root-fields at the upper lumbar levels were intact. That the columns of Goll have been found profoundly affected without bladder disturbance has been stated previously, and constitutes a stronger argument against Strümpell's view than the frequent observation of bladder trouble in spinal diseases, along with which these columns may be entirely free.

¹ It is now conceded that, as Westphal claimed, the patellar jerk is always abolished when the upper lumbar level of the root-zones (*bandelettes externes* of Charcot) is involved. Tshirijew has shown that the translation of the knee-jerk reflex occurs in a single segment of the rabbit's cord at the homologous level. In transverse sections a distinct fascicle may be seen coursing from the innermost root-fibres toward the antero-intermediate cell-group of the anterior horn; it furnishes a pictorial substratum, if not anatomical proof, for the patho-physiological observation, and harmonizes with the fact that it is the innermost rootlets which usually suffer first. Perhaps the delicacy of this tract accounts for the frequent disappearance of the jerk in old people as a result of senile sclerosis.

of the ascending root of the fifth pair in the oblongata to the tuber cinereum of Rolando. Sclerosis of this column, as well as of the ascending root in question (Demange), has been found in tabes, and usually in association with pronounced trophic disturbances. In a number of cases (Oppenheim, Eisenlohr, and others) where spasmodic laryngeal crises had been a marked feature during life, lesion of the floor of the fourth ventricle, or atrophy of the pneumogastric nerve, or even of its nucleus, was found. In one case with marked gastric crises I found sclerotic changes of the arteries in the ala cinerea.

With regard to the involvement of the peripheral nerves proper, aside from the optic, opinion is somewhat divided. The discovery of multiple neuritis, and the recognition of the fact that it had been erroneously confounded with tabes, led Dejerine to claim that tabes might be of peripheral origin. He even proposed to account for the oculo-motor trouble on the basis of an affection of the oculo-motor nerves. This explanation has been repudiated by Westphal and sound authorities generally. That the peripheral nerves are occasionally involved in tabes was already known to Friedreich in 1863,¹ and later Westphal found the cutaneous branches in an advanced tabic patient to present similar changes to those discovered by Friedreich: these findings are confirmed by his Japanese pupil, Sakaky. The nerve-tubes are atrophied, the axis-cylinder being often preserved, and the interneural connective substance is proliferated. But there is no constant relation between these changes and the symptoms of the disease; in one of Sakaky's cases the nerves of an extremity which had been the seat of severe sensory symptoms were entirely normal. The findings in the peripheral nerves of tabic subjects lose much of their value in view of their recent discovery in marantic persons² advanced in life, but who had no nervous disease whatever.

It has been attempted to bring the tabic process in relation to a supposed primary meningitis. Tabes is a rather common nervous affection, and primary spinal meningitis is one of the very rarest. The leptomeninges are found considerably thickened in one out of ten tabic cords, and those who defend the meningitic origin of the disease base their theory on this inconstant finding, and allege that in the cases where it is absent the meningitis has disappeared while the cord lesion progressed. It is a fatal objection to this view that the part of the posterior columns immediately adjoining the pia is often quite free from disease. A meningitic affection, either as an etiological or a complicating factor, can be admitted in those cases only where there is a marginal sclerosis.

The changes in the optic nerve resemble those of the white columns of the cord in their naked-eye and minute character as well as in the controversial nature of the various interpretations made. When affected, the nerve is found to be firmer than normal, and discolored; later it becomes quite gray, and may eventually shrink to two-thirds, and even less, of its normal diameter. It is generally believed that, as in the cord, the myelin undergoes wasting before the axis-cylinder disappears, and that the latter may survive a long time, thus explaining why the patient may retain his visual power for a considerable period after the ophthalmoscope determines the existence of atrophy. No satisfactory explanation

¹ *Virchow's Archiv*, vol. xxvi, pp. 399-452.

² Krause, *Neurologisches Centralblatt*, 1885, p. 53.

has as yet been offered for the optic-nerve affection of tabes. There is no direct continuity of the spinal and optic sclerosis. Two theoretical possibilities suggest themselves. The first is that the lesion of the cord exerts a remote effect upon the physiological, and through this the structural, condition of the optic nerve. That such an influence may be exerted is shown by cases of transverse myelitis low down in the cord, which, according to Erb and Seguin, were complicated by double optic-nerve atrophy. The second theory is that the involved part of the cord and the optic nerve present a similar vulnerability to the same morbid influences. This is illustrated in some cases of chronic alcoholic and nicotine poisoning, in ergotism, and in the spinal affections due to hereditary influences and developmental defects.

To discuss the nature of the disturbing influence which is responsible for the most characteristic evidence of the disease, the ataxia, would be equivalent to reviewing almost every mooted question in spinal physiology. It is to be borne in mind that ataxia is a collective term designating any inco-ordination of movement which is independent of motor paralysis. It may be due to abolition or impairment of tactile perception; it may be due to loss of the muscular sense; it may be due to hampered motor co-ordination; and, finally, it may be due to a disturbance of the space-sense. In my opinion it is only in exceptional cases that any one of these factors can be positively excluded. Occasionally, one has been noted when the ataxia was grave but the tactile sense was unimpaired, or where the muscular sense was perfect but ataxia was well developed. The difficulty with most such records is that no discrimination is made as to the kind of ataxia present. That loss of skill which the patient shows when he shuts his eyes and attempts to perform certain movements without their aid is undoubtedly due to diminished sensation, either tactile or muscular, and usually both. The inability to stand with the eyes closed is probably a cerebellar phenomenon, and in this respect we are on the way to return to Duchenne's opinion. It is true that the cerebellar organ is healthy in most tabic subjects, but its centripetal informer, the direct cerebellar tract, is either itself involved or affected in its origin in the columns of Clarke. But, besides the static ataxia and that motor ataxia which can be neutralized by the use of the eye, there is another disturbance, which, as Erb and his followers hold, cannot be accounted for on the strength of any sensory disturbance. It consists in an interference with the proper succession and rhythm of movement. It seems as if that automatic mechanism by which the individual or grouped muscular contractions engaged in locomotion follow each other with the smoothness of the action of perfectly-fitting cog-wheels were disturbed; the correct after-movement is hesitated over or skipped, or even takes place at the wrong moment, neutralizing some other step in the co-ordination required. The tendency of physiologists and pathologists is to attribute this form of ataxia to the disease of the intrinsic co-ordinating apparatus of the cord itself. The experiments of Tarchanoff on a headless duck, and the determination of the existence of cursorial co-ordinating tracts uniting the brachial and lumbar nuclei in mammals, as well as the observations made on automatic co-ordinate movement in decapitated criminals, demonstrate the existence in the cord of such an apparatus. The combination of the ganglionic centres which underlies this co-ordination

is affected by the so-called short tracts of the cord,¹ and it is precisely a portion of these which are involved in the lesion of the column of Burdach. A number of arguments have been advanced against regarding the lesion of this column, or indeed any of the lesions of the posterior column, as explaining the ataxia-producing effect of tabes. Westphal has interposed some potent objections. He holds that lesion of these columns will be found more frequently when examinations shall no longer be limited to those cases where disease is suspected because ataxia was observed during life. He found extensive disease of the posterior columns in sufferers from parietic dementia who did not exhibit the characteristic ataxic gait of tabes. I believe this objection can be met by the very cases cited by Westphal in its support. Where the spinal disorder preceded the cerebral—that is, where parietic dementia occurred as a complication of tabes dorsalis—true locomotor and static ataxia had been present before the insanity exploded. On the other hand, where the spinal disease followed the cerebral, typical ataxia did not ensue. This would seem to indicate that the destruction of cortical control is inimical to the development of typical tabes. Leyden has made a suggestion in the same direction when he attributes the lesser manifestness of locomotor ataxia in tabic females to their inferior cerebral organization.² A more convincing proof of the correctness of this conclusion is furnished by the fact that if the pathological process, after destroying the posterior columns and producing ataxia, invades the voluntary motor tract, the ataxic symptom becomes less palpable.³ This antagonism between lateral-column and posterior-column lesion is frequently exemplified in the combined forms of sclerosis. It would seem, then, that where the brain is healthy and the controlling voluntary tracts are unimpaired, the ataxia is aggravated, supporting the beautiful theory of Adamkiewicz, which assumes that the locomotor ataxia is due to a disturbance of the balance normally existing between the psycho-motor centres and those controlling the muscular tone as well as those mediating reflex excitability.⁴

¹ Intersegmental tracts.

² In one out of three female cases I found the active disturbance of gait as severe as in males, but Leyden's observation is supported by all who have seen a sufficiently large number of female cases.

³ Not because of paresis altogether, for it diminishes materially out of proportion to the paresis.

⁴ *Archiv für Psychiatrie*, x. p. 545. There is another observation which bears in this direction: James of Boston observed that absolute deaf-mutes in a large percentage of cases are insusceptible to vertigo or to the allied phenomenon of sea-sickness. Certainly, the auditory nerve is a space-sense nerve; its physiological elimination is, however, accompanied by an immunity against a symptom which may be an evidence of disturbed space-sense transmission. In like manner, the destruction of the central perceptive and voluntary centres in the parietic dement inhibits the legitimate results of posterior spinal sclerosis.

The degeneration of the crossed-pyramid tracts in typical tabes seem to be strictly an atrophy from disuse, perhaps facilitated by the general malnutrition of the cord. It is limited to that part supplying the most or solely affected extremities. Thus, where the lower extremities are alone grossly involved it is totally degenerated in the lumbar area, and only in its outer parts in higher levels. As if to fortify this comparison by analogous observations from every great segment of the nervous axis, a similar inhibiting influence of pyramid lesion on co-ordinating disturbance (muscular sense) is noted in secondary degeneration of the interolivary layer; when uncomplicated with pyramid lesion (Meyer and my own case,) ataxia is present; when so complicated (Schrader, Homén) it is not observed, even if determinable.

Lissauer¹ has recently determined the existence of a degeneration of certain fine nerve-fibres, apparently derived from the outermost of the radicles into which the posterior nerve-roots divide on entry. They are situated on that border of the apex of the posterior horn which is in contact with the lateral column, and were found degenerated in all cases except such as were in the initial period. No symptomatic relation has been claimed for this lesion.

One of the most important questions which have grown out of the pathological studies of tabes is the relationship between the lesions and the not infrequently observed restoration of functions which had been more or less seriously impaired in an earlier period of the disease. Even those symptoms which ordinarily comprise the continuous and essential clinical background of tabes may exhibit remarkable changes in this direction. I have two well-established observations—one of tabes of eight years' standing, the other of more recent date—in which that symptom which, once established, is the most constant, the reflex iridoplegia, disappeared, to reappear in two months in one case where it had been associated with myosis, and to reappear in eight months in the other, repeating this oscillation the following year. I have now under observation a tabic patient in the sixth year of his illness who two years ago had a return of both knee-phenomena to a nearly normal extent, to lose them in two months, and to regain the reflex on the left side four months ago, retaining it up to the present. These three cases were of syphilitic subjects. In a fourth advanced non-syphilitic tabic patient, whose ataxia had reached a maximal degree, I found a return of both knee-phenomena for three days after its absence had been established by medical examiners for over a year, and had probably been a feature for a much longer period. Hammond the younger and Eulenburg have reported similar cases. Nothing is more surprising to those unfamiliar with the progress of this disease than to find gross ataxia or the electrical pains and anæsthesia to disappear or nearly so; and the alleged success of more than one remedial measure is based on the fallacious attributing to the remedy what was really due to the natural remittance of the disease-process or of its manifestations. The financial success of quacks and the temporary but rapidly evanescent popularity of static electricity, Wilsonia belts, and like contrivances are owing to the hopefulness inspired in the credulous patient by the mere coincidence of spontaneous improvement and the administration of a new remedy, supplemented, it may be, by the influence of mind on body in his sanguine condition. It is to be assumed that the influences which are at work in provoking the trophic and visceral episodes of tabes are of an impalpable character, and that all theorizing regarding the reason of their preponderance in one and their absence in another case are as premature as would be any speculation regarding their rapid development and subsidence in the history of one and the same case. But we have better grounds for explaining the remissions of the ataxia and anæsthesia.

It is only in the most advanced stages of tabes that the destruction of the axis-cylinder becomes absolute or nearly so. Contrary to the opinion of Leyden,² who held that the tabic sclerosis differs from disseminated sclerosis in the fact that the axis-cylinder does not survive the myelin

¹ *Neurologisches Centralblatt*, 1885, No. 11.

² *Op. cit.*, p. 328, vol. ii.

disappearance, it is now generally admitted that a certain number of exposed or practically denuded axis-cylinders may be preserved in the sclerotic fields.¹ It is on the theory that these delicate channels may be oppressed at one time, perhaps by inflammatory or congestive pressure, and relieved at another by its subsidence, that we may assume them to be the channels through which the now limited, now liberated, functions are mediated. It is also reasonable to suppose that vicarious action may supplement the impaired function, and to some extent overcome the disturbing factors. This is illustrated by the controlling influence of the visual function—yea, even of the unconscious and ineffectual co-operation of completely amaurotic eyes—in neutralizing both locomotor and static ataxia. One patient who was well advanced in the initial period of tabes, and who had been encouraged to consider the medical opinion to that effect as the result of an exaggerated refinement of diagnosis, made repeated tests of the Romberg symptom in his own case, and deluded himself into the belief that the physician was mistaken because he succeeded in practically overcoming it with an effort that too plainly told its own story; but still he overcame it. Certain peripheral influences have the power of stimulating the dormant activity of potentially vicarious tracts, and perhaps also the blunted activity of those whose function is impaired. The outside temperature, certain barometric conditions, all may exert an influence in this direction for good or evil.

ETIOLOGY.—Authorities are now agreed that no single cause can be regarded as the sole responsible factor, in all cases of tabes, and that a number of etiological influences are combined in the provocation of this disease in most instances. When the distinctiveness of the affection was first recognized it was customary to attribute it to sexual excesses, and the unfortunate sufferer had frequently to bear the implied reproach of having brought his misery on himself, in addition to the hopeless prospect which those who followed Romberg and other authorities of the day held out to him.²

Heredity plays a very slight part in the etiology of tabes. Writers of ten and fifteen years ago attributed a greater importance to it than is now done. But this was due to the incorporation with tabes of the so-called family form of locomotor ataxia—a disease which is now regarded as a distinct affection.³

¹ Babinski (*Neurologisches Centralblatt*, 1885, p. 324) notes this feature, and, consistently with the findings of most modern observers, discovers much more resemblance to disseminated sclerosis than to the systemic sclerosis with which Strümpell and Westphal (in part) incline to classify tabes. Similar objections to the system-disease theory are advanced by Zacher (*Archiv für Psychiatrie*, xv. p. 340). I may not pass over in silence the fact that Babinski considers his observations to militate also against regarding any phase of the tabic sclerosis as a secondary process. But while it may fairly be asked that a sclerosis to be regarded as systemic must be shown to be total, this is not necessary for a secondary process, unless the primary involvement be total also; and that is not the case in tabes.

² This opinion survives in a large portion of the German laity and in French novels. About the time that the poet Heine was dying from an organic spinal affection two other prominent literary characters of Paris were affected with tabes. It so happened that all three were popularly regarded as libidinous, and one of their leading contemporaries, whose name escapes me, took occasion to issue a manifesto addressed to the jeunesse dorée which closed with the apostrophe, "Gardons à nos moelles."

³ There is but one record of direct heredity (the father and son being affected nearly at the same time), to my knowledge. It was observed at the Berlin Hospital by Remak (*Berliner klinische Wochenschrift*, 1885, No. 7). Both father and son were syphilitic.

More importance may be attached to individual predisposition, but thus far no distinct formulation of this factor has been attempted except by Schmeichler,¹ who offers the suggestion that there are persons with a predisposition to the development of connective-tissue proliferation in various organs of the body, and that in them tabes and other sclerotic affections are consequently more frequent than in others. This suggestion appears plausible, but it is unconfirmed by positive observations.

Sex appears on a superficial view to be one of the most important elements. It is generally admitted that at most one female becomes tabic for every ten males who do so. Of 81 cases in private practice, I observed but 3 females. Rockwell, Seguin, Birdsall, and Putnam give similar figures. This comparative immunity is probably due to the fact that the female is less exposed to over-exertion, to surface chilling of the feet, to the injurious consequences of sexual excess, and to syphilis² than the male. As a rule, the affection in females is more insidiously developed, progresses more slowly, is less marked by crises and trophic disturbances, and not accompanied by as severe pains and profound disturbance of co-ordination as is the corresponding affection in males.

The most important element in creating an acquired predisposition to tabes is undoubtedly the existence of constitutional syphilis. Some difference of opinion still exists regarding the proportion of syphilitic tabic patients, chiefly due to the neglect of Erb—when he first announced the prevailing view, and which is generally attributed to him—to differentiate between cases of demonstrated constitutional syphilis and the so-called spurious or soft chancre. But although there occurred a reaction against his view which went to as great an extreme in the opposite direction, the careful and critically registered statistics accumulated in the mean time strengthen the view that there are more syphilitic subjects among the tabic than among any class of sufferers from other nervous affections.³ Reumont, a physician at Aix-la-Chapelle, to which place syphilitic patients in general resort in large numbers, found that of 3400 cases of syphilis, 290 had nervous affections, 40 being afflicted with tabes. Bernhardt⁴ took occasion to examine a group of hospital patients who were free from tabes, and found that not fully 16 per cent. were syphilitic, while of 125 tabic patients, over 46 per cent. were determined to have had positive syphilitic manifestations. Several of those observers who have paid attention to the question of the syphilitic origin of tabes have admitted that the more searching their inquiry the larger the proportion of detected syphilitic antecedent histories. Thus, Rumpf's earlier table shows 66, and his later 80, per cent. of such antecedents. This latter figure exactly corresponds to the percentage of syphilis in my private

¹ *Op. cit.*

² Whether the shorter vitality of the syphilitic female as compared with that of the male is a factor in diminishing the accumulation of chronic tertiary sequelæ in that sex, or whether it be the lesser vulnerability of the inferior nervous system, I am unable to decide from the facts at my disposal. In private and clinical experience I have been struck by the fact that women affected with syphilis in the same way and under similar circumstances with tabic syphilitic males develop symptoms of functional disorder of the brain and cord, such as spinal and cerebro-spinal irritation. My cases referred to had in no instance any indication of a syphilitic condition or history, and a distinct and different cause was found in all three.

³ Excepting always those having the distinctive and undisputed syphilitic character.

⁴ *Archiv für Psychiatrie*, xv. p. 862.

cases. At a discussion held by members of the American Neurological Association in 1884, Webber gave 54, Putnam 49, Rockwell 40, Birdsall 43,¹ and Seguin 22 per cent.² as the proportion in their experiences.

Of European writers, aside from those already mentioned, Berger claims 43 per cent, and Bernhardt, in commenting on the increasing percentage obtained by accurate investigation, reports an additional series of 7 new cases in private practice, all of which were syphilitic. Fournier, Voigt, Cohnhausen, and George Fisher estimate the syphilitic tabic patients at respectively 93, 81, and 72 per cent. of the whole number. The almost monotonous recurrence of a clear syphilitic history in my more recent records is such that in private practice I have come to regard a non-syphilitic tabic patient as the exception. Among the poorer classes the percentage of discoverable syphilitic antecedents is undoubtedly much less. The direct exciting causes of tabes, exposure and over-exertion, are more common with them and more severe in their operation.

The proof of a relationship between syphilis and tabes dorsalis does not rest on statistical evidence alone. A number of observations show that the syphilitic virus is competent to produce individual symptoms which demonstrate its profound influence on the very centres and tracts which are affected in tabes. Thus, Finger³ showed that obliteration of the knee-jerk is a frequent symptom of the secondary fever of syphilis, and that the relation is so intimate between cause and effect that after the return of the reflex, if there be a relapse of the fever, the obliteration of the knee-jerk is repeated. Both the permanent loss of the knee-jerk (Remak) and the peculiar pupillary symptoms of tabes are sometimes found in syphilitic subjects who have no other sign of nervous disorder; and Rieger and Förster⁴ regard the syphilitic ocular disturbances, even when they exist independently, as due, like those of tabes, to the spinal, and not to a primarily cerebral, disturbance. Another argument in favor of the syphilitic origin of tabes is derived from the occasional remedial influence of antisyphilitic treatment. The force of this argument is somewhat impaired by the fact that the same measures occasionally appear to be beneficial in tabes where syphilis can be excluded. Still, the results of the mixed treatment in a few cases of undoubted syphilitic origin are sometimes unmistakable and brilliant.⁵ As some cases, even of long

⁵ In one case already referred to a return of both knee-phenomena and complete disappearance of locomotor and static ataxia were effected after a duration of four years. The treatment was neglected and the knee-jerks disappeared, and one has now returned under the resumed treatment, but accompanied by lightning-like pains. At a meeting of the Société médicale des Hôpitaux, held November 10, 1882, Desplats reported a case in which even better results were obtained. Reumont (*Syphilis und Tabes nach eigenen Erfahrungen*, Aachen, 1881) reports 2 out of 36 carefully observed syphilitic cases cured, and 13 as improved under antisyphilitic treatment.

standing, yield to such measures, while others, apparently of lesser gravity and briefer duration, fail to respond to them, the question as to whether syphilis is a direct cause or merely a predisposing factor may be answered in this way: That in the former class it must have been more or less directly instrumental in provoking the disease, while in the latter class it is to be regarded as a remote and predisposing factor, to which other causes, not reached by antisyphilitic treatment, became added. The claim of Erb, that "tabes dorsalis is probably a syphilitic disease whose outbreak is determined by certain accessory provocations," is not subscribed to unreservedly by a single writer of eminence.

The question has been raised whether the influence of syphilis is sufficiently great to justify a clinical demarcation between syphilitic and non-syphilitic cases. A number of observers, including Reumont, Leonard Weber, and Fournier, incline to the belief that there are more atypical forms of tabes in the syphilitic group. Others, including Rumpf, Krause, and Berger, are unable to confirm this, but the former admits, what seems to be a general impression among neurologists, that an early preponderance of ptosis, diplopia, and pupillary symptoms is more common with syphilitic than with non-syphilitic tabes. Fournier¹ believes that syphilitic patients show more mental involvement in the pre-ataxic period; but it is evident that he has based this belief on a study of impure forms. The advent of tabes in syphilitic cases does not in this respect differ from the rule. The most protracted and severe diplopia I have yet encountered in a tabic patient is one, now under observation, in the initial period of the disease, syphilis being positively excluded as an etiological factor.

It seems to be a prevalent opinion that the cases of syphilis in which tabes is developed include a large proportion of instances in which the secondary manifestations were slight and unlike that florid syphilis with well-marked cutaneous and visceral lesions which is more apt to be followed by transitory or severe vascular affections of the cord and brain.

Excesses in alcohol, tobacco, and abuse of the sexual function are among the factors which frequently aggravate the tendency to tabes, and one or more of them will usually be found associated with the constitutional factor in syphilitic tabes. Both alcohol and nicotine have a deleterious effect on nervous nutrition and on the spinal functions, as is illustrated in the effect of the former in producing general neuritis, and of both in provoking optic-nerve atrophy and general paralysis of the insane, not to speak of the pupillary states which often follow their abuse, and the undeniable existence of a true alcoholic ataxia. Sexual excesses were, as stated, at one time regarded as the chief cause: the reaction that set in against this belief went to the extreme of questioning its influence altogether. It is to-day regarded as an important aggravating cause in a large number of cases, and this irrespective of whether it be the result of a satyriacal irritation of the initial period or a precedent factor. In a large number of my patients (18 out of 23 in whom this subject was inquired into) the habit of withdrawing had been indulged in,² and, as the patients admitted, with distinct deleterious effects, such as fulness and throbbing in the lumbo-sacral region, tremor

¹ *L'Éncéphale*, 1884, No. 6.

² Coitus reservatus, the real crime of the Onan of Scripture.

and rigidity, with tingling or numbness, in the limbs, blurred vision, and sometimes severe occipital headache; in one case lightning-like pains in the region of the anus ensued.¹

Of single causes, none exerts so direct and indisputable an influence on the production of tabes as the action of cold and wet upon the lower segment of the body. It is usually the case that such exposure is frequently repeated and combined with over-exertion before the disease is produced, but it is occasionally possible to trace the very first symptom of the disease directly to a single exposure. A soldier who stands up to his knees in a rifle-pit half full of water finds his limbs numb or tingling; develops slight motor weakness, then lightning-like pains, and ultimately a typical tabes. In the case of a peddler who presented an advanced form of the disease, the first symptoms had developed after a single wetting of his feet: while walking along one of our watering-places with his wares the swell of a steamer inundated the beach. He had been subject to perspiring feet before that, and the perspiration remained checked from that time on.² The influence of surface chilling was remarkably manifest in all three of my female cases. In one of them it was due to frequent wetting of the feet; in the second, a midwife, the first symptoms began immediately after standing on a cold hearthstone while preparing some article needed in a lying-in case. In the third case, a lady who contracted and safely passed through a scarlatina in her twenty-eighth year was taken out driving while desquamation was going on. She became thoroughly chilled, experienced numbness in the fingers and toes, and from that day on developed a slowly progressing tabes involving all extremities alike.³

Spinal concussion has been mentioned by a number of authorities as a possible cause for tabes, as for other forms of sclerotic spinal disease. In 1 of 81 cases in my own observation the development of the disorder could be distinctly traced to a railway injury; in 2 a sudden aggravation was as distinctly referable to a similar cause.⁴ To what extent railroad

¹ Leyden states that coitus in the upright position has been accused of producing tabes, without mentioning his authority. I have no observation on this subject touching tabes, but am prepared to credit its bad effect from the account of a masturbator, who during the orgasm produced while standing felt a distinct shock, like that from a battery, shooting from the lumbar region into his lower limbs, and causing him to fall as if knocked down. He consulted me in great alarm—was scarcely able to walk from motor weakness, and had no knee-phenomenon; in a few weeks it returned, and no further morbid sign appeared. Masturbators of the worst type occasionally manifest ataxia, and in three cases I have been able to establish the return of the knee-jerk, together with other improvements in the spinal exhaustion of these subjects. The loss and diminution of the patellar jerk, and the frequently associated urinary incontinence, as well as certain of the peripheral pains found in masturbators, certainly prove that undue repetition of the sexual act (be it natural or artificial) is competent to affect the cord in a way that cannot but be injurious in case of a predisposition to tabes, if not without the latter.

² Checking of habitual perspiration by violent measures is mentioned by the German textbook writers as a frequent cause, but occurs quite rarely in the modern tabes.

³ In view of the absence of spinal—or, in fact, any nervous—symptoms prior to the exposure referred to, it does not seem necessary to insist that this was not an instance of a true post-scarlatinal tabes; and possibly the case thus designated by Tuzek (*Archiv für Psychiatrie*, xiii. p. 147) may have been really due to chilling of the delicate body-surface after desquamation or during that process. The typical form of myelitis and sclerosis after exanthematous fevers is rather of the disseminated type.

⁴ A fall from a chair, striking on the back of the latter, while endeavoring to keep a row of books from coming down in one case, and the shock of the Ashtabula disaster in the other. The latter patient, the same one who is referred to as describing the electric-

travelling, with its attendant continual jarring of the body, may predispose to the development of tabes or of other spinal diseases is as yet a matter of mere conjecture. That railroad travelling exerts a bad influence in some cases of the established disease is evident; but in others the patients rather like the motion, and claim to feel benefited by it.

A number of toxic agents have been charged with producing tabes; thus, Bourdon maintains this of absinthe; Oppenheim attributes one case to poisoning by illuminating gas, the exposure to its influence being immediately followed by a gastric crisis, and this by a regulation tabes.¹ It is supposed that most of the poisons acting on the cord in this or a similar way, such as arsenic, cyanogen,² barium, and chloral,³ do not produce a spinal lesion directly, but through the medium of a secondary cachexia. Of no agent is the effect in producing tabes so well studied as ergot of rye. It had long been known that ergot-poisoning provoked certain co-ordinating, motor, and sensory disturbances, but it was left for Tuczek⁴ to show that this vegetable parasite produces a lesion of the spinal cord which in its character and distribution apes typical posterior sclerosis so closely as to justify the designation of a tabes ergotica. Possibly, pellagra, which is sometimes manifested in a similar way,⁵ may yet be shown to have a like influence.

Among the occasional and exceptional causes of tabes, Leyden and Jolly mention the puerperal state; Bouchut, diphtheria; and several instances are recorded in which psychical shock was responsible for the outbreak of the disease. In a small number of cases I found that mental worry and anxiety coincided with the period of presumable origin of the disease.

Age seems to have no special determining influence. It is true that most sufferers from this disease are men in the prime of life or in the period following it. But it is precisely at these periods that the exposure to the recognized causes of tabes is greatest. It seems as if there were very little liability to the development of tabes after the fiftieth and before the twenty-fifth year; still, some cases of infantile tabes have been recorded.⁶

In the majority of cases tabes is due to a combination of a number of the above-mentioned factors. The majority of tabic patients in the middle and wealthy classes have had syphilis, and of these, in turn, the majority have been guilty of sexual excesses or perverted sexual acts, while excesses in tobacco and of alcohol are often superadded. Among

storm sensation in an earlier part of this article, had his foot amputated in consequence of that disaster; but, like one of the characters in *Jacob Faithful*, who felt his toes when the weather changed, though he left both legs at Aboukir, he felt the terrific pains of the disease in the absent foot as distinctly as in the other. Dumenil and Petit (*Archives de Névrologie*, ix. Nos. 25 and 26) relate cases in which a spinal concussion was the only ascertainable cause.

⁶ Excluding the so-called family form of locomotor ataxia: 6 rather imperfectly described cases are cited by Remak (*loc. cit.*), and 3 additional ones related by himself. Of the latter, 2 had hereditary syphilis, and of 1 the father was both syphilitic and tabic.

the poorer patients we find syphilis less frequently a factor, but still present, according to various estimates, in from 20 to 60 per cent. of the cases. Excesses in tobacco play a lesser, and excesses in alcohol a larger, part in the supplemental etiology than in the other class, while exposure to wet and cold and over-exertion are noted in the majority; indeed, in a fair proportion they are the only assignable causes.

DIAGNOSIS.—The recognition of advanced tabes dorsalis is one of the easiest problems of neurological differentiation. The single symptom which has given one of its names to the disease—locomotor ataxia—is so manifest in the gait that even the sufferers from the affection learn to recognize the disease in their fellow-sufferers by the peculiar walk.¹

Although there are other chronic affections of the cord which manifest ataxia, such as myelitis predominating in the posterior columns, disseminated sclerosis in a similar distribution, and some partially recovered cases of acute myelitis, the gait is not exactly like that of tabes. The uncertainty may be as great, but the peculiarly stamping and throwing motions are rarely present in these affections. The clinical picture presented by the ataxic patient, aside from his gait, is equally characteristic in advanced cases. Absence of the knee-jerk and other deep reflexes, the bladder paralysis, sensory disturbance, delayed pain-conduction, trophic disturbances, and reflex iridoplegia are found in the same combination in no other chronic disorder of the cord. It is supposable that an imperfect transverse myelitis in the lumbar part of the cord might produce the reflex, ataxic, sensory, sexual, and vesical symptoms of ataxia, but the brachial symptoms found in typical tabes as well as gastric crises would be absent. The pupillary symptoms would also fail to be developed, in all probability. It is to be remembered that only fascicular cord affections can produce a clinical picture exactly like that of tabes in more than one important respect. In analyzing the individual symptoms of the early stage the more important differential features can be most practically surveyed.

The discovery of no single symptom of tabes dorsalis marks so important an epoch in its study as Westphal's observation that the knee-phenomenon is usually destroyed in it. Had this symptom not been detected, so Tuzek admits, ergotin tabes would have eluded recognition.² It was claimed by a majority of neurologists at first that this jerk is always abolished in tabes, but it is now recognized that there are exceptions, as is shown by cases of Hirt,³ Westphal, and others, not to mention some well-established cases of its return during the progress of the disease.

The knee-phenomenon is supposed to be a constant attribute of physiological man. It is difficult to elicit it in children, and frequently impossible to obtain it in young infants. It also disappears in old age,

¹ At present I have six tabic patients under treatment, who are acquainted with each other, and who have made each other's acquaintance in the singular way of addressing one another on the strength of mutual suffering at Saratoga, at the Hot Springs of Arkansas, and in New York City.

² It is not to be wondered that, like most new discoveries, that of the pathological changes of the patellar reflex should have been made the basis of premature generalizations. The attempt of Shaw (*Archives of Medicine*) to establish a relation between disturbances of the speech-faculty and an increased knee-jerk has not met with any encouragement or confirmation, and has been rebutted by Bettencourt, Rodrigues (*L'Encephale*, 1885, 2), and others.

³ *Berliner klinische Wochenschrift*, 1886, 10.

without having any special signification, except that this occurrence seems to be in direct relation to senile involution. In 2403 boys between the ages of six and thirteen years, Pelizæus¹ found it absent in one only. It is customarily elicited by having the patient while sitting in a chair throw one leg over the other; hereupon the ligamentum patellæ is struck a short, quick blow. Under physiological circumstances the leg is jerked outward involuntarily after an interval of about one-fifth of a second—one that is scarcely appreciated by the eye. But if it be found absent by this mode of examination, the case is not to be regarded as one of absence of the jerk without further ado. The patient is made to sit on a table, his legs dangling down and his body leaning back, while he clenches his fists. By this means the jerk will often be produced where it appears to be impossible to evolve it by the ordinary means. It is also well to try different parts of the ligament, and when comparing both sides to strike on the corresponding spot and in the same direction. Many subjects who appear to be irresponsive will respond very well when a point on the outer edge near the tibial insertion is percussed. The elbow reflex, which has the same signification for the upper extremity that the knee-jerk has for the lower, is elicited in the same manner.

The absence of the knee-jerk is usually regarded as a suspicious circumstance in persons of middle life; and where it can be demonstrated that it has been present years previously and subsequently disappeared, it is looked upon as of grave import. I, however, published three years ago an authentic case of disappearance of the knee-jerk in a physician now in active practice in New York City who to this day enjoys excellent health and has developed no other sign of spinal disease. The knee-jerk is also abolished in a number of conditions not belonging to the domain of strictly spinal diseases, such as diphtheria, diabetes, secondary syphilis, and severe cases of intermittent fever. Of these, diabetes alone can be possibly confounded with tabes dorsalis. The difficulty of differentiating early tabes and diabetes is enhanced by the fact that on the one hand there are often ataxic symptoms with diabetes, while on the other both glycosuria and diabetes insipidus may complicate tabes. Senator, Frerichs, Rosenstein, Leval-Piquechef, Charcot, Raymond, Demange, Féré, Bernard, and T. A. McBride all recognize the occasional presence of the ataxic gait, paræsthesia, belt sensation, and even fulgurating pains, besides the abolition of the jerk, in diabetes mellitus.² In pure cases of diabetes, however, I am not aware that spinal myosis or the reflex paralytic pupil has been found.

Abolition of the knee-jerk is found in all organic diseases of the spinal cord which destroy any part of the neural arch at the upper lumbar level, where the translation of the reflex occurs, whether it be in the posterior root-zones or in the gray matter of the origin of the crural nerves. Thus, acute or chronic myelitis, disseminated sclerotic foci of this level, may cause obliteration of the reflex at any time of the disease; so may acute or chronic anterior poliomyelitis, neoplasms, and amyotrophic lateral sclerosis of the anterior cornua type if the destruction of the anterior cornua

¹ *Archiv für Psychiatrie*, xv. p. 206.

² I have now under observation a case of myelitis with predominating sclerosis of the posterior columns of five years' standing in a merchant who has been under antidiabetic treatment for eleven years.

be complete enough. It is also found abolished with all diseases of the peripheral nerves—traumatic and neuritic—which produce absolute motor paralysis of such nerves.

Among the sources of error possibly incurred in examining for this important symptom the presence of rheumatism is one. There is sometimes a tetanic rigidity of the joints which prevents the reflex from becoming manifest. It is also sometimes found to be absent immediately after severe epileptic attacks, according to Moeli.¹

The condition of the pupil is perhaps a more constant sign of early tabes than the loss of the knee-jerk; at least it has been found well marked in cases where the jerk had not yet disappeared. It may be regarded as a rule in neuro-pathology that wherever reflex iridoplegia is at any time accompanied by other oculo-motor disturbance, it is either of spinal origin or in exceptional cases due to disease of the pons varolii. The peculiar character of the pupillary disturbance of tabes furnishes us with a criterion for distinguishing it from one affection which in common with it exhibits loss of the knee-jerk—diphtheria. In diphtheria there is also a reflex disturbance of the pupil, but it is the reverse of that of early tabes. In the latter reaction to light is lost, but the accommodative contraction power is retained; in diphtheria accommodative contraction power is lost, but reaction to light is retained.

The bladder disturbance has already been described. It is found as a marked symptom so prominently in no other systemic affection of the cord, and in few of the non-systemic forms of sclerosis. In none of these is it associated with absence of the patellar jerk, reflex iridoplegia, and fulminating pains, as in tabes, except there be also some motor paresis. It is the combination of any two of the important initial symptoms of tabes without paralysis or atrophy that is regarded as indicative of the disease by most authorities. Thus the swaying in closing the eyes, if associated with the Argyll-Robertson pupil, is considered as sufficient to justify the diagnosis of incipient tabes, even if the knee-jerk be present and fulminating pains and bladder trouble absent. Undoubtedly, the tabic symptoms must begin somewhere. But at what point it is justifiable to give a man the alarming information that he is tabic is a question. I have a number of neurasthenic subjects now under treatment who have had reflex iridoplegia for years; in one the knee-jerk is slowly becoming extinguished; in two it has been becoming more marked after becoming less; in all the three mentioned there is slight swaying in closing the eyes and some difficulty in expelling the last drops of urine while micturating. I do not believe that such a condition justifies a positive opinion, although the surmise that they are on the road to developing tabes may turn out correct for all these and for some of those who have merely reflex iridoplegia.

Incipient tabes cannot be readily confounded with any other chronic disease of the spinal cord. Some of the cases produced by sudden refrigeration resemble a beginning myelitis. But the absence of true paralysis seems to distinguish it from the latter. In all the cases of so-called acute locomotor ataxia of myelitic origin that I can find a record of, paralytic symptoms were marked, if not throughout the disease, at least in the initial period.

¹ In three examinations after severe attacks of epilepsy I found it normal.

Other forms of sclerosis occasionally limited to the posterior columns imitate the symptoms of tabes. It is unusual, however, for such sclerosis to be distributed through so great an extent of the posterior columns as to produce symptoms consistent with tabes in both the upper and lower extremities. And even where this condition is complied with, the typical progress so characteristic of tabes is not adhered to. As previously stated, the progress is weakened by variations in certain symptoms. Such variations are found in other forms of sclerosis, but they are not as great, trophic disturbances not so common, and visceral crises not so violent, as a rule.

The discovery of ataxic phenomena as a symptom of peripheral neuritis has added another to the long list of pseudo-tabic affections. Indeed, Dejerine, who greatly advanced our knowledge of this affection, undertook on the strength of his discovery to place tabes among the peripheral affections complicated by secondary affection of the cord. In a large number of cases of peripheral neuritis, particularly the alcoholic form described by Fischer, the static ataxia, belt sensation, bladder trouble, and reflex iridoplegia are absent. In tabes the severe pains, if influenced by deep pressure at all, are affected favorably, but in peripheral neuritis pressure on the affected nerve-trunk greatly aggravates the trouble.

In addition, those severe forms of neuritis that lead to ataxia, abolition of deep and other reflexes, are accompanied by qualitative electrical changes and atrophic paralysis—features not found in tabes. Sometimes a disseminated neuritis will become so generalized as to cause diplopia and other evidences of ocular paralysis through the affection of the peripheral nerves, but, so far as my observations extend, not with the characteristic pupillary phenomena of tabes.

Cerebellar disease, alcoholic and hysterical neuroses, sometimes produce ataxia, and this may be associated with one or more of the other characteristic symptoms of tabes. Cerebellar ataxia is usually very different from that of tabes, as far as the locomotor element is concerned. In tabes it is the movements the patient makes which cause him to stagger; in cerebellar disease those movements made to prevent staggering are usually co-ordinated. The gait properly called cerebellar is therefore very different from that of tabes. There is, however, static ataxia in both cerebellar and posterior-column disease. In addition, the knee-jerk may be abolished in the former, heightening the resemblance: the history of the case is, however, decisive where these latter symptoms might lead to doubt. Bladder trouble in cerebellar disease is not an early feature, nor are paræsthesias and delayed pain-conduction intrinsic features, of cerebellar disease. Their presence is in favor of tabes.

Alcoholic ataxia is very rapid in its course, while tabic ataxia is exceedingly slow. In addition, the former is accompanied by atrophic paralyses as early features; if such occur in tabes, they occur late in the disease, and are not marked by degenerative electrical reactions as alcoholic ataxia is. This disorder is usually, too, accompanied by fever, which is an exceptional, and certainly never an intrinsic, feature in tabes. Discontinuing the alcoholic poison is usually followed by rapid amelioration of the ataxia. Hysterical ataxia exceptionally apes the ataxia of tabes; the presence of other hysterical phenomena, the rapid and bizarre change of the symptoms, are distinguishing features. There are cases of hysterical

ataxia accompanied by concentric limitation of the field of vision.¹ The outline of the limitation is strikingly like that accompanying atrophy, but repeated examination shows a variation of a kind not found in the latter. The blind field advances in one direction to recede in another on one day, and reoccupies the latter and recedes from the former on the next.

Ataxia after most acute diseases, such as scarlatina and typhoid, is not usually accompanied by loss of the knee-jerk, and never by reflex iridoplegia. The ataxia after diphtheria is complicated by the former, but, as already stated, the very opposite state of the pupil serves to distinguish it.

The hereditary form of tabes is frequently confounded to this day with true tabes dorsalis. The family history and age of the patient are collateral evidences of the nature of the case. In the hereditary form the sphincters, optic nerves, and the eye-muscles are not affected; in the acquired form the first and last are always involved; and this involvement occurs so early in the disease as to constitute a valuable discriminating feature. Although the locomotor ataxia is very similar in the two affections, static ataxia, the symptom manifested on closing the eyes, is not found in the hereditary form, while it is found more constantly than even the locomotor ataxia in the acquired form.

The electrical reactions in tabes are either normal or quantitatively slightly increased. This serves to distinguish it from all spinal affections accompanied by marked paralysis. In the later stages, when some atrophy results, there may be a quantitative decrease, but these are without qualitative changes. A change may occur in those exceptional cases where the anterior gray horns become involved, but we then have to deal with a true complication; and complications can be recognized only in their development and by the application of the diagnostic criteria characterizing the complicating disorder when of an independent occurrence.²

The TREATMENT of tabes dorsalis will be considered at the end of this article, together with that of the sclerotic processes generally. The duration and prospects of the disorder have been considered with the clinical history. In the vast majority of cases the course of the illness is progressive. A few cases have been reported, but in the only instance where an autopsy was made to test the matter it was found that the sclerosis had not been removed. It may be therefore stated that an arrest of the disease is possible, but that restitution of the nerve-elements, once destroyed, is impossible.

Spastic Spinal Paralysis.

SYNONYMS.—Primary lateral sclerosis, Tetanoid pseudo-paraplegia, (Seguin), Tabes dorsal spasmodique. This symptom-group was first

¹ Landesberg, *Journal of Nervous and Mental Diseases*, vol. xiii. 2.

² It is not impossible that many of the symptoms described as occurring in advanced tabes are due to independent focal disease. In the case of a female aged seventy years mentioned by Hirt (*Berliner klinische Wochenschrift*, 1885, No. 26), who developed hemiatrophy of the tongue, probably from a hemorrhage in the brain isthmus, there was no tabes, although this symptom when found with tabes is supposed to be part of the tabic symptom-group.

recognized by the American neurologist Seguin¹ thirteen years ago; two years later Erb² described it under the title at the head of this section, and about the same time Charcot³ attributed the well-marked clinical signs thus discovered on both sides of the Atlantic to a primary sclerosis of the lateral columns of the cord in that portion which is known as the crossed-pyramid tract, and whose isolated disease had been known to Türk,⁴ but not clearly brought into relation with what is now regarded as one of the most remarkable and recognizable of spinal symptom-groups. Our earlier knowledge of the disease has been much confused through the discovery by Charcot⁵ of the same lesion to which spastic paralysis is attributed by him, in a female who had been suffering from permanent contractures of all extremities, and which he persisted in regarding as hysterical. The only solution of the difficulty is to accept one of two alternatives—either believing that the sclerosis was in this case primary, in which case contracture cannot be regarded as hysterical, or that it was secondary to protracted disuse of the limbs, in which case it proves nothing. An additional source of confusion has been the discovery of an analogous affection, now regarded as clinically and pathologically distinct, known as amyotrophic lateral sclerosis, and of a corresponding affection of the lateral columns in a large number of cases of parietic dementia.

CLINICAL HISTORY.—Spastic paralysis manifests itself chiefly in three symptoms: first and most noticeable, a condition of rigidity of the limbs; second, an increase of all the muscular reflexes; and third, a true motor paresis. It manifests itself in the adolescent or middle period of life, usually without any noticeable cause, beginning in the lower extremities, and, if progressive, involving the muscles of the trunk and arms. The invasion of the disease is first marked by an increase in the excursiveness of the muscular phenomena, such as the knee-jerk and the ankle-clonus. But while this reflex irritability is originally only manifested when the diagnostician applies his special tests, it soon becomes so great that the most trivial influence suffices to bring about exaggerated muscular reaction. The mere tension of a tendon in walking, the weight of the limb, the slightest change in position, suffice to produce reflex muscular tension. The muscles feel firm and stiff to the touch, as if permanently contracted,

¹ E. C. Seguin, "Description of a Peculiar Paraplegiform Affection (tetanoid pseudo-paraplegia)," *Archives of Scientific and Practical Medicine*, February, 1873. Erb's statement (*Ziemssen's Cyclopædia*, vol. xi. 2, p. 628) that Seguin's description includes symptoms which do not properly appertain here can no longer be sustained, in view of the similar and identical symptoms which have been since attributed to the same affection and to amyotrophic lateral sclerosis by later writers. There seems to be no question that the priority of recognition of the clinical form belongs to this side of the Atlantic.

That Seguin's title was not as badly chosen as Erb implies in his first reference to it may be inferred from the fact that Strümpell, without any reference to Seguin, and evidently independently of him, uses the following language ten years later: "As also in these cases, the movements are not immaterially influenced by the ever-occurring spasms, a motor disturbance may be simulated which we feel inclined to term spastic pseudo-paralysis, or, more correctly, pseudo-paresis" (*Pathologie und Therapie*).

⁵ *Gazette hebdomadaire*, 1865, 7.

and the lower limbs, as a result of the combined contraction of special muscular groups, assume a characteristic position—namely, an extension contracture of the leg on the thigh and a flexion of the foot on the leg. In advanced cases the contracture is so extreme that it is almost or actually impossible to flex the leg and to extend (dorsiflect) the feet. This is particularly noticeable when it is attempted to overcome the strained position suddenly, while gradual traction will often succeed in relaxing the contracture. The latter procedure succeeds because sudden traction of the tendons and the reflex contraction thereby provoked are avoided by it. Gowers compares this symptom to the mechanism of a clasp-knife. When the leg is slowly extended it yields to the manipulator's influence, but as soon as it reaches full extension it remains like the blade of the knife fixed by a spring.

Although some degree of muscular weakness is experienced in the beginning of the affection—often more marked in one leg than the other—it is insufficient to account for the grave and characteristic disturbance of locomotion. This is due rather to the stiffness of the limb resulting from the morbid muscular spasm. As the limbs are rigid, the steps are short; the leg not being flexed, and consequently not being lifted from the ground, the gait consists in an awkward shuffle.¹ The feet are in continuous contact with the ground, and it is observed that there is a tendency to walk on tiptoe, owing to the contracture of the gastrocnemius, in this respect resembling the pes-equinus position. In some cases it has been observed that the reflex excitability was so great that the mere need of urinating brought on a sudden tonic spasm, and there have been noted others in which the very first spasmodic phenomena occurring in the history of the case appeared while the patient emptied his bladder.²

When the upper extremities are involved, the same initial muscular weakness and exaggerated reflex excitability are noted, but the contracture at the elbow, unlike that at the knee, is usually in the flexed position.

If from any cause the spastic phenomena happen to be in the background temporarily, so as to admit testing the voluntary muscular power, it is always found to be grossly impaired.³

As the disease progresses locomotion becomes impossible; the advancing rigidity of the trunk-muscles renders sitting impossible, and the patients become bedridden. But even in this advanced stage no sensory or vegetative disturbances were noted. The cutaneous reflexes sometimes appear exaggerated, but this is not an evidence of sensory hyperexcitability, but of the increased ease with which the motor response is elicited—a feature which is also illustrated by the spasm resulting from fulness of the bladder or even from the mere act of micturition. Ataxia has never been noted in pure cases, and the uncertainty in gait sometimes

¹ It was Theodore Simon, I believe, who first suggested the registration of peculiarities in gait by using sand on the floor or compelling the patient to walk over large sheets of paper with black-leaded shoes. Among the varieties of gait noted in paretic dementia by him he accurately describes that of spastic paralysis (*Die Gehirnerweichung der Irren*, Hamburg, 1871).

² Westphal, *Archiv für Psychiatrie*, xv. p. 224; *ibid.*, p. 229.

³ This statement is made by Westphal, but as he considers the only pure cases of pure primary lateral sclerosis to be those associated with paretic dementia, and it is in the latter form alone that there are marked exacerbations and remissions in the spastic symptoms, it probably does not apply to uncomplicated spastic paralysis.

noted at the onset of the disease is secondary to the motor weakness and the interference with free mobility by the, as it were, frozen state of the muscles. Occasionally the paresis becomes a veritable paralysis, but this occurrence is limited to one or several muscular groups. Cases are related in which the spastic symptoms occurred on one side, involving one arm and leg for years before involving the other. It is not improbable that these were cases of some obscure cerebral affection. Other exceptional cases in which the spastic phenomena appeared first in the arms are better authenticated.

The early occurrence of ankle-clonus in this disease heralds the appearance of apparently spontaneous clonus when the toes are put on the ground, and later on of cramps of the gastrocnemius or other muscles, which produce an exacerbation of the existing stiffness. Occasionally sudden spasms occur while the patient is at rest, and which resemble the sudden shocks which healthy persons occasionally experience when about to fall asleep.

The electrical reactions show little that can be called characteristic, and there is little unanimity among observers on this point. The majority agree that there is a slight quantitative decrease of both faradic and galvanic excitability in parallelism with the degree of paresis. In the pure form of the disease there are no other symptoms than those mentioned. Should evidences of involvement of the gray substance of the cord or the cranial nerves be added, it is a certain indication that we have to do with the similar but far from identical affection, amyotrophic lateral sclerosis.

The course of the disease is extremely slow and its development insidious. It is considered incurable, and although a few cases have been described as terminating in recovery, the most recent and reliable annals fail to make mention of any cure in a well-established case of spastic paralysis. The disease is not in itself fatal, death usually occurring from intercurrent affections.

ETIOLOGY.—Our knowledge of the causes of this disease is practically nil. It has been, like *tabes dorsalis*, attributed to a family tendency. Excessive sexual indulgence, over-exertion, and syphilis have been recorded as possible causes in the few cases in which an etiological assignment could be attempted. Tuzek surmises that the spastic phenomena of lathyrism, a constitutional disease analogous to pellagra and ergotism which is observed in those who live on bread prepared from a legumen grown in Italy (*lathyrus* bean), and which manifests itself in spastic symptoms, may be due to an affection of the pyramid tract, just as *tabes ergotica* is due to an affection of the posterior columns. One case of spastic paralysis of a severe nature, associated with scanning speech, in consequence of a lightning-stroke, is reported by Demme.¹ I have been able to assign a cause in but two cases of spastic paralysis. Both were in Quakers; in both there had been a history of almost incredible sexual excesses. The disease in both involved the muscles of the jaw and face. An autopsy in the one case revealed no lesion whatever.²

¹ "Bericht über die Thätigkeit des Jennerischen Kinderspitals," *Wiener medizinischer Blätter*, 1884, No. 23.

² The contracture in the lower extremities, differing from the rule, was a flexion contracture.

MORBID ANATOMY AND PHYSIOLOGY.—Although Charcot's announcement that spastic paralysis is due to sclerosis of the crossed-pyramid tract was made with great positiveness, the more careful authorities have not committed themselves to his view without reservation. Their reserved position is the result of some observations which certainly show that there is no constancy between the distribution of the lesion and the distribution of the spastic paralysis;¹ while, on the other hand, characteristic spastic symptoms have been noted with purely cerebral lesions.² Morgan and Dreschfeld³ publish cases in which the lesion was stated to be characteristic, but as the cell-groups in the anterior horn were found by them to have been more or less affected, it is evident they had cases of amyotrophic lateral sclerosis to deal with. In view of similar revelations in a large number of the cases that had been considered as spastic paralyzes during life, and in which similar findings were found after death, Westphal,⁴ one of the most critical students of the subject, concludes that thus far an anatomical basis has not been demonstrated with any constancy for the cases of spastic paralysis uncomplicated with paretic dementia. With this disease a sclerosis of the lateral column, apparently independent of the cerebral affection, is often found. It has no continuity, as a rule, with the cerebral lesion, and it may be limited to special districts of the cord. It is not usually intense enough to produce material destruction of the tract itself, and for this reason, probably, we do not find any other symptoms than a paretic weakness and an increase of the patellar and other muscular phenomena developed in the majority of paretics. In some, however, the characteristic spastic gait and muscular rigidity do develop. Westphal conjectures that if paretic demented lived as long as the sufferers from uncomplicated spastic paralysis, they would ultimately show the typical symptoms.⁵ Numerous observations, however, show that the presence and intensity of the spastic symptoms in paretic dementia are not related to the presence and intensity of lateral-column lesion. Thus, Zacher⁶ failed to find such lesion in a case where the spastic symptoms had been well marked. It must be remembered, in drawing conclusions regarding the pathogeny of simple spastic paralysis from the lateral-cord affection and associated symptoms of paretic dementia, that the possibility of the lesion of the pyramid tract in this affection being secondary to disuse⁷ cannot be excluded. On the other hand, the symptoms of most paretic demented presenting lateral-column

¹ Fischer and Schultze (*Archiv für Psychiatrie*, xi. 3) report an impure case in which, with exquisite spastic symptoms in the neck and arms, the degeneration of the pyramid tract was limited to the dorsal part of the cord.

² Schulz (*Deutsches Archiv für klinische Medizin*, Band xxiii.) and Strümpell (*Archiv für Psychiatrie*, x.).

³ *Journal of Anatomy and Physiology*, xv. p. 510. ⁴ *Archiv für Psychiatrie*, xv. p. 246.

⁵ Another feature which antagonizes the development of spastic phenomena in paretic dementia is the lesion of the posterior columns which often ensues. In proportion as this is developed it neutralizes the exaggerated knee-jerk, stiffness, and spastic gait.

⁶ *Archiv für Psychiatrie*, xiii. p. 155.

⁷ It has been claimed against this view that if this were so the degeneration of the pyramid tract should be accompanied by degeneration of the cells in the anterior horn. This claim assumes that the cells and the pyramid tract are directly continuous, but the most modern researches, those of Von Monakow, confirming an older observation of Homén's, show that a system of small cells in the lateral reticular processes is interpolated; which I can confirm. It is certainly compatible with an atrophy from disuse of the voluntary tract that the cells themselves, presiding over reflex and nutritive functions not necessarily disturbed in paretic dementia, should remain nearly intact.

lesion differ in some respects from those of a pure spastic paralytic. There is a precedent clumsiness and helplessness of movement; the patient stumbles and trips more than is the case with the pure spastic gait; he wavers after suddenly turning around, and there is considerable tremor with intended movement. There is also more exacerbation and remission of these symptoms than is the case with true spastic paralysis, and it is observed that the exacerbations usually follow apoplectiform and epileptiform attacks, thus showing that the cerebral condition, after all, may be the determining factor.

There is another respect in which the two conditions differ. Spastic paralysis is usually an ascending affection, the lower extremities being involved first, the trunk next, and the upper extremities last. But in paretic dementia the spastic phenomena develop in both upper and lower extremities simultaneously, and there are universal tremors, probably of irritative origin. The lower extremities are not commonly in the extension-contracture of spastic paralysis, but in the same flexed position as the arms, the adductors usually preceding the flexors in becoming rigid. If it be added to this that the lateral-column lesion in paretic dementia appears to answer all the requirements which could be made of the lesion on theoretical grounds were the case one of pure spastic paralysis—that is, that its area decreases upward—the inconsistency of the observed anatomical and clinical facts becomes strongly evident. Thus far, the attributing of spastic paralysis to a primary lesion of the pyramid tract rests in a few contested cases, on a number of doubtful analogies, and on the undoubted fact that sclerosis of this tract in the event of a myelitis is followed by pronounced spastic symptoms in all those muscles which derive their voluntary innervation from the part of the tract which lies below the level of the lesion.

The situation of this tract, which was not discovered by Türek and Flechsig, as is usually supposed, but accurately known to Burdach¹ in 1819, may be roughly stated as follows: It lies in the dorsal half of the lateral column, making up the bulk and core of this part of the column. It is separated from the pia mater by the direct cerebellar tract, and from the posterior gray horn by a narrow zone of fibres differentiated by Lissauer (see Tabes). It is connected with the lateral reticular processes, and in its cephalo-caudal course becomes gradually attenuated, giving off its fibres to these processes, thus to be exhausted in the lower part of the lumbar enlargement of the cord, where it approaches, if it does not actually reach, the surface. The fibres controlling the voluntary motions of the lower limbs, and which have a longer course to run before they reach the brain than those which mediate the voluntary control of the arms, are situated nearest the lateral boundary of the cord. Where the spastic phenomena are mainly marked in the lower limbs the sclerotic process has been found most marked in the corresponding area.

The progress of this affection has not been materially modified in any case by treatment. The same measures employed in sclerotic processes generally, particularly galvanism and warm baths, are recommended. It

¹ *Vom Bau und Leben des Gehirns*. This gifted author says that the crossed-pyramid tract lies in the lateral column of the cord, behind a line corresponding to the attachment of the ligamenta denticulata and removed from the surface.

is difficult to understand what good effect ergotin, which is mentioned by a number of the German writers, can have in a disease of this nature.

Amyotrophic Lateral Sclerosis.

Amyotrophic lateral sclerosis, so named by Charcot¹ and Joffroy, who first described it, consists in a disease affecting both the conducting tracts and nuclear centres of the motor system of the spinal cord and medulla oblongata, manifesting itself in a combination of atrophic and irritative phenomena on the part of the muscles. The relations between the symptoms and lesions of this disease rival in constancy and preciseness those noted in typical *tabes dorsalis*. As the variations in the mode of invasion and distribution of the lesion account for the widely-differing clinical types of the disease, and the advanced state of our anatomical and physiological knowledge of the cord enables us to interpret the reason of this difference, we shall invert the usual order and discuss the morbid anatomy first.

MORBID ANATOMY.—In advanced cases of amyotrophic lateral sclerosis there is found marked sclerotic degeneration of both the crossed and the uncrossed pyramid tracts; atrophy of the cells of the anterior horns; atrophy of some of the nuclei of the motor and mixed cranial nerve, particularly the hypoglossal and spinal accessory; atrophy of the anterior roots of the spinal and the roots of certain motor cranial nerves; and, finally, atrophy of the voluntary muscles. The greater part of the tract through which the voluntary impulse travels after leaving the voluntary motor-fields of the cortex is therefore continuously involved; and it would seem that there are cases (Kahler-Pick's) where the entire motor system is affected, the morbid process demarcating the course taken by the motor impulse through the cerebro-spinal fibre-labyrinth from the cortical motor-field down to the muscles.

The morbid process in the muscles consists of a narrowing of the fibres, which subsequently lose their transverse striation and undergo a granular disintegration. Sometimes a muscle disappears entirely; usually the connective-tissue elements, including the interstitial cellular and adipose tissue, undergo proliferation, so as to mask the wasting of the muscles to some extent.

The morbid process in the nervous system is also a simple degenerative process. The nerve-fibres and cells atrophy first, and the connective-tissue proliferation which marks the sclerotic change of the diseased area is a secondary process. There is still considerable dispute among authorities as to which segment of the motor-conduits the degeneration begins in. But from the great difference found in the individual cases which

¹ In 1869 and 1874 (*Leçons sur les Maladies de la Système nerveux*) Charcot termed this, and one other form of disease associated with muscular atrophy, amyotrophic, to distinguish them from the myopathic forms. He considers amyotrophic lateral sclerosis as deuteropathic, the nuclear atrophy being secondary to the lesion of the white substance, and the progressive muscular atrophy of the type described by Duchenne and Aran as a protopathic form of the amyotrophies. Among the true myopathies he enumerates pseudo-hypertrophic paralysis, Erb's juvenile form, Duchenne's infantile form, certain mixed forms, and, without justification, Leyden's hereditary forms (report by Marie et Guivron, *Progrès médicale*, 1885, No. 10).

have become the subject of patho-anatomical studies there can be little doubt that there is no uniformity in this respect. In some cases the lesion is far advanced in the lateral columns, while the anterior horn is but slightly involved; in others the reverse is found. Sometimes the nuclei of the motor cranial nerves are the chief foci of disease; at others they are the least affected parts of the motor apparatus. As we shall see, there are differences in the clinical picture corresponding to the variations of the anatomical findings.

CLINICAL HISTORY.—In typical cases the first symptom is a tired feeling in one arm or leg, usually the former; in dextral persons the right arm, the one which is subject to the severest strain, is most frequently the first to be affected. With the increase in this tired feeling there develops actual loss of power; the muscles become wasted, and the other arm becomes involved. Often it is observed that the right leg suffers with the corresponding arm, but as a rule the lower extremities do not become involved to any marked degree within the first six months of the illness. It is then noted that a gait not unlike that of spastic paralysis is noted, but with more loss of motor power and less stiffness. There is, however, this noteworthy difference between the affection of the lower and that of the upper extremities: that atrophy and loss of power are more marked in the latter, and spastic phenomena in the former. The knee-jerk and other deep reflexes are greatly increased, and ankle-clonus is usually very well marked. As with spastic paralysis, there are no visceral or sensory disturbances. Unlike that affection, there are qualitative changes in the electrical reaction of the muscles¹ in amyotrophic lateral sclerosis. The degeneration reaction is found in the atrophied divisions, and particularly in such groups as those of the thenar and hypothenar eminence, which undergo complete atrophy at a comparatively early period of the disease.

Soon after the spastic and atrophic involvements of the lower extremities, symptoms indicating the involvement of the cranial nerve-nuclei are developed, usually after the disease has lasted a year or so. Deglutition becomes difficult and speech indistinct, the general picture of a glosso-labio-laryngeal paralysis being imitated. The patient cannot pucker his lips, his lingual muscles undergo atrophy, and fibrillary and fascicular twitches are noted in the tongue and lips. But just as the atrophic affection of the muscles of the arms and legs differs from that of progressive muscular atrophy in the fact that the deep reflexes are exaggerated with amyotrophic sclerosis, so in the bulbar symptoms of the latter it is found, unlike the typical form of bulbar paralysis, that the jaw reflex is increased.

The duration of the disease may be stated at about three years, death usually occurring in consequence of the involvement of the cranial nerves. There are cases recorded where the disease was almost simultaneously developed in all four extremities and the tongue, reaching a high degree within a year (Mierzejewski). It is generally agreed that the reason contractures do not develop in typical cases of this kind, although the lateral column is sclerosed and spastic phenomena occur early in the disease, is the destruction of the cell-groups in the anterior horn. The reflex arch

¹ Moeli, Strümpell, Pick, and Mierzejewski describe cases in which only quantitative changes were found. They were such in which spastic phenomena preponderated at the time of the examination.

through which a reflex contracture would be mediated is broken, or rather weakened, in that part of its course which passes through these cells, and therefore a contracture is as efficiently antagonized as it would be if the posterior roots were divided. Still, in some cases a frozen attitude of the lower extremities is very well marked (Vierordt, Zacher). To reconcile these conflicting observations it has been suggested that it may be regarded as a question of speed between the progress of the pyramid-tract and the anterior-horn lesions. If the former be much in advance of the latter, spastic phenomena will preponderate and contractures be possible, to disappear with the subsequent anterior-horn lesion. But if the latter precede and preponderate, the spastic phenomena will be in the background and contractures impossible. Indeed, Zacher¹ suggests that there may be an ascending form in which the lesion of the pyramid tract is secondary to the nuclear atrophy, corresponding to the typical class of cases on which Charcot based his first description of the disease, and a descending form in which the pyramid tract is first affected and the nuclear cell-groups follow. Vierordt² and Kahler³ express similar opinions. The latter goes so far as to suggest that progressive muscular atrophy, progressive glosso-labio-laryngeal paralysis, and amyotrophic lateral sclerosis are really due to one and the same kind of degenerative process, merely differing in location. There is certainly, as he claims, a remarkably complete chain of cases, beginning with such (1) in which spastic paralysis preponderates, passing thence to (2) those in which some muscular atrophy preponderates, then (3) those in which muscular atrophy is in the foreground and the spastic phenomena are slight, and ending with (4) the pure atrophies. A similar transition may be established on the regional principle between pure glosso-labio-laryngeal paralysis and amyotrophic lateral sclerosis, for there are cases of this affection in which the oblongata symptoms preponderate throughout, and the focus of the disease is formed there, just enough lesion being demonstrable in the pyramid tract and the spinal gray matter to prove the family relationship of what clinically appears as a spastic bulbar paralysis.⁴

PROGNOSIS.—As far as the typical cases of this disease have been studied, a fatal termination seems to be invariable. Seeligmüller reports a few cases in which the progress appeared to become arrested, but it is not clear that these were not in reality cases of some juvenile form of muscular atrophy. Not only is the affection in adults fatal, but it is so in a short period of time as compared with other spinal disorders, and particularly with the related disorder spastic paralysis. Few patients survive the third year of their illness; a number do not live to that length.

The Combined Forms of Sclerosis.

A number of cases of chronic sclerotic disease of the cord have been discovered and analyzed during the past decade, which, while they show the regularity of distribution noted in posterior and lateral sclerosis,

¹ *Archiv für Psychiatric*, xv. p. 416.

² *Zeitschrift für Heilkunde*, 1884, p. 109.

³ *Ibid.*, xiv. p. 397.

⁴ Such a case is described by Freund in *Deutsches Archiv für klinische Medizin*, xxxvii. p. 405.

differ from them in involving at once more than one column of the spinal cord. Usually, it is the posterior column and the posterior part of the lateral column which are affected. The symptoms constitute a combination of those of *tabes dorsalis* and of spastic paralysis. But this combination does not represent a mere addition of symptoms; where the tendency of the two diseases conflicts, they neutralize each other. Thus the tendency of lateral sclerosis uncomplicated by posterior sclerosis is to increase the patellar jerk; when posterior sclerosis complicates it, the jerk is annihilated. The degeneration of the lateral column and the ensuing motor paresis in like manner neutralize the ataxic character of the gait by limiting its excursiveness.

The upper extremities are usually involved equally with the lower. In the cases of Kahler-Pick considerable atrophy of the muscles developed; in those of Prévost and Westphal this was not very noticeable. In a few cases, where the posterior sclerosis did not involve the lumbar part of the cord, spastic symptoms were noted in the lower extremity. In the only case of combined sclerosis now under my observation this peculiarity, noticed by Prévost, is well marked. In one of Westphal's cases there was evident mimic ataxia. The few cases of this affection observed show so many variations that it would be at present premature to attempt sketching a common clinical type. The majority of the subjects were affected between the twenty-fifth and forty-fifth years.

ETIOLOGY.—Little is known of the causes of this disease. Usually beginning insidiously, no special mode of origin can be determined. Surface chilling has been assigned in a case by Erlitzky and Rybalkin, and others are reported to have begun during pregnancy. One of Westphal's cases developed in a lithographer who had been subject to epileptoid fits.

DIAGNOSIS.—As yet we have no reliable criteria for distinguishing between a combined sclerosis and certain forms of diffused sclerosis during life. Ballet and Minor¹ found such a sclerosis diffusely involving the posterior and lateral columns of the cord in a case where they were justified from the symptoms in expecting a combined fascicular sclerosis of these columns, and after a careful study of all similar cases collated by them in consequence of this experience, they came to the conclusion that a number of affections of different origin, but eventually involving both columns, may impose on the observer as combined fascicular sclerosis during life. Diffuse meningo-myelitis is one of these affections, and is far from uncommon, while true system or combined sclerosis is apparently a very rare disease.

The Family Form of *Tabes Dorsalis*.

SYNONYMS.—Friedreich's disease, the Family form of locomotor ataxia, Hereditary ataxia, Hereditary *tabes*.

Friedreich discovered a peculiar form of co-ordinating disturbance in a number of children of the same family, which he brought into relation with a lesion of the posterior columns, and which has been since found by him and by subsequent observers to occur in other cases, always affect-

¹ *Archives de Neurologie*, vii. p. 44.

ing several members of the same family, as in the first case observed by him. The clinical and pathological features, though resembling those of the *tabes dorsalis* of adults in many respects, are distinct in others, and for this reason it is generally assigned a separate place in classification.

ETIOLOGY.—The disorder is usually manifested in juvenile life, the age of the affected subjects varying from the seventh to the twenty-fifth year. The male sex preponderates in the statistics of the affection. Some neuropathic vice can always be found in the patient's immediate ancestry, and the limitation of the disease to families burdened by such a diathesis is exemplified in the fact that the ninety individual cases thus far accurately studied occurred in thirty-six families.¹ The disease type of the ancestors of the patients is usually different from that of the latter. Alcoholism in the father is one of the commonest forms, but convulsions, hysteria, and insanity are also frequent features of the family history. In a few cases *tabes dorsalis*, properly so called, was present in the father. In others there was consanguinity of the father and mother. In Mussò's group the parents had been brother and sister, and their mother had been a melancholic dement. Three other grandchildren and six grandchildren by the incestuous marriage developed the family form of *tabes*. In this family the frequent experience of hereditary transmission was verified—that the neurotic taint skipped the intermediate generations.

CLINICAL HISTORY.—Usually the first symptom is ataxia of the lower extremities; occasionally this is preceded by severe frontal headache or by vague rheumatoid pains. The inco-ordination is very similar to that of true *tabes dorsalis*, but swaying on closing the eyes is not noticed early in the disease, as in the latter affection. The arms soon become involved in the ataxia, but cutaneous sensibility and the muscular sense remain either intact or nearly so—a fact utilized with some success by Erb in polemicizing against the theory of Leyden that the ataxia of *tabes* is due to imperfect sensation. Later in the disease, usually after a few years, a peculiar speech-disturbance is noticed, which resembles the scanning of disseminated sclerosis. It depends on ataxia of the tongue and lips. This is usually associated with nystagmus. About this time the patient develops a different set of motor symptoms from those characterizing the onset of the disease; contractures, paralysis, and atrophy are found in the affected extremities; sometimes the patients cannot ascend a stair, owing to their inability to lift the feet high enough. *Pes equino-varus*, deformity of other joints and of the vertebral column, have been observed² to result from the associated effects of paralysis and contracture. At this stage some sensory disturbance may be developed, formication having been observed toward the close of the history in a number of cases. But the distribution of this disturbance is usually different from that of *tabes dorsalis*, being more intense in the trunk than in the extremities or evenly marked in the entire periphery.

COURSE AND PROGNOSIS.—The progress of this disease is slow. It has not yet been known to be arrested by any therapeutical procedure. Death rarely occurs directly from the disease by exhaustion; more commonly life is cut short by some intercurrent affection. Unless this occurs

¹ Raffaele Vizzioli, *Giornale di Neuropatologia*, 1885.

² H. E. Smith, *Boston Medical and Surgical Journal*, 1885, vol. cxiii. p. 361.

the patients may survive the commencement of the illness from eight to forty and more years.

MORBID ANATOMY.—The sclerosis which is found to be the constant lesion underlying this disease corresponds in every character to a combined sclerosis of the pyramid tracts and the posterior columns. Usually, the crossed-pyramid tract is degenerated in its spinal course, and the uncrossed in the cervical and dorsal part, which, in many subjects at least, is its whole extent. The cerebral part of the pyramid tract is not affected. The nerve-fibres found normally in the gray substance are materially reduced, probably in dependence upon the atrophy of the great nerve-tracts.

The lesion of the posterior columns resembles that of true tabes very closely, particularly in the lumbar part of the cord. It is, however, not probable that it commences in precisely the same distribution, and if cases dying early in the disease be autopsied it will be interesting to see whether the initial sclerosis occupies identical fields—a contingency which is unlikely, owing to the profound difference in the initial symptoms of true tabes and the family form. It is claimed by Schultze that in addition to the pyramid and posterior tracts the cerebellar tract—or, rather, a large part of the periphery of the lateral column—may be sclerosed in this disease. In this way, since the direct pyramid tract in the anterior, the greater part of the border of the lateral, and the entire posterior column are degenerated, the sclerosis resembles a marginal ring¹ in shape.

Anatomically, the sclerosis of the family form of tabes resembles that form of combined sclerosis in which the lateral and posterior columns are together affected. It is probably due to a defective development of these tracts, rendering them liable to premature decrepitude or increasing their vulnerability. The latter alternative is exemplified in those cases where some acute disease of childhood, such as scarlatina or measles, acted as an exciting cause.

DIAGNOSIS.—There are two affections some of whose leading symptoms are so closely imitated by those of this disease that they may be confounded with it on first sight. These are tabes dorsalis—of which the family form is still regarded a variety, as the name indicates—and disseminated sclerosis. In the gait the former, in the nystagmus and scanning speech the latter, disorder is approximated. The distinction from true tabes has already been dilated on. (See Tabes.) The fact that relatives—usually the sisters and brothers—of the patient are affected in the same way in their youth speaks in favor of the family form. The deep reflexes are not abolished early, as in tabes, nor are anæsthesias or paræsthesias early symptoms, as in the latter. The speech-disturbance and nystagmus, which in most cases develop later in the family form, serve to distinguish it from true tabes in the advanced stage. It is at this period that the disease may resemble a disseminated sclerosis. The hereditary or family character does not aid us in making a discrimination here, as there is also a family form of the latter disease. But the absence of intention tremor, which we would assume to be present in a case of disseminated sclerosis of the cerebral type, and of optic-nerve atrophy serves to distinguish the two. Musso claims that the speech-disturbance is also different in character. There certainly is more lingual ataxia in the

¹ *Archiv für Psychiatrie*, xiv. p. 384.

family form of tabes, and less of typical scanning, but I am doubtful about our ability to differentiate these characters in all cases. The following table includes the main points of difference, clinically considered, between the acquired and the family form of tabes:

| | Tabes Dorsalis. | The Family Form. |
|--|--|--|
| Prodromata. | Marked and constant. | Absent or slight. |
| Static ataxia (Romberg symptom). | Early and constant. | Absent. |
| Involvement of upper extremities. | Usually late. | Early. |
| Ataxia of tongue, eyes, and trunk-muscles. | Absent or unnoticeable. | Always developed. |
| Paresis. | Rare. | Characteristic. |
| Anæsthesia. | Present in some form. | Absent or slight. |
| Paræsthesia. | Constant. | Rare. |
| Sexual desire. | Becomes extinguished. | Remains unaffected. |
| Deep reflexes. | Abolition usually initial. | Abolition in course of disease. ¹ |
| Sphincters. | Involvement is characteristic and early. | Involvement late, if at all. |

Disseminated Sclerosis.

SYNONYMS.—Multiple cerebro-spinal sclerosis (also spinal and cerebral form), Insular cerebro-spinal sclerosis, Focal sclerosis, Multilocular sclerosis; Herd-sklerose (Ger.); Sclerose en plaques disséminées, Sclerose en plaques généralisées (French).

The occurrence of disseminated patches of gray degeneration in the nervous axis was observed by Cruveilhier and Türk, but they regarded the affection rather from the anatomical than the clinical standpoint, and it was left for Frerichs to recognize its important position among the chronic affections of the brain and spinal cord. The earlier German investigators who followed him were cautious in generalization, and it was not until Vulpian, Charcot, and their followers announced the discovery of infallible diagnostic criteria that disseminated sclerosis received that attention at the hands of the profession which it merits. But the more thorough researches made during the last two decades have shown that this announcement was premature. The best authorities recognize the existence of a large number of cases in which the supposed pathognomonic signs of disseminated sclerosis are absent, notwithstanding the existence of characteristic lesions, and thus the more cautious earlier investigators are justified in the reserve they had maintained.

It is in perfect harmony with the irregular location of the disease and the lack of any constant rule governing the distribution of the sclerotic foci that there is no constant clinical picture by which its existence can be accurately determined in all cases. The diagnosis of tabes dorsalis, of spastic paralysis, of amyotrophic lateral sclerosis, and of transverse myelitis rests on exact and constant signs, but that of disseminated sclerosis does not. The dictum of Charcot, that there is always intention tremor and nystagmus in disseminated sclerosis, has long been overthrown. Well-determined cases are on record by De Fleury and Westphal, and a number have been observed by myself, where there was no

¹ There are conflicting observations on this point.

tremor or no increased tremor with intended movement, and no nystagmus, nor any other of the pathognomonic symptoms so considered by Charcot and his followers.

The morbid process of disseminated sclerosis consists in the development of patches of sclerosed tissue, scattered apparently without any regularity or rule through the brain and spinal cord. They are the results of insidious inflammatory changes. The symptoms marking their presence may include nearly every known focal and general symptom studied by neurologists, varying with the number, size, and distribution of the foci. Usually there is some disturbance of motility, both ataxic and paretic; in the majority there is tremor, which in a large proportion of cases is of a distinctive character, and disturbance of the functions of the cranial nerves, amblyopia, color-blindness, mental enfeeblement; and, above all, apoplecticiform seizures are frequent.

Some writers discriminate between cases in which the lesions are limited to, or most intense in, the spinal cord, and those in which the brain is chiefly or exclusively involved, and hence they speak of a spinal, a cerebral, and a cerebro-spinal form. This discrimination is not sufficiently supported by clinical evidence to be of any practical value. Each case is to be studied by itself during life and after death, and to be regarded as one of a series in which the lesion may be concentrated in any one segment of the cerebro-spinal axis. It seems that when the sclerotic foci are limited to or chiefly located in the spinal cord, the clinical signs are less pronounced than where the brain is seriously involved; those cases in which the symptoms are latent, or so vague that they cannot be distinguished from spinal irritation or spinal exhaustion, have been found to be of the spinal type. The cases of this character thus far observed are not sufficiently numerous to justify the creation of special subdivisions.¹

CLINICAL HISTORY.—*Prodromal.*—Disseminated sclerosis is usually inaugurated by a long initial period in which the symptoms are not characteristic, and in which, unless there be decisive pupillary or optic-nerve symptoms present, the nature of the disease is not recognized. The patients feel weak and tired; walking is difficult, and an element of unsteadiness suggests the development of a tabic disorder. In other cases ankle-clonus is found and tremor of the foot on extension (dorsiflexion); it is discovered that the unsteadiness is due to weakness or to rigidity of the muscles, and thus the impression of a developing spastic paralysis may be created. But symptoms on the part of the cranial nerves soon show that the case is one of disseminated sclerosis. Sometimes a marked belt sensation is developed, and other forms of paræsthesia are not uncommon; nay, the symptoms of spastic paralysis and tabes

¹ According as the formation of the sclerotic foci preponderates in a given segment of the nervous axis, the early signs of the disease may consist in disturbances of the cerebral or the spinal functions, and we may speak accordingly of a cerebral or spinal invasion type. But the principle of classification adopted by several recent writers, which would rank the spinal type among the spinal diseases, the cerebral type among the cerebral diseases, and which is compelled to erect a third category for the reception of the cerebro-spinal type under the name of cerebro-spinal diseases, is a bad one. Modern pathology recognizes the existence of affections which involve whole fibre-systems, which are intracerebral in one and intraspinal in other parts of their course, such as tabes and amyotrophic sclerosis, which would therefore have to rank among the cerebro-spinal, and not among the spinal affections, with which the authors referred to classify them.

dorsalis may be mingled. Diplopia of the same transitory character as in tabes usually accompanies the gradually-developing speech trouble. The reflex and mechanical excitability of the muscles is increased in all cases where the lateral column is extensively involved and the gray substance of the cord is—as it usually is in the main—intact. In some cases a slight tap on the knee when held in the position required to demonstrate the knee-jerk produces oscillatory movements of the limb; as the patient endeavors to suppress these they become more violent, extend to the trunk and head, and may eventually involve the opposite side. In those cases which show the cerebral-invasion type headache, vertigo, and speech disturbance, temporary darkening of the visual field, and loss of memory are the earliest symptoms directing attention to the existence of serious disease.

Whether the spinal or the cerebral symptoms preponderate, they continue increasing slowly and with temporary variations, which are particularly marked in the cerebral-invasion type. As a rule, the sensory disturbances are not pronounced at this time, but later, after the initial symptoms have existed for a few years, they become intense, and often extremely distressing. Those most complained of by the patient are neuralgic, lancinating, and other pains. The lancinating pains are, as a rule, not as severe as those of tabes dorsalis, but they are apt to be associated with a dull heavy pain which is located in a whole extremity, referred to the deep structures, and very persistent. This diffuse pain sometimes occupies all of the lower half of the body. As in tabes, the pain may be regarded the forerunner of anæsthesia, which rarely, however, reaches a high degree or an extensive distribution. Its distribution, like that of the other peripheral symptoms of disseminated sclerosis, is commonly irregular. Like the motor disturbance, which at this period consists in a combination of paretic and spastic—occasionally of ataxic—symptoms, it is most marked in the lower extremities.

In the majority of cases there is a peculiar tremor, which usually presents the character to which Charcot directed attention—namely, that it increases when the patient attempts to carry out a voluntary movement, and disappears, or at least diminishes, when the muscles of the part in question are at rest. This is the important symptom known as the tremor on intended movement or intention tremor. One of the time-honored means of testing it is to order the patient to take a glass of water and pass it to his mouth. While he reaches out for it some oscillatory unsteadiness is observed, but on grasping, this is increased, and on raising the glass the oscillations increase till he spills the water; if he succeeds in carrying it to his mouth, there is a clattering against the teeth, and but for the steadying aid of his mouth he would throw it aside by the violence of the disturbing movements. In incipient cases this intention tremor is best shown with delicate movements, and the more distinctly the more slowly they are performed. It has been suggested that the peculiar character of the lesion of disseminated sclerosis has some relation to the intention tremor. It is a remarkable feature of the morbid process that it leaves the axis-cylinder comparatively intact, beyond any other form of myelitis or encephalitis. The myelin, however, is destroyed, and the consequence is that the naked axis-cylinders lie in a newly-formed connective tissue, which has not the same faculty the myelin has of iso-

lating the nervous impulses conducted through the axis-cylinders. The result is, that when a nervous impulse, such as a voluntary movement, travels through a sclerotic focus, it may become deflected to neighboring fibres going to another muscle or muscular bundle than the one intended to be innervated. An unintended motion results; the patient makes a stronger effort, intended for the right channel, but again it slips off, to use a coarse simile, and thus a number of erroneous messages are transmitted, and an equal number of disturbing motions respond to these messages.

Whether this histological explanation be correct or not, the tremor is probably due to the lesion of the peduncular tracts of the brain. At least, this is rendered plausible for the tremor on intended movement, which indicates an interference with the transmission of voluntary impulses. Whether, as Pasternatzky¹ claims, the extreme muscular oscillation seen in advanced cases is due to irritation of the cortical motor fields, it is impossible to decide. No strong evidence can be adduced in favor of his view. A few cases have been described (Schüle, Jolly, and Greiff); and, in my opinion, such are far more numerous than is usually supposed, where the tremor did not have the so-called characteristic feature of ceasing in conditions of rest, claimed by Charcot, but continued as in paralysis agitans.² A collection of cases by Erb, Ordenstein, and Greiff shows clearly that with a typical dissemination of sclerotic foci in the cord the tremor on intended movement may be entirely absent, while no case is known where the crus and pons were involved to a similar extent in which it was absent. So it seems that a cerebral lesion is necessary to produce this symptom in its characteristic form.

In advanced cases of disseminated sclerosis the intention tremor becomes generalized; previously noticed, perhaps, only in one arm, it now affects all the limbs and the muscles which maintain the trunk and head in static equilibrium. The result is, that even when the patient is at rest sitting in a chair, his body, and particularly his head, are agitated by a violent and coarse tremor, which is increased on rising and walking, as well as on attempting to use the hands. Delicate mechanical occupations become impossible, and the handwriting shows a characteristic change, the forward strokes of the letters and the curvilinear back strokes, as well as the dots and crosses, registering the tremor of the hand in their peculiar irregularity.

The speech is usually rough and broken, and sometimes enunciation is impeded in a peculiar way, the patient appearing to scan his words. Krause³ has found relaxation of the vocal cords in a remarkable degree to underlie the change in phonation. The scanning of speech appears to be due to impeded innervation of the lips and tongue. When the patient is told to protrude his tongue, he does so either in spasmodic instalments of movement or with a sudden jerk after delay. The same delay and apparent halting are noticed in the mimic expressions that are observed

¹ *Jahrbücher für Psychiatrie*, iii. 3, 1882.

² For several years I had been puzzled by the fact that Charcot's formula failed to correspond to the clinical picture in the majority of cases, and I registered such cases as incipient multiple sclerosis or as a connecting group between paralysis agitans and that disease.

³ *Neurologisches Centralblatt*, 1885.

in speech. The features sometimes express an emotion opposite to the one experienced by the patient.¹

Whether diplopia occur as an early symptom or not, nystagmic oscillation of the eyeballs is commonly found in the developed affection. This nystagmus is usually universal, noted in associated movements in every direction, and aggravated by excitement, by constrained positions, and by any act of innervation of the eye-muscles. It may be looked upon as an intention tremor of the latter, and attributed to sclerotic foci in the cerebral axis, particularly in the tegmental part of the pons varolii.

The deep reflexes are in some cases but slightly affected. Where spastic phenomena preponderate, they are exaggerated, and where the posterior root-zones are involved in the lesion, they may be, as in tabes dorsalis, diminished or absent. The nutrition of the muscles is not impaired in the early stages, and indeed most functions which depend for their proper performance on the intact condition of the gray substance, such as the power of retaining the urine, micturition, and the functions of the rectum, are properly performed at this period. The cutaneous reflexes are not markedly abnormal in the majority of cases. They sometimes become diminished in the last stages.

In cases regarded as disseminated sclerosis and similar disorders approximating the combined form of sclerosis, Westphal² noticed a paradoxical muscular phenomenon which is the reverse in action of the tendon reflexes. It is best observed in the tibialis anticus: if the foot be extended (dorsiflected)—in other words, if the origin and insertion of this muscle be approximated—the muscle contracts firmly, keeping the foot in the enforced position, as if frozen into that attitude. The same occasionally occurs if the patient voluntarily extends his foot. Westphal observed the same phenomenon in the disease described by him in which the symptoms of disseminated sclerosis are present, but the corresponding lesion is not visible.³

In a number of cases the mind becomes involved. Simple dementia is the commoner condition, and some indication of passive mental enfeeblement is found sooner or later in the history of the disease in the majority of cases. In addition, there may be a morbid emotional condition, usually in the direction of depression. I have been struck by the frequent association of a melancholic state with large foci in the oblongata. When it is borne in mind that the patient exhibits tremor and speech-disturbance in addition to his mental trouble, it will be understood that with some modifications of the typical signs the case may simulate one of parietic dementia; and there are cases in which it is exceedingly difficult to decide

¹ This symptom is found where there are other reasons for suspecting the existence of large foci in the pons. I have observed it in one case of tumor of this region, and one of a focal disease of undetermined anatomical nature in the same location, in a remarkable form. In the former case the patient not only exhibited the facial contortions of hearty laughter when she felt as if about to break out in tears, and broke out in tears when she felt amused, with perverse regularity, but both emotional manifestations occurred simultaneously. The other case is still under observation. There was complete anarthria in the first, and nearly complete anarthria in the second case—a fact not unrelated to the inferred site of the lesion, and which may be associated with the fact that where the perverse mimic expression occurs in disseminated sclerosis the speech-disturbance often has an anarthric character.

² *Archiv für Psychiatrie*, x. p. 243.

³ *Ibid.*, xiv. p. 132. It is a noteworthy fact that this sign has been observed by its discoverer also in paralysis agitans.

whether they belong to an aberrant type of disseminated sclerosis or to the sclerotic type of paretic dementia. There are some which constitute veritable connecting-links between the two affections.¹

Like tabes dorsalis, the progress of disseminated sclerosis is often marked by episodes. Some of these differ in no way from the visceral crises of posterior-column sclerosis; every form of these symptoms found with that affection may occur in the present one, while episodes involving the cerebral functions are much more common. The latter manifest themselves as apoplectiform or epileptiform seizures. They are preceded by headache and vertigo, or, if these be continuously present, by an aggravation of them; then unconsciousness develops, either accompanied by convulsions or not, and the face is flushed, the pulse full and frequent, and the temperature raised. Consciousness returns in a few hours or a day, the attack rarely lasting more than two days, and it is found that the patient is hemiplegic. But, unlike the hemiplegia found after vascular rupture, embolism, or structural cortical disease, it is rapidly recovered from.

In a case of Gnauck's an attack of scotoma scintillans, associated with a noise of thunder in the right ear and pricking pains on the right side of the face, preceded anæsthesia and the formation of a small defect of the visual field.

There is a close resemblance between these apoplectiform and epileptiform seizures and those of paretic dementia, not alone in clinical character, but also in the surprisingly complete and rapid recovery from the more serious symptoms. But just as in paretic dementia, especially in its advanced stage, each seizure leaves the patient somewhat more impaired in mind and body than he was before, so it is in disseminated sclerosis; each attack marks a step forward in the invasion of the morbid state.

Eye-trouble is much less frequently a premonitory sign of disseminated sclerosis than of tabes. A few such cases are on record. Magnan observed the development of the characteristic symptoms of disseminated sclerosis fourteen years after an amaurosis which followed typhoid; and Gnauck reports another in which first a right ptosis, and then a right amblyopia, preceded the ordinary symptoms. In exceptional cases this premonitory eye-trouble may, like that of tabes, rapidly lead to extreme amblyopia or even amaurosis. The visual disturbances are remarkable for their rapid changes. They appear within a short period, attain their maximum rapidly, and may occasionally retrograde as quickly. They develop under two forms—the central and the peripheral scotoma, or, rather, limitation of the visual or color field. The former, like the amblyopia of alcoholic and nicotine intoxication, consists in an inability to differentiate between red and green in the centre of the visual field. It never, in my experience, proceeds as far as the toxic amblyopias; that is, to the complete extinction of vision.² The peripheral limitation of vision may be for both quantitative and qualitative light-perception, but it is not, as a rule,³ concentric as in tabes, but sector-like.

¹ Zacher, *Archiv für Psychiatrie*, xiii. p. 168; the writer, *Journal of Nervous and Mental Diseases*, April, 1877, and *Insanity, its Classification, Diagnosis, and Treatment*, p. 240.

² Gnauck says that the central color-blindness may become total, and the red-green blindness extend to the periphery.

³ Concentric limitation of ten to thirty degrees has been noted for color-perception.

The atrophy of the optic nerve in disseminated sclerosis is typically partial, in the majority of cases manifesting itself as a sharply-marked discoloration of the temporal half of the papilla. In others the nasal half of the papilla also becomes discolored, but so much less intensely that the difference between the earlier involved and later involved portions is quite easy. It is doubtful whether the subjective visual disturbance is always an indication of the extent to which the optic nerve is involved. There are good reasons for believing those amblyopias and limitations of the field of vision which show marked remissions and exacerbations to be due to some dynamic central condition involving the visual centres and tracts. Thus it has been observed that almost total amaurosis occurred after an apoplectiform attack, to disappear later on. Occasionally the amblyopia is bilateral and the optic-nerve lesion unilateral. The frequency of this affection is stated by Gnauck¹ as follows: In one half the cases there is diminished vision, and in half this half optic-nerve atrophy with limitation of the visual field. It is only in exceptional cases that an optic neuritis can be determined to have preceded the atrophy.

The pupils are perfectly normal in some cases; in others myosis of the spinal type is observed; and this I found to be nearly constant in all advanced cases. Irregularity in outline and inequality exist in a small proportion, and reflex iridoplegia is found in about 10 per cent. of the cases.

Thus far, the symptoms which occur either in a majority or in a large percentage of cases have been enumerated. The typical course of disseminated sclerosis may be stated as consisting in their gradual development and intensification, covering a period of from four to twenty or more years. There are a number of cases in which so many of the symptoms regarded as typical are either absent or where some given symptom-group preponderates over the others to such an extent that they require special mention.

It is not difficult to understand that disseminated sclerosis may ape other forms of spinal disease. Its symptoms depend on the location of the sclerotic foci. If these are situated chiefly in the crossed-pyramid tract, spastic phenomena will predominate, and the case may resemble a spastic paralysis.² If they be distributed in both the posterior and lateral columns, the symptoms will resemble those of a combined form of sclerosis in which the tabic and spastic signs are associated, as far as they do not, in the nature of the case, neutralize each other. This was well shown in a case of De Fleury's. Not infrequently an unusually large focus involves the entire transverse section of the cord, and the case becomes complicated by the symptoms of a transverse myelitis. In such a case, described by Rovigli,³ a large transverse focus in the cord had led to ascending secondary degeneration in the column of Goll and descending degeneration of the crossed pyramid tract. In a large series, instances of which are related by Kilian,⁴ Siemens,⁵ Schultze,⁶ Zacher,⁷ and Greiff,⁸

¹ Of 50 cases, 22 had no visual trouble, 8 showed simple diminution of perception, 5 added limitation, and 15 changes of the optic disc, a case of total atrophy and amaurosis being included in the latter.

⁸ *Ibid.*, xiv. p. 287.

the disseminated foci were complicated by a diffuse lesion distributed like that of a diffuse or fascicular myelitis; and there seems to exist every connecting-link between ordinary chronic myelitis, strictly so called, and disseminated sclerosis.

Not only does disseminated sclerosis occasionally imitate or approximate the regular (fascicular) affections of the cord, as well as diffuse cerebro-spinal affections, but it may appear under the mask of a nuclear oblongata paralysis.¹ And cases are on record where, in addition to the disseminated sclerosis, there occurred sclerotic atrophy of an entire hemisphere or of its capsular tracts, thus leading to a hemiplegic resemblance of the motor paralysis. In my experience the cases presenting the type of a nuclear oblongata paralysis run a more rapidly fatal course than others. The shortest history in my series, one of four years, was of such a case. A number of instances are on record by careful observers—and are probably much more numerous than is commonly suspected—where no decisive evidence of spinal or cerebral disease could be detected during life, and yet disseminated foci of sclerosis existed in the nerve-centres. In such cases the symptoms may be in the direction of simple nervous prostration, more commonly of spinal irritation. I have now under observation a case which for years had been regarded as one of spinal irritation, and which made that impression on me until I discovered the existence of optic-nerve atrophy, which was the only indication that the symptoms depended on gross structural disease.²

Among the anomalous forms of disseminated sclerosis there is one which is characterized by the preponderance of paraplegia and contractures in a combination which is usually found in spinal diseases of a different type. The coexistence of dementia, however, usually enables the observer to determine that the lesion is both cerebral and spinal, although those signs which might enable him to decide the disseminated focal character may be absent.

MORBID ANATOMY.—In advanced cases of disseminated sclerosis the lesion is visible to the naked eye on the surface of the brain and spinal cord. Grayish maculas, sometimes elevated, more rarely a little sunken, and occasionally showing a buff or reddish tinge, are seen on the surface of the spinal cord, the oblongata, pons, and crura. On making sections across the region of the spots, it is found that the color-change is not superficial, but extends inward, involving large parts of the transverse area of the cord or the cerebral axis; and patches lying more deeply in their substance are revealed whose existence could not have been suspected from a mere surface inspection. Exceptionally, patches are found involving the entire transverse section of the spinal cord in a length of a half to two inches. And, similarly, in the brain nearly the entire area of the pons or one of the crura or an entire division of the internal capsule may be occupied by a sclerotic focus. Otherwise, they may vary from almost microscopic dimensions to the size of a chestnut or even larger. Bourne-

¹ It is customary to speak of symptoms referable to the oblongata as bulbar. The designation *bulbus rachidicus* is now obsolete, and just as we speak of a capsular hemiplegia, a pons paralysis, or a spinal hemiplegia, so we should say an oblongata paralysis, discriminating between the nuclear, the neural, and the tract affections by means of a prefix.

² At present the symptoms of disseminated sclerosis are unmistakable. Cases are mentioned by Strümpell and others in which they remained indecisive throughout.

ville¹ has described cases in which the nerve-centres appeared normal to the naked eye, while the microscope revealed the existence of sclerotic foci. It is, however, unlikely that the fresh brain- and cord-tissue, when the site of disseminated sclerosis, will appear perfectly healthy to the naked eye under fairly good illumination. Much less intense lesions than those of disseminated sclerosis reveal their presence by changes in color and consistency.

On examining the diseased spots more narrowly, they are found to be slightly diaphanous. Usually, they are rounded or elliptical, but they are often drawn out, as it were, in the most irregular shapes, and not infrequently appear to be the result of a confluence of originally remote and separate foci. In the cord they are sometimes wedge-shaped, extending inward from the periphery. To the touch they appear firm—sometimes not much more so than the normal tissue, contrasting with it as hard-boiled white of egg would contrast with soft-boiled; in advanced cases they become of almost leathery consistency, and there are instances recorded where they actually creaked under the knife. A clear fluid usually runs from their cut surface, and the latter does not jut up on section like normal nerve-tissue.

The distribution of the diseased areas follows no known law. They may be numerous and of large size in one segment of the nervous axis, and small, few in numbers, or even absent, in others. In some altitudes of the cord the lateral, in others the posterior, in still others the anterior, columns are chiefly involved. The cerebrum usually contains a larger number of foci irregularly scattered in the centrum ovale of Vieussens, the internal capsule and its surrounding ganglia, as well as in the corpus callosum. Throughout the nervous axis it seems that the lesion chiefly affects the white substances, and even the roots of the peripheral nerves, both cranial and spinal, are occasionally found to contain small foci, gray, firm in consistency, and as distinctly outlined as those of the central organs.

The morbid process consists in an atrophy and gradual disappearance of the myelin, which is preceded, if not caused, by an increase of the enveloping interstitial substance. This change is of the same character as that found in chronic myelitis. The septa and trabeculæ of connective tissue become thicker, formless connective substance and fibrillar tissue, which seems to arise in, if not in part from, it, constituting the new formation. The neuroglia-nuclei are increased, enlarged, and develop into spider-shaped cells, whose long processes contribute (according to some authors exclusively) to the newly-formed fibrillar network.

While the myelin undergoes wasting, the axis-cylinders remain intact for a long period, and even in intensely sclerosed regions they may be found in nearly their normal number, but naked and in direct contact with the pathological fibrillæ. Some of them become hypertrophied, increasing to twice, thrice, and, according to Leyden, even more, of their normal diameter. This change seems to inaugurate the last phase of the process: the axis-cylinders, becoming sclerosed and brittle, ultimately disappear, and no trace, or at best but doubtful traces, of the normal nerve-tissue are left behind. The blood-vessels, following the rule of

¹ *Mouvement médicale*, 1869, No. 27.

the sclerotic process, take part in it. Their walls become thickened, richly nucleated, and the lumen becomes narrowed in consequence. In the smaller vessels complete obliteration of the lumen is sometimes observed.

The gray substance is not involved as frequently as the white, but it opposes no barrier to the extension of the morbid process when once established in its neighborhood. The nerve-cells show the same resistance which the axis-cylinder does; that is, they retain their outline and fibre-connections a long time in the midst of the diseased area. But eventually they become discolored, undergo hyaline or granular disintegration, their processes shrink, and finally they disappear.

Ribbert and Zacher consider the sclerosis of tabes and the disseminated affection to be much more similar than Leyden and Charcot supposed. They locate the starting-point of the morbid process in the vascular and connective tissues; and Greiff, in harmony with this view, finds that the foci occur most frequently in those parts of the cord where the connective-tissue trabeculæ are most numerous, as in the posterior columns and at the junction of the anterior and lateral columns.

Although the morbid foci appear to the naked eye to be uniform, and to be sharply demarcated in the normal tissue, closer examination shows that the areas of maximum lesion are surrounded by a narrow transition zone by which the lesion seems to mark its eccentric progress, and occasionally a focus of intense disease lies in a diffused area of slight changes, resembling those of diffuse myelitis. Sometimes the cord appears to be almost continuously involved by a lesion of moderate intensity, and a few disseminated foci in the brain alone prove that the case belongs to this form of sclerosis.

A few years ago Greiff described what he considered a new lesion in multiple sclerosis, under the name of disseminated vitreous degeneration of the cerebral cortex.¹ I have been familiar with this lesion since 1876: it can be produced at will in perfectly healthy brains, and consists in a precipitation of leucine crystals extracted from the brain-substance by the action of alcohol. His accompanying figure² represents this artificial lesion very accurately; and Greiff, if he fails to recognize that his vitreous degeneration is a spurious lesion, at least identifies it with the milary sclerosis of Bucknill and Tuke and the spheres of Schüle, which are now generally recognized to be the results of post-mortem manipulations and not actual lesions.³

In judging as to the nature and intensity of the inflammatory process

¹ *Archiv für Psychiatrie*, xiv. p. 286.

² *Ibid.*, xiv., Plate ii. Fig. 5.

³ Attention was first called to the artificial nature of these bodies by the writer in the *Journal of Nervous and Mental Diseases*, October, 1877, and a more accurate description was given in the *Chicago Medical Review* of 1880, and in a demonstration before the New York Neurological Society in 1883. In commenting on the latter a German critic stated that the facts related had been long known in Germany (*Neurologisches Centralblatt*, 1883, p. 283). On inquiring of the critic what publication contained any reference to this discovery, he frankly stated that he knew of none, but had had in mind what he considered a tradition of the laboratory. It was in the same year that Greiff worked at the Heidelberg laboratory under the eminent supervision of Fürstner, and it was a few years previous that Schüle, one of the collaborators of *Ziemssen's Cyclopaedia*, had made the same mistake. So it seems that the tradition is in some danger of expiring, and that it would do no harm to accept the caution, even though it travel across the Atlantic in the reverse of the usual direction. It has been amply confirmed by Savage and Plaxton (*Journal of Mental Science*, October, 1882, and April, 1883).

which leads to the development of the sclerotic foci, it must be remembered that we are acquainted thus far only with the terminal period of the disease, when, as is to be presumed, the active inflammatory changes have gone by or are in the background. It is very probable that the newly-formed tissue is more nucleated in early periods than is found in the cases which constitute the material of pathological laboratories. In a case of protracted nervous exhaustion accompanied by spinal irritation in an alcoholic subject who was murdered, and whose brain and cord I had an opportunity of examining, I found, both in the cord and brain, districts in which the white substance showed a slight grayish discoloration and increased consistency. Minute examination failed to show any qualitative change in the conducting elements, but the interstitial tissue was hypertrophied, richly nucleated, and showed Frommann's cells in abundance.

ETIOLOGY.—Heredity has been observed in a number of cases by Duchenne, Erb, and Frerichs. The latter two had each an opportunity of recording this inheritance in several members—sisters or brothers—of the same family. In these cases the transmitted affection developed in adult life. Dreschfeld, however, cites a case where two brothers developed its symptoms in a marked degree in infancy. As an associated feature it is found with some cases of congenital defect. Thus Pollak¹ discovered disseminated sclerosis in an infant which had a defective corpus callosum and exhibited the characteristic signs of the focal affection side by side with the imbecility due to imperfect cerebral development. As a rule, the disease is developed after the twentieth year. But cases have been related (De Fleury) where the patient developed the disease and died with an apoplectic onset in earlier life. One of the youngest on record is described by Hödemacker.² The subject developed the disease at the seventh year, and died with it at the fourteenth, having shown the characteristic symptoms, besides more muscular atrophy than is common. The sclerosis in this case belonged to the type which has been referred to as a connecting-link between diffuse and disseminated sclerosis. Pelizæus³ reports five cases developing in the same family in early life, corresponding somewhat in their relation to multiple sclerosis of advanced life, as the family forms of tabes and spastic paralysis correspond to the typical adult forms of those diseases. All the cases were of males, and the ancestral taint had been present in male members of the family, passing through the females to their progeny without breaking out in the mothers. Each branch of this family appeared to develop its own peculiar type of the disorder.

CAUSES.—Disseminated sclerosis may develop as a sequel of an acute myelitis. An excellent observation of Singer,⁴ in which a unilateral optic-nerve atrophy of central origin occurred after recovery from an acute inflammation of the cord, proves that sclerotic foci may develop secondarily to an acute process. Westphal believes that obstruction to the circulation, both of blood and lymph, in the cord may act as a predisposing factor in the production of multiple sclerosis. He rests this opinion on a case where the cord had been compressed by a tumor, and

sclerotic foci of probably later date were found in the neighboring segments of the cord.

The myelitic affection discovered by the same observer¹ to be an occasional sequel of typhus, smallpox, diphtheria, measles, and erysipelas is a true disseminated sclerosis. The foci are usually very small and very numerous. A focal sclerosis of the posterior columns of the disseminated type has been found by Brigidi-Bandi in a case of pellagra which presented ataxic symptoms.²

Among the exciting causes, prolonged exposure to wet and cold are acknowledged to occupy an important position. The frequent combination of these factors with over-exertion and depressing emotions among the poorer classes probably account for its great frequency among them. In some cases excessive grief has been the only discoverable etiological factor: in three of my own cases this was so prominent and connected a feature that I could not doubt its influence, if not as a primary at least as an exciting cause.³ Fright has been distinctly connected with the outbreak of the disease in a number of cases.⁴ There is considerable unanimity among observers regarding the effects of shock and injury in producing disseminated sclerosis, usually of that anomalous type which approximates the diffuse or fascicular form. Railway spine is undoubtedly the mask of a disseminated inflammatory trouble in a number of cases; the only authority of weight who opposes this view is Charcot, and his opposition is abundantly neutralized by a number of carefully-studied American and European cases.

Hysterical and other obscure neuroses have been claimed to act as predisposing causes. But, inasmuch as it is well established that sclerosis is not a legitimate sequel of even the most aggravated forms of true hysteria,⁵ and, on the other hand, that disseminated sclerosis, particularly in the early stages, may progress under the mask of spinal irritative or other neuroses, it is reasonable to suppose that cause and effect have been confounded by those who advanced this view. According to Charcot, the female sex shows a greater disposition to the disease than the male. Erb, who bases his remarks on the surprisingly small number of nine cases, is inclined to account for Charcot's statement on the ground that it was at a hospital for females that Charcot made his observations. On comparing the figures of numerous observers, it will be found that in the experience of one the females, and of the other the males, preponderate.

¹ *Archiv für Psychiatrie*, iii. p. 376, iv.; Oertel, *Deutsches Archiv für klinische Medizin*, viii.; Damaschino, *Gazette médicale de Paris*, 1871, p. 505. In one case now under observation a typical disseminated sclerosis developed in a robust young man of thirty after typhoid fever.

² *Lo sperimentale*, December, 1879.

³ The coincidences among these three cases were remarkable. All three were Germans, all three musicians, two had lost an only son. In all, the emotional manifestations were pronounced from the initial to the advanced period of the disease.

⁴ A Bohemian cigar-maker was startled by the sudden firing of a pistol-shot in a dark hallway, and on arriving at the factory, and not fully recovered from the first fright, he was again startled by the sudden descent of an elevator and the fall of a heavy case from it close to where he stood. From the latter moment he trembled, and his tremors continued increasing till the last stage of his illness was reached. This was my case of shortest duration, four years, and of nuclear oblongata paralysis type.

⁵ Charcot's observation of lateral sclerosis in hysterical contracture, although made so long ago, has not been confirmed, and the most careful examinations in equally severe and protracted cases have proven altogether negative.

In my own experience the males far exceed the females both in private and in dispensary practice. Of 22 cases with accessible records, only 7 were females.

Syphilis has also been assigned as a cause. The connection is not as clear as in tabes. In the few cases where there appears to be a direct causal relation the lesion is not typical. There are sclerotic foci, but in addition there is a general lesion, particularly of the posterior columns of the cord, such as is found with parietic dementia. And it has been noted that periendymal and subendymal sclerosis is more frequent with the cases of alleged syphilitic origin than with those of the typical form.

DIFFERENTIAL DIAGNOSIS.—In view of what has been already stated regarding the numerous clinical types found in disseminated sclerosis, it is easily understood why the diagnosis of this disease is becoming more and more uncertain: every new set of researches removes some one or several of the old and cherished landmarks; and it may be safely asserted that only a minority of the cases show that symptom-group which was formerly claimed as characteristic of all. The discovery of a series of cases by Westphal,¹ in which the typical symptom-group of Charcot was present, but no sclerosis, deserving the name found after death, as well as the interesting experience of Seguin, who found well-marked disseminated sclerosis in a case regarded as hysterical *intra vitam*, illustrates the increasing uncertainty of our advancing knowledge. It was believed within a few years that the presence of cranial nerve-symptoms was a positive factor in determining a given case to be one of disseminated sclerosis, but in the very cases described by Westphal such symptoms were present notwithstanding the lesion was absent. Up to this time, however, no case has been discovered in which, optic-nerve atrophy being present in addition to the so-called characteristic symptoms of intention tremor, nystagmus, and scanning in speech, disseminated foci of sclerosis were not found at the autopsy. This sign may be therefore regarded as of the highest determining value when present; but as it is absent in the majority of cases, its absence cannot be regarded as decisive. The presence of pupillary symptoms also increases the certainty of the diagnosis when added to the ordinary and general symptoms of the disorder related above.

Although the difference between the tremor of typical disseminated sclerosis and that of paralysis agitans is pathognomonic, yet the existence of a group of cases of disseminated sclerosis, as well as of one of cases of paralysis agitans without tremor, renders an exact discrimination in all cases impossible. It is a question, as yet, whether the form of paralysis agitans without tremor described by Charcot, and which is marked by pains in the extremities, rigidity, clumsiness, and slowness of movement, general motor weakness, a frozen countenance, impeded speech, and mental enfeeblement, is not in reality a diffuse or disseminated sclerosis.

The diagnosis of this disease, while readily made in a large number of cases on the strength of the characteristic symptoms detailed, may be regarded as impossible in a minority which some good authorities incline to regard as a large one.

¹ *Archiv für Psychiatrie*, xiv. p. 128.

Diffuse Sclerosis.

SYNONYMS.—Chronic myelitis, Diffuse myelitis, Simple or Diffuse spinal sclerosis, Chronic transverse myelitis, Sclerosis stricta sic dicta (Leyden, in part), Gray degeneration.

The various forms of sclerosis thus far considered were at one time considered as varieties of chronic myelitis, and under different names, founded on leading symptoms, were considered to be merely local, and perhaps accidental, variations of one and the same morbid process. More accurate clinical and pathological analysis has separated from the general family of the sclerosis one clearly demarcated form after another. *Tabes dorsalis*, disseminated sclerosis, amyotrophic lateral sclerosis, and the combined forms of sclerosis have been successively isolated. Still, a large number of cases are left which cannot be classified either with the regular affections of the cord, limited to special systems of fibres, or with the disseminated form last considered. They agree with the latter in that they are not uniform; they differ from it in that they are not multilocular. Not a few modern authors have neglected making any provisions for these cases, while others treat of them in conjunction with acute myelitis, of which disease it is sometimes regarded as a sequel. The term diffuse sclerosis is here applied to those forms of chronic myelitis which follow no special rule in their location, and to such as are atypical and do not correspond in their symptomatology or anatomy to the more regular forms of sclerosis. In regional distribution the foci of diffuse sclerosis imitate those of acute myelitis: they may be transverse, fascicular, or irregular.

MORBID ANATOMY.—In typical cases the lesion of diffuse sclerosis constitutes a connecting-link between that of the disseminated form and posterior sclerosis. Its naked-eye characters are the same. There is usually more rapid destruction of the axis-cylinders, more inflammatory vascularization, proliferation of the neuroglia-nuclei, and pigmentary and hyaline degeneration of the nerve-cells, than in the disseminated form.

Syphilitic inflammation of the cord extends along the lymphatic channels, including the adventitial spaces, and leads to a diffuse fibrous interstitial sclerosis. In one case in which I suspected syphilis, though a fellow-observer failed to detect it after a rigid search, I found a peculiar form of what would probably be best designated as vesicular degeneration, according to Leyden, though associated with a veritable sclerosis. The lymph-space in the posterior septum showed ectasis; the blood-vessels were sclerotic, and each was the centre of the mingled sclerotic and rarefying change. It appears that while the interstitial tissue hypertrophied, the myelin of adjoining nerve-tubes was pressed together till the intervening tissue underwent pressure atrophy. The result was, the myelin-tubes consolidated, some axis-cylinders perished, others atrophied, a few remained, and, the myelin undergoing liquefaction, long tubular cavities resulted, running parallel with the axis of the cord, and exposed as round cavities on cross-section (Fig. 32). The changes in the cells of the anterior horn in the same cord (Fig. 33) illustrate one of the common forms of disease to which they are subjected in the course of sclerotic disease.

The so-called myelitis without softening, or hyperplastic myelitis of

Dujardin-Beaumetz, which is ranked by Leyden and Erb among the acute processes, properly belongs here. It is characterized by a proliferation of the interstitial substance, both of its cellular and fibrillar elements. The nerve-elements proper play no part, or at best a very slight

FIG. 32.

or secondary one. In the sense that this affection occurs after acute diseases and develops in a brief period it may be called an acute myelitis, but both in its histological products and its clinical features it approximates the

FIG. 33.

sclerotic or chronic inflammatory affections of the cord. As far as the clinical features are concerned, this is particularly well shown in the disseminated myelitis found by Westphal after acute diseases, such as the exanthematous and continued fevers.

CLINICAL HISTORY.—Impairment of motion is the most constant early feature of chronic myelitis; in the transverse form it may be as absolute as in the severest forms of acute myelitis; as a rule, however, it is rather a paresis than a paralysis. The patient is usually able to walk, manifesting the paraparetic gait: he moves along slowly, does not lift his feet, drags them along, makes short steps; in short, acts as if his limbs were heavily weighted. This difficulty of locomotion is preceded and accompanied by a tired feeling before other sensory symptoms are developed. Rigidity of the muscles, like that found in disseminated sclerosis, is a common accompaniment, and may even preponderate over the paresis to such an extent as to modify the patient's walk, rendering it spastic in character. In such cases the muscles feel hard to the touch, and the same exaggerated reflex excitability may be present as was described to be characteristic of spastic paralysis.

If, while the leg is slightly flexed on the thigh, the foot be extended,¹ so as to render the Achilles tendon and the muscles connected with it tense, and the hand while grasping the foot suddenly presses the latter to still further extension, a quick contraction occurs, which, if the pressure be renewed and kept up, recurs again and again, the succession of the involuntary movements resembling a clonic spasm. This action is termed the ankle-clonus or foot-phenomenon. Gowers has amplified this test of exaggerated reflex excitability by adding what he calls the front-tap contraction. The foot being held in the same way as stated above, the examiner strikes the muscles on the front of the leg; the calf-muscles contract and cause a brief extension movement of the foot. It is believed that the foot-clonus and the front-tap contraction are always pathological, but a few observers, notably Gnauck, leave it an open question whether it may not occur in neurotic subjects who have no organic disease. Gowers considers the foot-clonus found in hysterical women as spurious, and states that it differs from the true form in that it is not constant, being broken by voluntary contractions, and does not begin as soon as the observer applies pressure. But I have seen the form of clonus which Gowers regards as hysterical in cases of diffuse sclerosis. With regard to the front-tap contraction, its discoverer² admits that it may be obtained in persons in whom there is no reason to suspect organic disease. It is significant only when unequal on the two sides.

In severe cases contractures are developed in the affected muscular groups, being, as a rule, preceded by the rigidity, increased reflex excitability, and the thereon dependent phenomena above detailed. These contractures may be like those of spastic paralysis, but usually the adductors show the chief involvement, and sometimes the leg becomes flexed on the thigh and the thigh on the abdomen in such firm contraction that the patient, albeit his gross motor power is not sufficiently impaired, is unable to move about, and is confined to his bed, his heel firmly drawn up against his buttock. It is stated by Leyden that the contracted muscles occasionally become hypertrophied—an occurrence I have not been able to verify. As a rule, some muscular groups are atrophied, though

¹ By extension the approximation of the dorsal surface to the tibial aspect of the leg—what some German writers call dorsal flexion—is meant.

² Gowers, *The Diagnosis of the Diseases of the Spinal Cord*, 3d ed., p. 33.

the limbs as a whole, particularly in those patients who are able to walk about, are fairly well nourished.

Pain in the back is a frequent accompaniment of diffuse sclerosis. It is not pronounced, but constant.

The drift of opinion to-day is to regard pain in the spinal region as not pathognomonic of organic spinal affections. It is true that pain is a frequent concomitant of neuroses, and that it is more intense and characteristic in vertebral and meningeal disease; but in denying a significance to pain in the back as an evidence of diffuse disease of the cord itself, I think many modern observers have gone to an extreme. It is particularly in diffuse sclerosis that a dull heavy sensation is experienced in the lumbo-sacral region; and in a number of my cases of slowly ascending myelitis and of tabes dorsalis the involvement of the arms was accompanied by an extension of the same pain, in one case associated with intolerable itching, to the interscapular region. It cannot be maintained that the pain corresponds in situation to the sclerotic area. It is probably, like the pain in the extremities, a symptom of irradiation, and corresponds in distribution to that of the spinal rami of the nerves arising in the affected level.

As the posterior columns are usually involved in transverse myelitis, the same lancinating and terebrating pains may occur as in tabes dorsalis. As a rule, they are not as severe, and a dull, heavy feeling, comparable to a tired or a burning sensation, is more common. A belt sensation, like that of tabes, and as in tabes corresponding to the altitude of the lesion, is a much more constant symptom than acute pains.

Cutaneous sensibility is not usually impaired to anything like the extent found in advanced tabes. It is marked in proportion to the severity of the motor paralysis; where mobility is greatly impaired, profound anæsthesia and paræsthesia will be found; where it is not much disturbed, subjective numbness, slight hyperæsthesia, or tingling and formication may be the only symptoms indicating sensory disturbance; and there are cases where even these may be wanting.

The visceral functions are not usually disturbed. In intense transverse sclerosis of the upper dorsal region I observed gastric crises, and in a second, whose lesion is of slight intensity, but probably diffused over a considerable length of the cerebro-spinal axis, there is at present pathological glycosuria. The bladder commonly shows slight impairment of expulsive as well as retaining power, the patients micturating frequently and passing the last drops of urine with difficulty. Constipation is the rule. The sexual powers are usually diminished, though rarely abolished. As with sclerotic processes generally, the sexual functions of the female, both menstrual and reproductive, are rarely disturbed.

It is not necessary to recapitulate here the symptoms which mark diffuse sclerosis at different altitudes of the cord. With this modification, that they are less intense, not apt to be associated with much atrophic degeneration, nor, as a rule, quite as abruptly demarcated in regional distribution, what was said for acute myelitis may be transferred to this form of chronic myelitis. The progress of diffuse sclerosis is slow, its development insidious, and the history of the case may extend over as long a period as that of diffuse sclerosis. Sooner or later, higher levels of the cord are involved in those cases where the primary focus was low down.

In this way the course of the disease may appear very rapid at one time, to become almost stationary at others. Of three deaths which occurred from the disease in my experience, one, in which there were distinct signs of involvement of the oblongata,¹ occurred from sudden paralysis of respiration; a second from a cardiac complication, which, in view of some recent revelations concerning the influence of the tabic process on the organic condition of the valves of the heart, I should be inclined to regard as not unconnected with the sclerosis; and in a third, from bed-sores of the ordinary surgical variety. The malignant bed-sore is not of frequent occurrence in this disease.

PROGNOSIS.—The disease may, as in the instances cited, lead to a fatal termination, directly or indirectly, in from three to twenty years. The average duration of life is from six to fifteen years, being greater in cases where the sclerotic process is of slight intensity, even though it be of considerable extent, than where it is of maximum or destructive severity in one area, albeit limited. I am able to say, as in the case of *tabes dorsalis*, that a fair number of patients suffering from this disease whom I have observed for from two to six years have not made any material progress in an unfavorable sense in that time. One cure² occurred in this series, of a patient manifesting extreme contractures, atrophies, bladder trouble, and ataxiform paresis, where the cause was plainly syphilis, and the histological character of the lesion is somewhat a matter of conjecture in consequence. Diffuse sclerosis of non-syphilitic origin—and this may apply also to established sclerosis in syphilitic subjects—is probably as unamenable to remedial treatment as any other sclerotic affection.

The same rules of **DIAGNOSIS** applicable to transverse myelitis of acute onset apply, level for level, to the diagnosis of transverse myelitis of insidious development, the history of the case often furnishing the only distinguishing point between the acute and the chronic form.

The main difference between the diffuse sclerosis and acute myelitis, clinically considered, consists in the gradual development of symptoms in the former as contrasted with their rapid development in the latter disease. Acute myelitis is established within a few hours, days, or at most, in the subacute forms, a few weeks; chronic myelitis requires months and years to become a clearly-manifested disorder. It is the essential correspondence of the symptoms of both conditions, intrinsically considered, which renders it impossible to distinguish clinically and in the absence of a history of the case between some cases of acute myelitis in the secondary period and the processes which are primarily of a sclerotic character.

It is unusual to find the degeneration reaction in myelitis of slow and gradual development. Sometimes there is diminished reaction to both the faradic and galvanic currents, or the so-called middle form of degeneration reaction is obtained from atrophied muscles, the nerve presenting normal or nearly normal irritability, and the muscle increased galvanic irritability and inversion of the formula.

¹ On one occasion the patient had momentary anarthria, followed a day later by two successive periods of anarthria, lasting respectively about twenty seconds and one minute, one of which was accompanied by diplopia of equally brief duration.

² The patient went, under direction of Leonard Weber and R. H. Saunders, to Aix-la-Chapelle, where this happy result was obtained after mixed treatment had practically failed.

Among the less reliable or accessible points of differentiation between the residua of acute myelitis and the chronic form is the history of the onset and the age of the patient at the time of the onset. Myelitis in young subjects is more likely to be of the acute kind; in older persons it is more apt to be chronic.

In the diagnosis of diffuse sclerosis the question of differentiation from neuroses not based on ascertainable structural disease, such as are called functional, will be most frequently raised. In differentiating between organic and functional spinal disorders all known exact signs of organic disease must be excluded before the case can be considered as appertaining to the latter group. Symptoms of hysteria, nervous exhaustion, and spinal irritation frequently coexist with diffuse sclerosis as well as with the disseminated form; and this is not surprising, for, instead, as seemed at one time to be believed, of the neurotic taint granting comparative immunity against organic disease, it is the reverse, and it is not at all uncommon to find a strongly-marked neurotic diathesis in the family history of sufferers from diffuse sclerosis. That ordinary hysteria, epilepsy, and what is vaguely called nervousness are common features in the ancestral record of the hereditary forms of spinal disease has already been stated in considering those affections.

One of the commoner forms of the grave phase of hysteria is paraplegia.¹ Often muscular atrophy—which ensues from disuse—exaggeration of the deep reflexes, and retention of urine are added to the paraplegia and heighten the resemblance to an organic affection. Its development, though sometimes sudden, often occupies weeks or months, and may be preceded, exactly as in chronic myelitis, by weakness in the legs, and not infrequently by combined ataxia and weakness. It is much more difficult to discriminate here than is generally held or than is enunciated in textbooks. The sufferer from hysterical paraplegia does not always give other indications of the hysterical neurosis, and even if she did show a globus and tenderness at certain points, it is a question whether it could be called a scientific diagnosis which determined the case to be one of functional trouble on these signs alone. More than one error has been committed in this respect. In chronic myelitis retention of urine is less common than incontinence, which is the reverse of hysterical paraplegia. Pupillary symptoms do not occur with the latter affection. If there be sensory anæsthesias, they are bizarre in character or distribution, and do not usually harmonize with the distribution of the paralysis. In most cases moral influences can be exerted so as to increase the power of movement far beyond what would be possible in an organic disease; and while an electrical examination will not always yield positive results in chronic myelitis, yet no case of chronic myelitis with complete or nearly complete paraplegia but will show at least quantitative changes of such extent as to prove beyond doubt that the case is of an organic character.

There is one point in which spinal and cerebral disease involving the motor tract differs in the majority of cases, which may be utilized in dis-

¹ I have observed for two years a stationary brachial diplegia, of undoubted hysterical origin, although the patient had never shown any ordinary hysterical manifestations, and had had no other hysterical symptom than chromatopsia, and that only for a short period. From its long duration, constancy, and the resulting atrophy of disuse it had been regarded as a case of peculiarly limited chronic myelitis.

tinguishing obscure affections of the former from those of the latter kind. In cerebral paralysis of any standing the superficial reflexes, such as the cremaster and abdominal reflexes, are usually diminished or abolished, while the deep or tendon reflexes are exaggerated. In spastic conditions due to spinal disease—say sclerosis of any kind affecting the lateral column and leaving the motor nuclei of the anterior cornua unaffected—the deep reflexes are similarly increased, but the cremaster reflex is increased also.¹ This feature of the superficial reflexes is significant in the case of cerebral disease only when unilateral.

The initial period of diffuse sclerosis is sometimes confounded with rheumatism—an error less pardonable than in the case of tabes, inasmuch as in diffuse sclerosis the pains are not usually premonitory, but associated with motor paresis. It is erroneous to regard a pain as rheumatic because it is aggravated or relieved by changes in the weather. There are many subjects of myelitis who regard themselves as veritable barometers, and with more justice than most rheumatic patients.

In some cases of chronic alcoholism there are motor weakness and a gait much like that of diffuse sclerosis.² It is to be remembered that the solar tickling reflex is very often abolished in alcoholic subjects, and profound diminution of the normal cutaneous sensibility of the leg and feet usually coexist. But unless there is peripheral neuritis—which is an exceptional and, when present, well-marked affection—the absence of profound nutritive changes of the muscle, the presence of the alcoholic tremor, the absence of sphincter and bladder trouble, and the great variation of the symptoms from week to week, and even from day to day, serve to distinguish the alcoholic spinal neurosis from myelitis.

The Secondary Scleroses.

In studying the lesions underlying the symptoms of organic spinal disease, the occurrence of fascicular scleroses, secondary to such disease and due to the destructive involvement of nerve-tracts, was repeatedly noted. Türck may be regarded as the discoverer of these degenerations, and the reliability of this old observer may be inferred from the fact that one bundle of fibres liable to individual degeneration still goes by his name, and that, as far as he was able to discriminate between the various paths which secondary degenerations follow through the cerebro-spinal fibre-labyrinth, his statements have not been materially modified by more recent investigators, such as Bouchard, Vulpian, and Westphal.

The discovery by Meynert that the great cerebro-spinal tracts attain the white color which they owe to the development of myelin around their component axis-cylinders with advancing maturity, and that the tracts of noblest, and therefore most intelligent, function were the last to show this sign of maturity, was greatly extended by Flechsig, who found that each tract receives its myelin at a definite period of intra-uterine life, the lowest or the nerve-roots first; then the short or intersegmental or—as

¹ Attention has been called, I believe, by Westphal, to the fact that the cremaster reflex may not be demonstrable when reflex excitability is at its highest, because the cremaster muscle is already in extreme spastic contraction.

² Wilks' alcoholic paraplegia.

the physiologist may call them—the automatic tracts; then the long or controlling tracts; and last, the associating tracts of the cerebral hemispheres which mediate the complex relations underlying mental action. It was this discovery which gave a new impulse to the study of the secondary affections of the cord and brain. The accuracy with which secondary degeneration follows the lines marked out by the normal course of the tract is as great, diminishing when the tract diminishes, changing its position or direction and decussating where the latter changes its direction or position or decussates, that it constitutes not alone an interesting subject for pathological study, but has become one of the most reliable guides of the cerebral anatomist. It is of great importance to the pathologist to be able to differentiate between the primary disease and its secondary results, and, as the controversy concerning the so-called system diseases shows, even the most studious observers are uncertain in this direction in many cases.

MORBID ANATOMY.—Secondary degeneration manifests itself by a discoloration of the affected nerve-tract, which accurately corresponds in area to the normal area of that tract. The more recent the degeneration the less pronounced is this change. In advanced cases the color may be a dark gray, in moderately old ones a reddish or yellowish gray, and in those of very recent origin no change may be visible to the naked eye. It is claimed, however, that even here a loss of translucency of the white substance, giving it a sort of cheese-like opacity, may be detected. On hardening the specimen containing the degenerated tract in Müller's fluid or a simple bichromate salt solution, the affected area, instead of appearing dark on section in contrast with the gray substance—which in such preparations appears yellowish or a light brown—contrasts with the former by its lighter tinge. This contrast is observable even in cases where the naked eye was unable to detect the change in the fresh specimen. It can be sometimes found as early as the tenth day after the primary lesion, and is apparently simultaneously developed in the whole length of the nerve-tract affected.

The minute changes characterizing secondary degeneration begin in the essential conducting elements, the axis-cylinder, which exhibits a finely granular or molecular disintegration, and disappear. According to Hömén, it shows an initial swelling and a failure to stain properly before this. The myelin then follows suit: it becomes fragile, forms variously-shaped globules, and also disappears, and together with this a nuclear proliferation is noticed in the interstitial substance; fatty granule-cells are observed in large numbers, and manifest a tendency to accumulate in the perivascular districts. These cells are not permanent; their gradual diminution is accompanied by a proliferation of the interstitial tissue, which ultimately appears as a pure connective substance composed of fine fibrillæ arranged in undulating bundles. The entire process may be not inaptly compared to an hypertrophy of the interstitial substance resulting from overfeeding of its cellular elements by the morbid pabulum furnished through the disintegration of the nervous substance proper.

The disappearance of the nerve-tubes, and the formation of a new tissue in their place, which, like all tissues of the same character, undergoes shrinkage, leads to considerable deformity in the shape of the part which is the site of secondary degeneration. This is seen in the accom-

panying figure, where in an old-standing secondary degeneration of one interolivary layer the corresponding half of the medulla is greatly

FIG. 34.

Secondary Degeneration of Interolivary Layer: *D Ds D*, degenerated area; *r*, the distorted raphe.

reduced in diameter as compared with the other side (Fig. 34), and the entire raphe is distorted. When one side of the cord is the site of such a change a similar asymmetry results.

According as the original lesion is incompletely or completely destructive, a larger or fewer number of axis-cylinders may be found preserved in the sclerotic tissue. It is not yet determined whether in some instances these fibres may not represent an admixture from another source than are comprised in the mainly affected tract.

Secondary degenerations are classified as ascending and descending. An ascending degeneration is one which is found situated brainward of the primary lesion; a descending one is found caudad of the lesion. It was once maintained that the direction of the secondary degeneration was constant for each individual tract. This seems to be true for a few. Some tracts, particularly in the brain, degenerate on both sides of the lesion, as I showed with regard to the interolivary layer.

The best studied form of secondary degeneration is that of the voluntary motor conduit known as the pyramid tract. Beginning in the so-called motor area of each cerebral hemisphere, the Rolandic loop passes into the anterior part of the posterior half of the internal capsule, to be thence continued through the crus, pons, and the pyramids of the oblongata to the decussation or crossing-point of the pyramids. Here the greater part of the tract crosses into the opposite lateral column, occupying the position described in the section on Spastic Paralysis. A smaller part remains on the same side of the continuous interpyramidal and ventro-spinal fissure, constituting the direct fasciculus of Türek.

The crossed-pyramid tract diminishes as it passes caudad in the cord, giving off its fibres to the lateral reticular processes of the cord, whence

—whether interrupted by cells (Von Monakow) or not—they probably reach the great cells in the gray substance from which the anterior root-lets spring. The direct fasciculus probably terminates in a similar way, and perhaps makes good, as it were, its failure to participate in the gross decussation at the level of the foramen magnum by decussating in detail along its entire length. It is usually exhausted before the lumbar cord is reached, whereas the crossed tract in the lateral column continues down as low as the origin of the sacral nerves. A destructive lesion anywhere in the course of the pyramid tract, whether it be in the motor area of the cortex, in the loop of Rolando, in the internal capsule, the pons, or the cord itself, will provoke descending degeneration; that is, sclerosis of so much of the tract as lies below the lesion. Thus such degeneration is found with porencephalic defect of the motor area. I found it in a paretic dement who had extensive cortical destruction following a submeningeal hemorrhage. It has been observed after focal lesion of the pons (Homén, Schrader), and after transverse lesions of the cord, either myelitic, traumatic, or as the result of compression by vertebral disease. As a rule, the cells in the anterior horn are not involved, and some observers question whether this ever occurs. I have never found such involvement, although in its gross dimensions the anterior horn as a whole appears atrophied. This atrophy I have been able to account for satisfactorily by the disappearance of many of the fibres which run into the gray substance from the reticular processes.

While the distribution of degeneration in the cord is rather uniform, varying only in harmony with the ascertained individual variations in the relative preponderance of the crossed and uncrossed parts of the pyramid tract, there is much more variation in the cerebral distribution of the degeneration according to the extent of the original lesion. Thus, if the entire capsule be destroyed, the greater part of the crus is involved. If only the posterior division in its anterior part be destroyed, the degeneration is in the crus, limited to that part which runs a subpial course on the crural demi-cylinder, occupying from a fifth to a third of its surface-area. Still more limited degenerations are described, but as yet are too few in number to base other than tentative conclusions on them. Among these is one occupying a thin strip on the inner side of the crus, which degenerates after lesions near the genu of the capsule, and probably represents the tract which governs the cranial nerve-nuclei. An excellent observation by Von Mannkopf shows that the course of the motor fasciculus is subject to some individual variation even within the capsule.

A number of forms of secondary degeneration are described, involving intracerebral tracts, such as those connecting the cerebrum and cerebellum. The degeneration of the visual tract, from the optic nerve to the occipital lobe, observed by Richter and Von Monakow, with some conflict of opinion between these observers, is often as perfectly demonstrative of the course of the optic fasciculi as degeneration of the pyramid tract is demonstrative of the course of the voluntary innervation of the muscles moving the limbs.

The secondary degenerations following lesion of the pons varolii are acquiring special interest in view of their relation to special nerve-tracts of the spinal cord of hitherto unknown function. The purest instance

of an isolated degeneration of other than the pyramid tract is the case illustrated in the accompanying diagrams. It involved the interolivary layer, was both ascending and descending, being traced above into the subthalamic region, and below decussating into the opposite side of the oblongata, to terminate in the nuclei of the columns of Burdach and Goll. The leading symptom manifested by the patient was a hemiplegia of the muscular sense.¹

FIG. 35.

Secondary Degeneration of Interolivary Layer, Caudal or Descending Portion: A, in caudal half of pons; B, cephalic end of oblongata; C, middle of oblongata; D, at level of so-called upper pyramidal or interolivary decussation; E, at level of true pyramidal decussation. The atrophy in this level has entirely crossed the middle line; in D it is seen in the act of crossing.

Ascending degeneration is found in a very distinct form after compression of the cauda equina. It is limited to the posterior columns, occupying nearly the entire area of the latter in the lumbar cord, particularly the triangular field of Burdach's column mentioned in the article on *Tabes*. In the dorsal and cervical cord it is limited to the columns of Goll, and terminates in the clava of the oblongata at the nuclei of those columns.

Higher lesions produce the same ascending degeneration of the column of Goll, and in addition involve other, probably centripetal, tracts which happen to be injured at their origin or in their course. For example, a transverse lesion of the dorsal cord would produce ascending degeneration for its whole length of the column of Goll and of the direct cerebellar tract. In addition, it would, in obedience to the law previously stated, produce descending degeneration of the pyramid tract. This combination is almost a typical sequence of compression myelitis of the cord, as

¹ Besides my case, others have been recorded by Homén, Meyer (Strassburg), and Schrader, which are impure. In the former and latter degeneration of the pyramid tract, in the second degeneration of the olivary fasciculus, coexisted. It is not generally known that Westphal, in one of the first volumes of the *Archives* now edited by him, found an ascending degeneration of the same tract for a short distance.

well as of ordinary transverse sclerosis. Recently, Gowers¹ has described a secondary degeneration in such a case of transverse lesion not previously noticed. It is found in cases showing gross disturbance of cutaneous sensibility, and occupies a narrow belt encircling the anterior quarter of the circumference of the crossed-pyramid tract. It is continuous, in my opinion, with a tract which in the upper cervical cord is situated in a corresponding situation, and which degenerated a short distance caudad in a case of secondary degeneration of the olivary fasciculus described by Meyer, and in which similar sensory symptoms were noted.

CLINICAL HISTORY.—Secondary degenerations are passive results of other more active processes, and few clinical signs are attributable to

FIG. 36.

Decussating Degeneration of Interolivary Layer: *Dr*, *Dant*, the crossing degenerated fasciculi; *Arc*, the undegenerated fasciculi, after emerging from the partly sclerosed raphe.

them. The most important of these is the contracture which is found in old hemiplegias, and attributed, like the secondary exaggeration of deep reflexes in such, to the descending degeneration of the pyramid tract. Bouchard believed that it was the retraction of the sclerotic strand which acted as an irritant on the neighboring fibres. The development of spastic symptoms in amyotrophic lateral sclerosis and in focal lesions of the crossed-pyramid tract is in favor of this view. On the other hand, the occurrence of flaccid hemiplegia, and its conservation for years after the most extensive lesions, is against it, as it is in these very cases that the secondary degeneration is most intense. That the retraction of a

¹ *Diseases of the Spinal Cord*, and *Neurologisches Centralblatt*, 1886.

longitudinal strand exercises any serious effect on neighboring and parallel fasciculi is questionable, as the process is slow. There is, however, one situation where such influence is very likely to occur—the decussations of the oblongata. In the case already referred to, the retracting sclerosing bundles undoubtedly must have exercised a damaging effect on their fellows of the opposite side, which, interdigitating with them, were compelled to pass through the sclerosing tissue. It has occurred to me that the slight sclerosis which is sometimes observed in the crossed-pyramid tract of the same side of a cerebral lesion, even where that lesion is strictly unilateral, is due to a similar influence. I think it can be shown that such sclerosis cannot be traced to the primary lesion; it begins at the decussation, and it is more than probable that the firm constriction to which the healthy fibres are subjected in crossing through their shrinking fellows of the opposite side is not alone the cause of the symmetrical yet slighter lesion, but also accounts for the observation by Pitres and Charcot of a slight motor weakness observed on the same side as the hemiplegia, producing lesion in ordinary cases of capsular hemorrhage.¹

The PROGNOSIS and TREATMENT of secondary degenerations are practically involved in the primary lesion which gave rise to them. The contractures attributed to secondary sclerosis of the motor tracts is to be treated on the principles mentioned in the following section.

The Treatment of Spinal Sclerosis.

As the histological character of the different forms of sclerosis is similar—at least in the terminal period—the causes producing them identical even in name, and the indications furnished by leading symptoms analogous if not identical, the treatment of these various disorders is naturally based on the same leading principles. There are two objects to be aimed at in dealing with these chronic disorders: The first is the cure or arrest of the morbid process itself; the second is the amelioration of distressing and disabling symptoms.

It is generally recognized that a perfect cure of a sclerosis is a consummation never to be realized by any plan of treatment now at our disposal. The experiments of Kahler and others have shown that spinal tissue, once destroyed, is not regenerated. The post-mortem examination of cases of tabes which were considered as cured during life (Schultze) has shown that the sclerosis had not been removed; the process had merely become quiescent, and the apparent recovery had been due to the vicarization of other nerve-elements than those destroyed for the latter.

But if attempts at the regeneration of destroyed fibres and cells are to be regarded as futile, the arrest of the destructive process is to be considered as an object which offers better chances of realization, and which is worth attempting for other than merely conservative reasons. In a number of the forms of sclerosis described, notably in tabes and the disseminated form, it is remarked that the axis-cylinders lying within the

¹ Some of the French observers claim that this occurs only in the early period, but a careful study of the matter by R. Friedländer shows that the weakness of the side not usually regarded as involved is found in the later periods, and well marked then (*Neurologisches Centralblatt*, June 1, 1886).

morbid district are in part intact and in part but slightly affected. Here and there groups of nerve-tubes may be found which retain even their myelin. While subject to the vicissitudes inseparable from their position in the midst of active pathological changes, these channels of nerve-force, though anatomically patent, may have their function perverted or destroyed, just as a nerve outside of the cord may be paralyzed by pressure or anæmia though its structure be intact. Should the active phase of the sclerotic process be arrested, these intact or nearly intact fibres will resume their function, and thus an apparent improvement will be effected. The spontaneous ameliorations in the course of *tabes dorsalis* and the less marked ones of diffuse sclerosis, coupled with temporarily improved sensation in the former and improved motion in the latter disease, show that retrogressions of this character are possible and do occur. How is the physician to imitate the action of nature? how to intensify it so as to secure the permanent improvement which nature unaided does not grant? The first factor to be considered is the removal of the cause of the disease. A number of cases are due to exposure to wet and cold and to over-exertion. Such exposure and over-exertion, if not already rendered impossible by the disease, is to be discontinued. A large number of cases of *tabes*—according to many authors, a majority—a considerable number of cases of diffuse sclerosis, and not a few of other forms, are connected with the syphilitic dyscrasia. Here, at the very outset, we have a definite indication for treatment, and while we may be disappointed in the results of such treatment in a large proportion of cases, yet enough of well-assured and substantial success has been and is obtained to render it almost a matter of duty for the physician to try antisyphilitic measures in every such instance.

The mixed treatment in chronic spinal disorders should be followed out for long periods and faithfully. Most *tabic* and other sclerotic subjects affected with constitutional syphilis are in what is called the tertiary period of that disease, when iodide of potassium is less useful than mercury. I have never gained anything by pushing either drug to the extreme point in advanced cases, and it should be borne in mind that mercurialization carried too far may itself prove directly injurious to the nerve-centres.¹ In cases where gastric crises, gross ataxia, muscular atrophy, and bladder disturbance have been of long duration this treatment is rarely successful.² But in the initial and early periods of *tabes* and in diffuse sclerosis of slight intensity the effect is sometimes gratifying, and of such a nature that it cannot be attributed to a coincidence with spontaneous remissions of the disease. In one case both knee-jerks and the pupillary reflexes returned, to disappear on premature discontinuance of the treatment; and on resumption one knee-jerk again returned, and has remained demonstrable now over half a year. In a second case the fulminating pains and the bladder disturbance disappeared, a slight indication of the pupillary reflex developed, and the patient has remained stationary with this gain for a period of three

¹ Mendel thus found in his experiments made on dogs, developing cerebral disease from rotation with the head directed toward the axis of rotation, that dogs who had previously received subcutaneous injections of corrosive sublimate showed an increased vulnerability to the action of the rotary apparatus.

² A remarkable exception is related in the section on Chronic Myelitis.

years.¹ In a third case, one of established ataxia, with which luetic osseous lesions occurred, the pupillary reflex has returned twice, disappearing after the first reappearance. In one case of combined sclerosis in which no syphilitic antecedents could be found the paresis of the arms has disappeared, and the ataxic paresis of the lower extremities has improved to such an extent that the patient can stand with his eyes closed and his feet together, and on one leg with the eyes open—feats which a year ago he was unable to perform. None of the changes in symptoms taking place in these cases occur spontaneously in sclerotic spinal disorders, and they must be attributed to the treatment. Such treatment is best carried out in conjunction with warm bathing. The Hot Springs of Arkansas, those at Las Vegas, New Mexico, and the baths of Aix-la-Chapelle in Europe enjoy a special reputation in this field. The springs of Arkansas, as regards the intrinsic character of the water, possess advantages which are probably not excelled by any European baths, but the therapeutical management² is far from that ideal point of development attained, for example, at Aix-la-Chapelle.

Optic-nerve atrophy, according to the best authorities, constitutes a contraindication to the use of mercury in any form. It may be laid down as a general rule that the more rapidly the symptoms indicating a sclerotic process are developed, and the more recent its advent, the more energetically should the treatment be pushed. Mercurial inunctions and the so-called heroic doses of iodide are to be employed. But in cases progressing slowly and of long antecedent history what may be called a dilute plan is more apt to yield good results. Small doses of mercury,³ given steadily for years, and iodide of potassium, administered in well-tolerated doses for periods of ten days, alternating with corresponding periods of intermission, have, in my opinion, delayed or arrested the progress of tabes and other forms of sclerosis for the long periods referred to in the preceding sections.⁴ Although the antisymphilitic measures adopted in sclerosis of syphilitic origin are the most important, and the prognosis of no such case can be regarded as hopeless as to recovery or duration until they have been tried, other procedures, detailed under the head of Peripheral Treatment, should not be neglected. While some very severe cases improve rapidly on antisymphilitic treatment, other much less severe and more recent cases, in which the same cause is assigned with equal reason, are not affected by it in the slightest visible degree. The reason for this difference is unknown, but it necessitates the bearing in mind that by

¹ There was concentric limitation of all color-fields, and only central perception of green; to-day, if anything, the color-fields of this patient are a little greater than in the physiological average. The case was undoubtedly one of initial tabes.

² Mercurial ointment is used by the hundredweight, to quote the expression of a patient, and in certain establishments the sufferers from the common taint plaster each other from head to foot, as with mud, with this panacea for most of those ills which flock to the springs. Still, there seems to be no doubt that enormous quantities of mercury are borne well by those who use the baths, and who under other circumstances are susceptible to its most undesirable effects.

³ The tablet triturates of biniodide of mercury or corrosive sublimate furnished by Fraser & Co. of New York I have found peculiarly useful; one one-hundredth or more of a grain may be thus administered every two to four hours.

⁴ I am now employing the same treatment in some cases showing no syphilitic history. If any medicinal measures can act upon connective-tissue proliferation, it is these very ones.

limiting the treatment to the etiological indication valuable time may be wasted in which the symptomatic indications could be profitably followed.

In cases of sclerosis due to other causes than syphilis a number of medicinal agents have been recommended as calculated to affect the central disease directly. Ergot is recommended in sclerotic troubles, particularly tabes, by a large number of writers. It is admitted that this substance can produce tabes itself, so that its administration in the large doses recommended by some is not without its possible dangers. I have seen a patient well advanced in the disease who had received the drug for three weeks consecutively in such quantities¹ that on estimates made I came to the conclusion that he had received more than some of the persons in whom Tuzek discovered the development of ergotin tabes. Favorable results are reported ensuing after its use in the early stages, particularly where signs of irritation preponderated, such as lightning-like pains, hyperæsthesia, and frequent erections; and it has been suggested that the beneficial action is due to an effect on the blood-vessels, which are supposed to be congested in the beginning of the disease. Proof of such congestion has not been furnished: the vessels are usually sclerosed and their lumen narrowed. In view of the undeniable danger which attends the administration of ergot in tabes, it may be properly insisted that its indications be more precisely formulated than has yet been done. It is commonly noticed in the natural progress of tabes that the lightning-like pains disappear, usually about the time the anæsthesia becomes greater. The anatomical parallel is supposed to be the destruction of the nerve-tubes whose previous irritation caused these pains. If, as is claimed—and it seems to be substantiated—ergotin does produce amelioration of the lightning-like pains, it would prove a damaging revelation which showed that it did so in imitation of the natural process; that is, by increasing the sclerosis.

The first drug to which an influence was assigned upon the sclerotic processes, and which has maintained its reputation longest, is nitrate of silver.² Its claim to being regarded as a remedy may be best characterized by the fact that an author who is far from being prejudiced against it, and who recognizes the claims of Wunderlich, its advocate, speaks of it as a valuable placebo.³ I have never obtained any effects from this drug in the sclerosis, or from the chloride of gold, which has been also recommended for these affections, nor have I seen any in cases where either or both had been faithfully tried by others for years. The same is to be said of the chloride of barium, which has been warmly extolled on the basis of a very limited trial in disseminated and diffuse sclerosis.

The direct application of the galvanic current to the spine is recommended, more particularly by Erb and Neftel.⁴ I am unable to state

¹ An expert ophthalmoscopist found that the retinal vessels, which were somewhat dilated in this patient, were not influenced by the treatment.

² One of the first patients on whom Wunderlich tried this drug died while I studied at Leipzig. He had extensive argyria and sclerosis of the posterior columns.

³ Leyden, *op. cit.*, vol. ii. p. 359.

⁴ In describing a case in which this measure not only ameliorated lancinating pains and vesical symptoms, but also, applied to the head, relieved the diplopia—usually a spontaneous occurrence, according to both American and European writers—this writer takes occasion to state that in the year 1869 tabes dorsalis was practically unknown to American physicians (*Archiv für Psychiatrie*, xii. p. 619). Duchenne described progressive locomotor ataxia in that and the preceding year; the necessity of referring to the unfavourable

anything regarding currents derived from as many as twenty of Siemens cells and applied in the ascending direction, as the latter recommends beyond an experience which occurred in the practice of a colleague, who, alarmed by the event to be related, referred the patient subjected to this treatment to me. The patient suffered from *tabes dorsalis*, the symptoms being limited to the lower extremities, the ulnar distribution, and the pupils. The belt was in the lower thoracic region; the ataxia and lightning-like pains were not great. After a single application of an ascending current from twenty-two cells, continued for ten minutes, the patient suddenly felt a severe dull pain in the occiput and terrible lancinating pains in the distribution of the occipital nerves. With this there occurred scintillation before the eyes, and at the subsequent examination I found that the belt sensation had moved into the neck. The coincidence was so close, and sudden changes in the distributional area of tabic symptoms are otherwise so uncommon, that I attributed the observed change to the treatment.

Erb does not recommend such powerful applications. But the most sanguine electro-therapist must admit that the action of galvanic currents on the spinal cord is an exceedingly uncertain one. It is questionable whether weak ones deflect sufficient current-loops to reach the cord and to exert any material effect. As to currents powerful enough to produce an effect, it is not known, except in the loosest and most empirical way, what that effect is. The procedure followed by Erb is to use large electrodes, the cathodal one being a little smaller than the anodal, the former being placed stabile, over the upper cervical sympathetic ganglion of one side, the latter labile, on the opposite side of the vertebral spines, moving gradually downward, the session not exceeding three minutes. This is repeated daily or every alternate day.¹ It would prove a strong proof that this treatment really affected the morbid process in a remedial direction if any of the exact signs of the disease were to be modified by it, be it ever so slightly. If, after galvanization of the cervical cord and the sympathetic nerve, the initial myosis of *tabes* were temporarily lessened or the reflex contraction to light restored for ever so short a time, a brighter future would dawn for electro-therapeutics than seems now to be in store for it.²

Peripheral Treatment.—A number of therapeutical applications are made to the periphery where the symptoms of the sclerotic process are localized. The rationale of such applications is based on the assumption that peripheral conditions are capable of modifying the nutrition and functions of the cord. This is proven not alone by a host of observations made

miliarity of American physicians with a disease not at the time recognized on either side of the Atlantic is hence not apparent. Leyden (*op. cit.*, vol. ii. p. 325) candidly admits that the German medical profession was at first averse to recognizing Duchenne's limitation: this reproach cannot be laid at the door of American physicians, as I can distinctly recollect the demonstration of several well-marked cases exhibiting the characteristic symptoms then known, in the year 1870. The disease obtained recognition in American textbooks and journals as early as in those of any other land.

¹ Why, if the procedure be really remedial or efficiently palliative and devoid of evil consequences, it is not recommended to be repeated oftener I am at a loss to explain or understand. There are some factors involved in practical electro-therapeutics which it is scarcely possible to discuss without encroaching on delicate ground.

² In healthy persons the extent of the knee-jerk is increased by the spinal ascending galvanic current, and possibly this observation may lead to the establishment of a rational basis for its use in cases where the reflex is abolished or diminished.

on the normal cord, but is also disastrously illustrated in the part played by surface chilling in the etiology of many acute and chronic diseases of the cord. Notwithstanding this latter, a large and influential body of German neurologists recommend cold baths and cold spinal douches in these affections. I have seen such excellent results from the use of warm baths that I am compelled to plead, in defence of my ignorance of the effect of cold ones, that I have never dared to use them. In numerous cases the beneficial effect of a warm bath is almost instantaneous. Warmth in any shape, whether atmospheric or in the shape of baths, is usually agreeable to patients suffering from the various forms of sclerosis. Cold, on the other hand, is disagreeable, aggravates the symptoms, and in many cases at least hastens the progress of the disease. A winter spent in the latitude of New York or Boston means so much ground lost by the patient, and a sojourn during the colder months in Southern California, New Mexico, Florida, or the West Indies enables the patient to avoid this loss. As regards the choice of climate and baths for sclerotic patients, I should be inclined to roughly formulate the indications as being identical with those of chronic rheumatism. The reaction against the use of warm baths in Germany, where they once were popular,¹ is due to the employment of too high temperatures. Hot baths, in the strict sense of the term, including the various forms of vapor-bath, act badly. They increase instead of calming the irritative symptoms, as moderately warm baths do, and they entail too sudden a change in the bodily state. That, for the present, it is advisable not to adopt unreservedly either the extreme plan once in vogue or the equally extreme one which constitutes the reaction against it, is shown by the observations of Richter of Dall-dorf, who records some discouraging results obtained by the use of cold baths in cases of *tabes dorsalis*. It is but necessary to refer to the fact that the lancinating pains of the latter disease, the rigidity of diffuse myelitis, and the spasms of lateral sclerosis are usually most severe in cold weather, and that the diseases mentioned appear to be rare in warm countries, to show the need of caution in using a therapeutical measure so similar in its action, even if it be but momentary and followed by a reaction, to those which provoke or aggravate the original disease. Eulenburg has seen five recoveries in *tabes*, and under such different plans of treatment that the latter is not credited by him with the good result. Three were treated with warm baths, one with cold baths, and one with nitrate of silver. It is seen here that the warm baths were used with good results more frequently than the cold.

One of the most singular delusions of modern therapeutics—nerve-stretching—has, following the prediction made by several on both sides of the Atlantic, become obsolete. Introduced by Langenbuch, a surgeon, and attacking the disease at the sciatic nerve—a point where, as well-versed students knew, it was not located—the operation was looked upon with distrust from the beginning. The enthusiasm with which it was taken up by surgeons and by the interested portion of the laity—ever hopeful as *tabic* patients are of new drugs and methods of treatment—has led to a large number of trials, now numbering several hundred, and from which the useful lesson can be gathered that the good ripens slowly. Nerve-stretching in an organic disease of the spinal cord may take its

¹ The mud-baths of Cudowa in Galicia had a very high reputation.

place among the needless vivisections; it has not influenced the progress of a single case in any essential feature. On the contrary, it has more than once been directly responsible for acute myelitis, spinal hemorrhage,¹ and pyæmia. In a number of cases reported by Langenbuch,² Benedict, Erlenmeyer, Schweminger, Debove, and W. J. Morton, the ataxia of the patient has been reported as relieved; in one case, exhibited by the latter operator before the American Neurological Association, this appeared quite evident, but not because the disease proper had been influenced, but for the same reason that prevents the development of marked ataxia in combined sclerosis. Just as the lateral-column lesion inhibits the ataxia which is due to the posterior-column lesion, so the motor paresis produced by stretching the sciatic nerves neutralizes the manifest features of the ataxic gait. As soon as the paresis is recovered from, the ataxia returns in its original form, unless, happily, one of the common spontaneous changes for the better occur. As a therapeutic procedure nerve-stretching is to-day properly limited to affections of the peripheral nerves.

One of the most useful peripheral remedies in the sclerotic processes is the faradic wire brush. It is both an anodyne and remedial for anæsthesia. A number of the tabic patients to whom I referred as not having deteriorated within long periods are provided with a portable faradic battery, and apply the brush to the spots affected by terebrating pains the moment these commence, obtaining instantaneous relief. As has been shown by Rumpf,³ the cutaneous space-sense becomes more delicate in healthy and improved in tabic patients under its continued use. And while the inco-ordination of tabes is in part independent of the disturbance of cutaneous sensibility, yet if the latter can be refined the ataxic disturbance may be mitigated—a result occasionally obtained through the methodical use of the wire brush.

It is frequently found that sufferers from tabes dorsalis and other forms of sclerosis accompanied by ataxia walk much better in their stocking feet and in slippers than they do in the conventional street shoe or boot. The reason for this is obvious. The patient's gait is impaired by the disease, and, whether the ataxia be a pure co-ordinatory trouble or no, subjective uncertainty regarding contact with the ground which is experienced by most ataxic patients is an aggravating factor. Our modern foot-clothing, with its inflexible soles and raised heels, handicaps the patient as it were, depriving him of the use of what little tactile sensibility may be left him.⁴ The use of low-heeled shoes with thin and flexible soles is therefore advantageous.

¹ Zacher, *Archiv für Psychiatrie*, xv. p. 430.

² Westphal showed after the autopsy of Langenbuch's first successful case that there had been no spinal lesion whatever.

³ Report of a discussion, *Neurologisches Centralblatt*, 1885, p. 526.

⁴ The question whether tabes dorsalis is a disease of civilization has not been raised in any treatise I am acquainted with. Myelitis, both acute and chronic, occurs, however, rarely in the lower animals, as do also central dilatation of the cord and congenital defects of the latter. Posterior sclerosis I can find no record of in veterinary pathology. The influence of the repression of normal aids to locomotion by the foot-gear of civilized life as a possible predisposing factor in the etiology of ataxic troubles is a legitimate subject of inquiry. The lateness of the infant of civilized parents in acquiring the art of skilled locomotion may be in part, as philosophers claim, a penalty of exuberant development of the higher and inhibitive centres. But what part has the artificial obliteration of solar sensibility and pedal flexibility played in this inherited feature? What is its influence in establishing a pathological vulnerability?

The tremors of sclerotic affections, particularly those accompanying the disseminated forms, are from their distressing character prominent objects of special treatment. The bromides have been given with alleged good effect which I am unable to confirm. Curare has caused the tremor to disappear for two days in one of Erlenmeyer's patients. I have seen good results from the descending galvanic current applied in long sittings to the head and neck, sliding in to the point of tolerance, and sliding out before discontinuing. The mydriatics, atropine, and particularly hyoseyamin, often remove tremor radically for the time being; unfortunately, it is necessary to give them in almost toxic doses to obtain this effect. Recently, Feris recommended veratrum in doses of half a milligram repeated every four to five hours. It acted very well in every case in which I tried it, but, as it became necessary to increase the dose, the same objection was encountered as in the case of hyoseyamin. All these measures should be used as emergency remedies only; they cannot, in the nature of the case, prove curative, while their continued use produces a physiological indifference to their effect, and to that extent decreases their value as the case progresses.

MANAGEMENT OF SPECIAL SYMPTOMS AND COMPLICATIONS.—Among the most distressing features of many sclerotic affections is pain, which is usually associated with sleeplessness. The fulminating variety may be often relieved by the use of the actual cautery applied over the affected level of the cord and along the course of the nerve involved. But in the majority of cases morphine will have to be resorted to. Erb cautions against the use of this anodyne in cases where there is much reflex irritability of the cord, as morphine is said to increase this irritability when administered in small doses, and to reduce it again only when larger ones are administered. It is the latter alone which are serviceable with pain, and I have not yet seen any bad effects in the direction apprehended by Erb from such doses as it is necessary to give. That the physician administering it should be always on guard against the possible formation of a drug habit it is unnecessary to add. But it is also unnecessary to add what alternative he shall adopt when his choice lies between the lesser evil of the opium or morphine habit and the terrible martyrdom which some patients would be compelled to submit to if not allowed to indulge in it.¹ The evil effect of opium and its preparations on the visceral functions is to be neutralized, as far as possible, by the administration of laxatives and bitter tonics.

The deep-seated diffuse pains, such as are found in disseminated and diffuse sclerosis, are not as markedly relieved by opium as the terebrating and lightning-like variety. Frequently spastic or other signs of increased reflex excitability are associated with them; and as both are favorably influenced by the bromides, the latter are doubly indicated in such conditions.

With pains of a rheumatic character static electricity has been recommended. It undoubtedly relieves such pains, as skilfully-applied gal-

¹ Few sufferers from spinal disease use anodynes habitually; opium and its preparations are not fascinating to the majority of persons. On the other hand, there are two cases of *tabes dorsalis* now under my observation in which the patients have been compelled to use hypodermic injections of Magendie's solution for two and three years without any materially bad effect.

vanism would. Its chief effects, it seemed to me from a six months' trial with it, are on the imagination and hopes of the patient.¹

The bromides and camphor² are recommended for the obstinate priapism found in some cases of early tabes and transverse myelitis. I have seen better results from warm hip-baths and general baths in this condition than from any drug. As a general rule, the exercise of the sexual function, where not already forbidden by the results of the disease, should be limited as much as possible. The frequency of normal seminal emissions in a given case is a guide to the amount of indulgence in this direction which may be permitted. Where there is the slightest indication of irritative or destructive lesions in the upper lumbar cord sexual acts should be entirely prohibited, for under these circumstances no greater injury could be done the weakened centres than to permit them. This is particularly noticed in those cases of tabes dorsalis which are marked by satyriasis in the early period.

The treatment of the bladder trouble and of bed-sores is carried out in the manner described in the section on Acute Myelitis. For bed-sores Hammond recommends the application of a stabile galvanic element consisting of a plate of silver and one of zinc, the two being united by a wire isolated in the usual way. The silver plate is laid on the bed-sore; the zinc plate, covered by a piece of moistened cloth, is laid on the unbroken skin somewhere in the neighborhood. The result is a weak current under whose stimulant effect the healing process takes place very rapidly. I have seen excellent results that had been obtained by this means in indolent ulcers of the leg. It does not, however, seem to have been tested with the malignant variety of bed-sore.

With regard to the management of muscular atrophies by electricity, massage, and strychnia, the same rules are to be followed which are laid down in the section on the Myopathic Atrophies. It is only to be specially remarked that few authorities encourage the administration of strychnia in sclerotic affections, and fewer still in such large doses as could be of any benefit in a wasting process.

Faradization of the affected eye-muscles is often useful in diplopia. The current may be applied by means of a cup-shaped eye-electrode, or, better, by using a finger as an electrode.

The moral management of sufferers from sclerotic spinal affections is very important. The popular notion about spinal disease generally is such that the announcement made to a patient that he is suffering from any form of it is as alarming as would be the discovery of a tumor in his brain or a cancer in his stomach, and exerts a depressing effect. This it should be sought to avoid. A large number of sufferers from sclerosis live longer and suffer less than a portion of those afflicted with rheumatic and gouty affections; and the physician is justified in obtaining the desirable effect which a hopeful or resigned state of the mind undoubtedly has on the body, by laying great stress on this undeniable fact.

¹ A large apparatus of the new and improved make was at my disposal at the nervous department of the Metropolitan Throat Hospital. It was very popular with sufferers from rheumatism, who had been allowed to accumulate in the class before I took charge, and with a parietic dement who suffered with the rheumatoid pains often found with diseases such as his.

² Particularly the monobromate of camphor.

CONCUSSION OF THE BRAIN AND SPINAL CORD.

By WILLIAM HUNT, M. D.

THE writer was asked to contribute a short article upon Concussion of the Brain and Spinal Cord for this work, as these injuries are apt at first to come under the notice, if not charge, of the general practitioner. The article will therefore not be an exhaustive one, and there will be little but the details of personal experience and less quoting of authorities. Much has been written recently upon the subject both in volume and in pamphlet.

Diverse views of equally competent judges of the matter have been put forth, and the brains and spinal cords of the partisans appear to have received as severe a shaking up as the real recipients of the lesions, if absolute lesions there be.

This, in fact, is the point of controversy, for there are those who seem to deny that there can be a jarring or shaking of the cerebro-spinal mass sufficient to cause positive symptoms without producing positive lesions, whilst others are as firm in their convictions that pronounced symptoms may follow a mere disturbing ripple of the nervous elements. How is the question to be settled? The slightly shocked or injured recover rapidly, whilst some who only appear to be as slightly injured or shocked at first, go on to death, during the progress to which event there is no doubt as to the existence of lesion and no difficulty in finding it at the autopsy. Hence, say the lesionists, the first ones had it, but got well, whilst the non-lesionists affirm that it never existed in them.

The logician would think that these differences in opinion were only differences in degree about the same thing, but nevertheless, the question is one for serious discussion, and is of much greater importance than would appear to be the case to the average layman.

This importance lies in the medico-legal aspects of the suits arising out of the alleged injuries and their consequences. Judges, lawyers, and doctors know them well. In doubtful cases authorities of equal eminence are quoted, and the results of trials are equally as doubtful as to whether justice or injustice has been done. These remarks, as will be seen, are especially applicable to injuries of the spine, but they also may have place in the consideration of consequences arising from concussion of the brain.

Concussion of the Brain.

Whatever doubts there may be as to concussion of the spine, there are none, I believe, who deny the appropriateness of the expression as to the brain, it being, by its anatomical relations, so much more exposed to shock than the spine.

We understand that pure concussion, uncomplicated with fracture, refers to a condition caused by external violence, direct or indirect, which communicates a jar or shock to the cerebral mass, and which expresses itself by certain well-defined symptoms. The nervous system and the circulation are most manifestly involved, but in a pure case it may be said that all of the symptoms arise from central nervous disturbance. Even could it be shown that they were dependent on temporary congestions, these congestions, I think it will be admitted, would be due to vaso-motor derangements.

The anatomical appearances after early death from concussion of the brain are often insufficient for us to comprehend the fatal result, for we know that the organ will bear, both from disease and other kinds of injury, vastly greater inroads upon its structure and surroundings without causing death. Often there is mere localized cerebral congestion, with no ruptures of vessels; then there are slight extravasations shown as points or dots of blood in the nerve-matter; and, again, there is what is called the bruised brain. Sometimes there is nothing abnormal whatever to be found. Most of these cases, under modern criticism, have been justly shut out from the record as having no value; for it has been shown that the post-mortem examinations of them have been very imperfect, the brain only having been inspected, whereas the chest, the abdomen, or the spine might readily have revealed the cause of death.

It is fair, however, to assume that there must be a capacity for serious results in the vibratory jar, as the discoverable lesions in many well-examined cases have been in themselves insufficient to kill. The rapidity of recovery of those who get well also bears weight on this point.

Of nineteen cases of recovery from concussion of the brain of which I have record, the average stay in hospital was eight days. The range of stay was from one to twenty-five days. Many of these were at first profoundly shocked, some of them apparently hopelessly so when we compared their symptoms with those who died. As they recovered, however, in so short a time, there surely could not have been any gross lesion to account for their symptoms. What else, then, can account for them than vibratory jar? and if this can produce such severe results within the line of recovery, why cannot the degree of it be so extended as to involve, for example, the respiratory centres, and so kill without leaving perceptible sign?

The SYMPTOMS of concussion of the brain range from a mere daze or stunning to those of deep unconsciousness. There is no paralysis of the extremities in pure cases. Often the patient is very restless, and throws his limbs about in all directions. When these are quiet there is response to irritation and electricity. Loud speaking to him may elicit some attention, but the answers are mostly incoherent. There is pallor, often extreme, coldness of surface, and sweating. Vomiting is usual, and may come on immediately or later, and it continues as long

as there is anything to discharge; sometimes there is retching. In favorable cases the cessation of vomiting is accompanied by a slow return to consciousness, which may be preceded by delirium. This return is never sudden, and the method of it serves to distinguish the case from that of some forms of epilepsy. The pulse is generally frequent and feeble, often irregular; in extreme cases it may be slow and feeble, very rarely, if ever, strong or bounding. After reaction it becomes more natural, and if recovery follows it will not show much variation. The temperature is depressed at first. In one characteristic case it was 98° on the first day, reached 101° on the third day, and receded to $98\frac{1}{2}^{\circ}$ on the eighth day, when the brain symptoms disappeared.

There may be retention of urine and sluggishness of the bowels, but in bad cases coincident with the vomiting there is sometimes involuntary discharge both of feces and urine. The respiration is irregular, sometimes almost ceasing, and then returning with great rapidity.

Much has been said and written about the condition of the pupils in concussion of the brain. I have made this matter a subject of observation, and am convinced that the state of the pupils is of no diagnostic value whatever as to determining the existence of concussion or compression. Their state is of great value in telling us that the functions of certain brain-centres are partially or wholly impaired. The progress of the case will tell us whether the impairment is due to clot or effusion, congestion or jar.

It is wrong, therefore, to say that the pupils are one way in compression and another in concussion. It is right to say that in either case they are sluggish or wholly irresponsive to light. In one person they may be dilated, in another contracted, and in the same person the eyes may present marked contrasts.

In the light of modern physiology this is what might be expected. The condition of the pupils is dependent on that part of their nerve-connections which is involved in the injury, and also upon the method of that involvement. Clinical experience, I think, amply sustains this view.

The reaction from what may be called pure concussion is generally slow. The patient is apt to be dazed for some time, although the pulse and temperature may be normal. When there is a rebound with fever, and florid complexion, and suddenly or gradually another but deeper unconsciousness supervenes, it is almost certain that positive lesion took place at the time of injury, and that the reaction has brought with it great congestion if not extravasation.

Now, really, compression to be followed by inflammation is the condition demanding attention.

DIAGNOSIS.—The history of the case and the symptoms as detailed will enable us to reach a conclusion in most cases as to the existence of concussion of the brain. There are some conditions, however, from which it is to be carefully distinguished. These are simple fracture, with or without depression, compression from any cause, drunkenness, and epilepsy.

There may be such profound shock with fracture that at first concussion symptoms mask those of the lesion, or even keep them for a time completely in abeyance. The head bruises are often very deceptive to the touch in the search for fracture.

I am in the habit of directing students to feel their own scalps, in order that they may appreciate the fact that the touch gives no sensation whatever of the natural thickness of the cranial covering. It seems as though something like a piece of thin parchment only intervenes between the fingers and the bone. The fact is, the scalp varies from an eighth to a quarter of an inch thick, differing in different places, and where muscles, as the temporal, for example, are beneath it, the bone is much deeper. The importance of this observation lies in the fact that a pulped bruised mass of scalp will cause the edges of its healthy surrounding part to feel almost precisely like bone around the borders of a depressed fracture. The accompanying general symptoms will mostly not be in accord with this condition, but in some cases the deception is so complete that it is very difficult to persuade those not familiar with the fact that a fracture does not exist, and to induce them to refrain from rash proceedings.

One case I can call to mind where the opinion of the attending physician was only changed by the ultimate favorable result, which left no sign of permanent injury of any kind. These cases are particularly apt to occur with children.

I remember also another source of deception. A boy was severely injured by a blow upon the forehead. Concussion was marked. There was a lacerated wound reaching to the edge of the orbit; fractured bone could be felt, and at first sight what appeared to be brain-matter was oozing from the wound. A hasty unfavorable prognosis was given to the parents. On closer examination it was found that the fracture was of the external wall of the frontal sinus, and the supposed brain-matter was the delicate fat-lobules of the orbit. The patient recovered rapidly.

There is a marked distinction between the ordinary symptoms of concussion and those of compression, whether from depressed fracture or effusion, as of blood in apoplexy. Here there are flushed, often swollen, countenance, stertorous breathing, slow and it may be strong pulse, deep or absolute insensibility, and fixed pupils. The injury, if there is one, is mostly palpable and explanatory. If it is concealed, the other symptoms point to the true nature of the case.

The diagnosis from drunkenness is not always easy, although deep intoxication is more apt to be accompanied with compression than with concussion signs. Drunkards often have bruises on their heads caused by falls, and some of them are pale and sick after debauch. The smell of liquor is not always reliable, for it is so common after accident for friends to administer stimulants before the patient is seen by a medical man that he might be easily misled into too hasty a judgment. The general appearance of the old stager is well known, but in cases where there is the least doubt the patient, whether in hospital or in private, should be kept a sufficient time under observation for the effects of drink to pass off. Then it will be seen whether this has masked a more serious condition. Too hasty conclusions in this matter have led to most unpleasant occurrences. These are well known in police administration and to hospital men.

The convulsions of the epileptic, the foaming mouth, and the quick return to partial or complete consciousness will generally serve to distinguish the case from one of concussion, but at times there are those who

require also to be kept under observation for some hours, and even a day or more, in order to come to a correct conclusion.

The **PROGNOSIS** in concussion is generally favorable, but if complete unconsciousness is present it is doubtful as to the individual so long as this lasts, for, as before intimated, the cases which recover may present as marked symptoms at first as those which prove fatal.

Recovery is mostly complete, but not suddenly so. The after-effects in any case may prove serious.

There is, however, an unwarranted tendency to attribute any defect in character, and even criminal lapses, to a blow upon the head, especially should the history or marks of one be discovered as having occurred at any time, no matter how long, previous to the inquiry.

The blow may be the cause of subsequent epilepsy, chronic inflammations, and insanity or imbecility. These cases have, however, an almost continuous history of trouble from the date of the injury, the manifestations varying in severity from time to time as pathological changes go on or as exciting causes develop them.

TREATMENT.—Absolute simple rest in bed is all that is necessary in mild cases of concussion. The patient should be well watched for any symptoms which might supervene and show that the injury was more severe than at first supposed. On the other hand, serious symptoms may be present without indicating any great gravity in the case. Children, for example, often have convulsions from the slightest cause. I have attended them when these set in immediately after the injury, but in a day or two there was entire recovery.

The more serious cases equally require rest, but also something more. To bring about reaction from shock, sinapisms to the extremities, to the nape of the neck, and over the stomach should be used. Hot-water bags should be placed along the sides of the body and limbs. Alcoholic stimulants must be sparingly used, if at all: they are rarely necessary. The stomach will often reject them unless in minute doses. If too much is absorbed, unpleasant consequences to the brain may follow. In extreme cases hypodermic injections of brandy or ether may be administered. Ammonia, camphor, and other diffusible stimulants may be useful, either externally or internally.

If the reaction is regular, with gradual restoration to consciousness and no noticeable rise in temperature, nothing further is required but a continuance of the rest and the use of cooling drinks and spare diet. The bowels and bladder must be attended to; the catheter may have to be used.

Restlessness, with or without delirium, is not unusual, but it generally subsides under full doses of bromide of potassium.

When reaction is followed by high fever, and especially when there is with it a passing on into secondary unconsciousness independent of true sleep, we have almost surely internal compression from congestion, effusion of serum, or hemorrhage to deal with. Now, blood may be taken generally or locally with great benefit. Cups, both dry and wet, to the temples and back of the neck are very useful. Leeching also is an efficient method of depletion. Ice in bags or towels, or cold water, should be applied to the head. Hot water, say about 120° to 130°, to the head is often of great service and very soothing.

The choice between cold and hot water is to be determined by the effects produced. Sometimes surprisingly good results come from alternating their use. Hot mustard foot-baths may be given in bed while the patient is kept lying on his back with the limbs flexed.

The result only in these severe cases will determine whether the symptoms were due to great congestion or to extravasation, possibly with brain lesion. Complete recovery takes place in the first condition. In the latter a fatal termination is much more probable, and if there is recovery it is apt to be only partial, and the patient may be the victim of nervous troubles more or less pronounced throughout a long life.

Concussion of the Spine.

John G. Johnson of New York is authority for the statement that English railways paid in five years two million two hundred thousand pounds, or eleven million of dollars, as damages awarded by juries in cases of concussion of the spine. The statement appears almost incredible, but the facts are ample to sustain it.

It also illustrates the powerful influence of one great authority (Erichsen) better than anything I know of in the history of the medical profession. After this celebrated surgeon's lectures and work on concussion of the spine, etc. were published, dating back to 1866, the great body of medical men received them as the standard and guide in all such cases. They were a godsend to plaintiffs and prosecuting attorneys, and the defendant had a poor chance with juries when the possible miseries of any one who claimed compensation for injury to the spine was pathetically pictured to them.

That the defendants have suffered injustice in a great number of cases I think there can be no doubt. Is it any wonder, therefore, that a reaction has occurred of late, and that the views formerly held by professional men have been subjected to sharp criticism founded upon a much more scientific and practical knowledge of the subject at issue?

As in all reactions, extreme views have been reached by certain observers, and there are those who seem to hold that concussion of the spine cannot occur. By spine here is meant the spinal cord or marrow.

It has been well remarked, I think by Page, that we do not speak of concussion of the skull. We always say concussion of the brain. The use of the term spine has given rise to much confusion, but the professional man will understand what is meant when so-called concussion of the spine is under discussion.

The advocates of the rarity or even impossibility of the injury call attention with much force to the anatomical facts. First, to the immense strength, pliability, and cushioning of the bony and ligamentous encasement or column; then to the ample calibre of the canal in which the nervous cord is suspended, and to the pliant structures intervening between its inner walls and the cord itself. From without inward, in the canal, we have fat, watery connective tissue, and the plexus of spinal vessels; then comes the dura mater, loosely investing the cord and unattached to the bone, not forming here, as in the skull, the internal periosteum. Within the dura mater is the arachnoid, its visceral layer sepa-

rated by a wide interval from the viscus or cord, which interval contains the cerebro-spinal fluid; then the pia mater or vascular membrane, which closely invests the cord.

Besides these structures there is the ligamentum denticulatum passing from the dense pia mater to the parietes of the canal and supporting the cord and roots of the nerves in the most efficient way—pliable enough to yield and break the force of vibrations, and strong enough to sustain.

Thus we see that the cord is much more securely protected from the effects of external violence than the brain, and we can understand that there is reason for the doubt of the sceptics as to the frequency of the injury described as concussion of the spine.

Clinical observation is, I think, of far greater value in determining questions of the kind than any theory, however strongly supported by anatomical facts. Does transient concussion of the spine occur as transient concussion of the brain occurs? Page, if I understand him, says not. In his work on *Injuries of the Spine and Spinal Cord* (London, 1883), in criticising a well-known case as to the claim of persistent paraplegia without discoverable lesion, he says: "We italicize the word persistent, for simple concussion of the brain may give rise to a transient unconsciousness, and, if the analogy holds good, concussion of the spine should per se produce a transient paraplegia. *We know of no case, nor can we discover the history of any case, where this has happened.*"

I italicise the last sentence. In 1881 a boy came under my care who was shot in the back three inches to the right of the third or fourth dorsal vertebra. He at once had characteristic symptoms in the legs of being wounded in the spine in such a way as to affect the cord somehow. There was partial paraplegia, with pains in both limbs. Under rest these symptoms soon disappeared. In a few days I made a deep incision and removed some clothing and fragments of bone, and then from the depths of the spinal gutter I took a large conical ball which was resting against the bony bridge of a vertebra. The boy recovered rapidly. I saw him some months afterward perfectly well.

Surely, this was a case of spinal shock or concussion with transient paraplegia, and the cause of it could have been nothing else than the impact of the ball against the column, producing vibratory jar sufficient to affect the cord. The immediate symptoms and the rapid and complete recovery are, in my opinion, inconsistent with any theory of congestion or pronounced lesion of the medulla.

Here is another case of transient paraplegia also occurring in 1881, and, to my mind, still more significant: A man fell from a height of about twenty feet and landed directly on his feet. He was immediately paraplegic. On examination no injury to the spinal column could be detected, but there was fracture of both calcanea. The spinal symptoms were thoroughly marked. Besides the paralysis of the limbs there was loss of control of the bladder and bowels, and the other accessories in such cases. But all went on to recovery. *Pari passu* with the fractures the spinal symptoms improved. It is not necessary here to give further details, but simply to state that in four months, the time required being chiefly due to the fractures, the patient was discharged able to walk and well in every other respect.

If this is not a case of transient paraplegia owing to spinal shock or

concussion, I am willing to admit that I do not know the requirements of the critics when they ask for such cases. I think that it is no matter how the blow or shock to the column is received, whether direct or indirect, so that it is shown that the medulla is influenced within the line of recovery, without having suffered fairly presumable lesion.

President Garfield surely suffered from transient spinal shock produced immediately by impact of the bullet upon the column. The symptoms soon passed off, and at the post-mortem the cord was healthy in every respect. The differences between his case and the others I have mentioned were those of degree only, his concussion not being severe enough to cause paraplegia.

Spinal concussion or shock from railway collisions does not differ from forms of the same injury received in other ways. It is absurd, therefore, to give a peculiar pathological history to so-called railway spine. That the injury occurs, I have no doubt; that the medulla is seriously affected in the vast majority of cases, I have very great doubt.

I cannot now, after thirty years of hospital and private practice, call to mind a single case of concussion of the spine arising from other accidents than on railways which has had the terrible after-history that is so often attributed to them; and I have seen in that time many cases of spinal injuries of all kinds.

There is another fact of personal experience. I have examined many cases of claimed irreparable or serious injury to the spine in private, both for plaintiff and defendant, in impending suits, but I cannot remember a single application of a patient for admission to the hospital to be treated for the after-effects of concussion of the spine, the original injury having been received in a railway collision.

As all sorts of people ride on railways, it is strange that the numerous recipients of concussions of the spine are pecuniarily independent of hospitals. One old fraud I do remember who fell from a street-car and claimed lasting injury to the upper part of the spine and the head, and adequate compensation for it in court. I was not called as a witness at the trial, and the plaintiff recovered very heavy damages. These were afterward reduced to a much smaller amount when it was discovered what I knew about the case.

Other structures of the spine besides the medulla are much more subjected to injury than it is, and their consequences often mislead both patient and doctor, especially the former.

The ligaments and muscles are exposed to contusions, strains, ruptures, and twists which are wrongly attributed to concussion. From these injuries and from so-called concussions the patient recovers rapidly or slowly according to their extent. If damages are looked for from a corporation, he is in a state of what may be called expectant pecuniosity, and shows no amendment until the question is settled. Otherwise, he gets well, as those do who are injured but have no expectations.

There is a striking want of confirmation by post-mortem examination of the terrible effects which are said to follow concussion of the spine.

In fact, the records of such examinations are so few, notwithstanding the immense number of those who have claimed to have the injury that the sceptics are somewhat justified in attributing the few cases which have shown great pathological changes in the cord and its membranes to the

coincidence of disease, as myelitis or syphilis, or to much graver injuries than concussion.

I have reported a case in full in the *Medical News and Abstract* (Philada., Nov., 1881) which illustrates how coincidence might easily play its part in a supposed concussion. This feature of it is not alluded to in that paper. A gentleman began to complain of pain posteriorly at the root of the neck. Paralytic symptoms gradually developed. It is unnecessary to repeat the details here, but the history was a most dreadful one, and precisely that of the few serious ones described in the works on concussion. Within a year the patient died. The autopsy revealed a meningitis and softening and destruction of the cord to the extent of two and a half inches of its brachial enlargement. There was no other disease. Now, this patient frequently travelled on railways, and if he had been subjected to the slightest accidental shock it would have been received on all sides as the cause of the disease. There was, however, no such history, nor was anything ever known to account for the fact that a man in otherwise perfect health should have two and a half inches of his spinal cord as it were spontaneously destroyed.

I will state in passing that this case did not confirm the views of Johnson and others as to there not being any severe pain on pressure in myelitis. It showed also that clinical observation is not always in accord with plausible anatomical facts or reasoning.

Thus, Johnson says: "It is a mistake to suppose that meningitis or myelitis is accompanied by pain on pressure: the spinal cord is surrounded by a bony wall thicker than the bones of the skull, and you might as well press on the head to see if the brain is diseased."

Now, in this case the pain was simply atrocious and greatly increased by pressure. To relieve both it and the disease the actual cautery was applied on both sides of the spinous processes; and some estimate may be made of the sufferings of the patient, who would not take ether, when he exclaimed as the hot irons were burning through his tissues, "Oh, that is better than the pain."

To sum up, then, I think I have shown that concussion of the spinal cord proper occurs. I also believe it may occur in a railway collision just as it occurred in the man who fell twenty feet. Why should not a traveller sitting in a peculiar position—with his feet, for example, firmly against a partition or wall of the car—suffer it in a collision.

On the other hand, the great majority of those who after accidents claim injury to the spinal cord as the cause of their disabilities are wholly mistaken. The question is of great importance, for upon it depends the testimony as to whether the patient has sustained temporary or permanent injury.

Each case must be studied on its own merits. There is no class of injuries so full of opportunity for the exaggerator or malingerer. The history of many of them is by no means complimentary to human honesty. Those interested can study the special works on the subject: space is not given to detail them in this paper.

THE SYMPTOMS and PROGNOSIS of concussion of the spine may be almost inferred from what has been written above. There are tinglings, pain, and sometimes cramps in the limbs; there may be partial or complete paraplegia which is transient in character. Complete paraplegia is

very rare, and when it exists it almost always indicates a more serious injury than concussion. The case I have cited is an exceptional one.

The bladder is almost always affected; there is either suppression or incontinence. The bowels are sluggish for a time. The pulse is mostly quickened; the temperature does not vary much from the normal. Priapism, which is so frequently present in wounds involving the spinal column and cord, is not present in concussion.

I have in the *Medical News* (Nov., 1881) given my reasons for believing this symptom to be due to a coincident impression or laceration of the sympathetic nerve when there is a fracture or other injury of the vertebra. This view I have been able to sustain by a case reported in the *Medical News* (Philada., Feb. 25, 1882).

The PROGNOSIS of concussion of the spine is generally favorable. The recovery is slow in pronounced cases. Where such terrible consequences follow as are described in some of the cases which have been caused by railway collision, there is reason to believe that the original injury was either too severe to come under the head of concussion, or that some coincident deterioration was present at the time of the accident.

The DIAGNOSIS from fractures and dislocations is mostly easy. In these cases the local and general symptoms are nearly always so definite as to give no trouble in coming to a conclusion as to their nature. In obscure cases time will develop the truth.

In the TREATMENT of concussion of the spine the great remedy is rest. Under this alone the slight cases will rapidly recover. The more severe ones will require other aids, such as cupping, both wet and dry, to the spine over and about the chief seat of complaint. Sinapisms, blisters, and iodine are useful in the order named. Opium will be borne much better for the relief of pain and restlessness than in like injuries of the head. The natural functions must be looked after. Both the catheter and enemata may be required. Great care must be taken to provide against chafing of the skin and bed-sores. For this I know of nothing better than repeated sponging with alcohol, and drying the surface at once by a good rubbing. The points of pressure should be frequently changed by shifting the patient.

As soon as the acute symptoms pass away the patient should be encouraged to rise and use moderate exertion. This, if well borne, should be increased day by day, for it will be soon found whether the efforts are injurious or not. All the requirements are present in these cases to produce chronic hysterical invalids, both male and female. It is therefore incumbent upon the medical attendant to protect his patient from discouraging surroundings of any kind. It is also his duty to so act that while he will be careful to work no injustice, he will at the same time be on the watch for malingering, for this will often be practised, especially by those who are among the expectants already mentioned in this article.

INTRACRANIAL HEMORRHAGE AND OCCLUSION OF THE CEREBRAL VESSELS, APOPLEXY, SOFTENING OF THE BRAIN, CEREBRAL PARALYSIS.

By ROBERT T. EDES, M. D.

THE various subjects embraced in this article are so closely united to each other, both in a clinical and in a pathological point of view, that they must be considered to a certain extent in common. It is of course more systematic to group them entirely according to the obvious and final lesion, as hemorrhage, thrombosis, or embolism; but when it is considered how very closely the symptoms of one affection may counterfeit those of another—so closely, in fact, that a diagnosis with absolute certainty is not only difficult, but often impossible—and also that similar conditions of the vessels may give rise either to rupture or occlusion, so that not infrequently two sets of lesions may be found in the same brain, and, finally, that the basis of prognosis and of the later treatment is not unlike in different lesions,—we are surely justified in bringing them, at least in the beginning, under a common head.

Intracranial hemorrhage, and especially cerebral hemorrhage, is the lesion which more frequently than any other gives rise to the group of symptoms known as apoplexy, and from this fact has arisen the frequent incorrect application of the word apoplexy, in a pathological as well as a clinical sense, to indicate an extravasation of blood, as in the so-called pulmonary apoplexy, where the anatomical lesion, being an extensive effusion of blood into the tissues of the lung, bears an apparent resemblance to the state of the brain often found in apoplexy primarily and properly so called, the symptoms, however, being entirely different. This error receives additional support from the fact that in some injuries to the brain, especially to the base, pulmonary hemorrhage may secondarily take place. Apoplexy, however, is not always the result of hemorrhage, but occurs with many cases of embolism and of thrombosis, and is sometimes, so far as we can tell, dependent upon neither of these conditions, recovery in one set of cases taking place so rapidly as to preclude the supposition of a considerable organic lesion, and in others, which are fatal, nothing being found beyond an excess of serum or of vascularity, and sometimes not even that. The first of these conditions has been called simple apoplexy, but with our present knowledge its simplicity seems to border closely on ignorance, or at any rate is not of a character

to satisfy the inquiring mind. It is therefore better to retain the term apoplexy strictly as a convenient term for a certain set of symptoms, but, whenever possible to substitute for it an anatomical description of the lesion found post-mortem or diagnosticated with reasonable probability during life.

The practitioner may very properly, and without laying himself open to criticism of his diagnostic accuracy, return the cause of death in a case of sudden death, or where his opportunity for observation has been limited, or where no post-mortem examination has been held, as being apoplexy; but in others, where the symptoms were decisive or a post-mortem has disclosed the exact lesion, the condition of the cranial contents should be stated. It is also a not uncommon mistake—or rather piece of carelessness—to speak of small hemorrhages in the brain as small apoplexies. A small extravasation may give rise to slight symptoms or next to none, but a real apoplexy can hardly be small, although it may be short.

The root from which the word apoplexy is derived seems to have been used by the classic writers in something like its present clinical significance (*Ἀπορληχτος*, seized with (apoplexy or) stupor—Aristophanes; mad—Demosthenes; *Ἀποπλησσομαι*, to be struck with amazement—Sophocles). *Morbus attonitus*, another of its names, expresses a somewhat similar idea.

Morgagni was familiar with cerebral hemorrhage, and Bonetus in the *Sepulchretum* gives several cases. The allusions of Galen and Hippocrates supposed to refer to this lesion are not unequivocal, although the Father of medicine could hardly have helped being familiar with the symptoms of so striking a form of disease.

Cerebral softening has been recognized since the early part of the present century, and in some of the cases thirty years ago an efficient cause, in the form of arterial disease, assigned to it; but the complete theory of its causation forms a part of the general doctrine of embolism and thrombosis which was so largely developed and systematized by Virchow. Andral and Durand-Fardel had apparently no idea of the exact mechanism of its origin, the latter supposing it to depend upon inflammation, while Todd mentions a case where softening giving rise to paralysis depended upon a dissecting aneurism of the carotid. He seems to have generalized so far as to say that white softening is atrophic, but the precise way in which this localized atrophy was usually brought about evidently escaped him. According to him, the suddenness of the attack was owing to a gradual disorganization of the brain-substance with few or no symptoms, and then a sudden rupture of diseased fibres by some accidental cause or by their having reached the extreme limit of cohesion.

Intracranial hemorrhage may be situated outside of the dura mater, separating this membrane from the bones of the skull and producing more or less compression of the brain. It is usually the result of a blow, but not necessarily of a fracture of the skull. When a fracture is present, blood may pass through it from the interior and give rise to an external extravasation in addition to that which is likely to be the direct result of the blow upon the skin and subjacent soft parts. The middle meningeal artery is a frequent source of this hemorrhage. Hemorrhage in this position will naturally give rise to symptoms of compression, and, if the fact of the blow be not known or the fracture manifest, may be mistaken for some of the deeper-seated forms.

Blood may be effused upon the surface of the brain in the so-called cavity of the arachnoid—that is, outside of the pia mater—or in the meshes of this membrane, following its course along the sulci. This also is not infrequently the result of violence either with or without fracture of the bone. Its source is likely to be found in the veins which empty into the longitudinal sinus from the surface of the brain. Rupture of a lateral sinus from a not very severe blow has been the source of large and fatal hemorrhage.¹ Blows upon the head, with or without fracture of the cranial bones, are likely to cause rupture of the cerebral substance with hemorrhage, and this may find its way to the outside and cover more or less of the surface. Such injuries to the brain, it is important to note, do not necessarily correspond immediately to the place of the blow or to the external ecchymoses. Meningeal hemorrhage in this region may, however, be observed when no injury has been received, or at least when there is neither history nor external traces of any.

The conditions under which it occurs may not vary greatly from those of the more ordinary intracerebral effusion. In two instances under the observation of the writer the source of hemorrhage has been a vessel of small, but not the smallest, calibre (artery), situated near the fissure of Sylvius, in the lower parietal or temporo-occipital lobe. In children meningeal hemorrhage is, with only a few exceptions, the usual lesion of apoplexy. The blood is usually dark and coagulated in recent cases. Blood found under the membranes where no fracture has taken place is, however, more likely to have been derived from the brain-substance and to form part of a cerebral hemorrhage.

Hemorrhagic pachymeningitis, indicated by a layer of fibrin included between the dura on the one hand and a false membrane on the other, is met with in connection with meningeal and cerebral hemorrhages. It is supposed to depend on a small and thin hemorrhage upon the surface of the brain, which forms, by its irritant action, a false membrane about itself. It is found usually over the vertex.

Hemorrhage into the ventricles is nearly always the consequence of a hemorrhage in the brain-substance breaking through, although it may in rare cases originate in the vessels of the choroid plexus, velum interpositum, or meninges. Its source, however, is sometimes so near the surface as to cause but little laceration of the cerebral tissue. The blood breaking into any one of the ventricles may be found in one or all of them (except the fifth), and form quite an accurate cast of their shape.

The most common form of intracranial hemorrhage, however, which most nearly concerns us here, and which is generally meant when sanguineous apoplexy is spoken of, has its principal seat in the brain itself, which is, of course, more or less lacerated. Such hemorrhages may vary greatly in size, from a mere red point (punctate or capillary), of which many may be present at once, to one of many ounces, filling a large cavity of nearly the length of one hemisphere, and pushing the torn and compressed brain-substance before it in every direction. The amount of laceration produced of course varies greatly; sometimes it seems as if nothing more than a pushing aside of fibres without rupture had taken place, while at others large masses of tissue are torn away and mixed up with the blood into a pulp.

¹ *Cincinnati Clinic*, p. 135, 1874.

In a recent hemorrhage the clot itself, speaking of those of a size above the capillary, is usually homogeneous, the brain-substance surrounding it ragged, œdematous, yellowish or red, and frequently containing many minute secondary hemorrhages. The rest of the brain is frequently found anæmic from pressure, the convolutions flattened, the surface dry, and the section exhibiting a diminished quantity of blood. In older cases, however, and probably also in some where atrophy, senile or otherwise, has preceded the hemorrhage, this condition is not found, and we may have the convolutions shrunken and the meshes of the pia containing an excess of serum.

If death does not take place speedily, the clot undergoes degenerative changes. Its color becomes somewhat lighter, chocolate color, reddish-yellow, or yellowish-red. A portion is absorbed, and after a time the cerebral substance in the neighborhood forms about it a wall of some density, so that finally nothing is left but a cyst with fluid or semifluid contents, and often remains of connective tissue. Sometimes the absorption of a clot of moderate size is so complete that only a firm mass of a reddish or yellowish-brown color marks the seat of an old hemorrhage. The brain-substance in the neighborhood may be more or less atrophied, and a distinct depression may be noted over the position. The microscope shows in a fresh hemorrhage only broken-down nerve-tissue and blood and vessels more or less degenerated. In an older one the blood-corpuscles have disappeared, but masses of pigment of a dark yellow or a brownish-red remain to show the former presence of blood. This pigment occurs in the form of rounded granules or of small rhombic crystals, and has received the name of hæmatoidin. The light-yellow masses often found along the course of the cerebral vessels are not evidence of hemorrhage, but of congestion merely. The so-called inflammation or granulation corpuscles, which are simply the fattily degenerated cells of the organ in which they are found, and which usually possess no distinctive form, being simply round masses of fat-drops, are often met with in the brain in hemorrhage or softening. It is sometimes perfectly evident, however, from their form, triangular or pyramidal, that they are degenerated nerve-cells. The blood-vessels, those just above the size of capillaries, are usually in a condition of fatty degeneration, masses of dark granules occupying more or less densely the line of their walls. A mere deposit of fatty granules inside the perivascular sheath, but outside of and not involving the walls of the arteries, may present the appearance of a degeneration of the walls themselves. This condition may be a consequence of any lesion involving degeneration of brain-tissue, and in no way a cause.

The intermediate stages of transformation in a hemorrhage are less frequently found than the recent or old ones, since the patient, if he does not die within a few days, is likely to live for some weeks or months.

The changes taking place in the clot itself within the first few days are not very marked, but the walls of the cavity may become softer and more deeply colored, at first red and afterward yellow. Blood-crystals have been detected on the seventeenth day (Virchow). The following descriptions have been given of clots of different ages: Eleven days—reddish-yellow softening clot, with brain-tissue stained for half an inch in depth, and brain rather hard in vicinity. Eighteen days—cavity with its

edges anteriorly and superiorly sharply defined, with the edges posteriorly ragged and yellowish, filled with a tolerably firm brick-red mass adherent to surrounding brain, and showing in the centre a softened clot about the size of a pea. Twenty-eight to thirty-five days—soft, brownish, and semifluid. Forty-one days—spot of softening filled with brownish material. One hundred days—somewhat darker, and a little more distinctly marked from surrounding tissues; by microscope granular corpuscles, groups of fatty granules along the swollen vessels, granules of pigment. Eighty-three years—old hemorrhagic focus in right optic thalamus, color yellowish, and areolar structure.

The thirtieth day is given as about the time at which the walls of the cyst become more firm and distinct. The following statement is prepared from a considerable number of cases given by Durand-Fardel: From four to six weeks, the clot is dark-colored, from black to ochrey or reddish-yellow. It varies in firmness. The capsule is tolerably firm. From two to four months, it seems to be generally softer, pultaceous, grumous, or the clot still remaining swimming in serum; in some cases lighter in color. In six months it has lost more in color, and the cavity may be smaller. In a year there is still considerable color left. In a few cases after some years the blood has been found in the form of a dried mass, not changed or darker in color.

Hemorrhages of several months' standing may be indicated either by a brownish-red patch somewhat firmer in texture than the surrounding brain-substance, or by a cavity with firm walls, which often has strings and septa of connective tissue running across it, so as to convert it into a kind of spongy mass filled with brownish fluid.

The most important changes which are found in most if not all cases of ordinary hemorrhages (*i. e.* such as do not depend upon violence or cachexia) are those of the blood-vessels. They are not, however, visible in the ordinary inspection of the brain at an autopsy, but require to be carefully sought for, either with the microscope or a somewhat tedious process of washing. For this reason there are no trustworthy statistics of large numbers to determine in how large a proportion of all the cases alterations in the blood-vessels are to be found, and in what form. There can be but little doubt, however, that those cases in which no form of arterial disease is present (if, with the reservation just noted as to violence or cachexia, such exist) are to be looked upon as rare exceptions.

The presence of miliary aneurisms in the brain had been noted in some cases, and even in cerebral hemorrhage, without the great importance of the observation having been perceived; but the extended and careful observations of Charcot and Bouchard first showed how extremely common their presence is, while in many instances they were found actually ruptured. These aneurisms are present in the largest numbers in the regions of the brain where hemorrhage is most frequent, and at the age when death from apoplexy is most likely to occur. They have been found at the age of twenty, but very rarely at early ages, while after forty they are not uncommon. It is of course not always that they have gone on to rupture, but may occasionally be found where no hemorrhages have taken place. It is not going far, however, to infer that in such cases the hemorrhage was not very distant.

These aneurisms are dependent upon a periarteritis which is diffused

more or less widely over the cerebral arteries, but not over those of the rest of the body. The larger arteries get a thin and shining appearance, compared by Charcot and Bouchard to the skin of an onion, while the smaller ones present besides distinct aneurisms, bulgings and irregularities of outline. This condition may be—and, as would be at once suggested from the age at which both lesions are met with, is—very likely to be associated with atheroma, but it is not the same thing, since the development of the aneurisms depends upon a periarteritis, and that of atheroma upon an endarteritis. It may be remarked, also, that atheroma usually does not affect the very small arteries which bear the aneurisms and give rise to the hemorrhage.

These aneurisms are visible to the naked eye, being from two-tenths to one millimeter, or a little more, in diameter, while the artery to which they are attached can be seen by the naked eye or with a lens magnifying two or three diameters. They may be strung along a small artery like beads or be found in groups like a bunch of grapes. Charcot and Bouchard found them in every case of cerebral hemorrhage which they examined, and, although the possibility of other sources was admitted, concluded that in by far the greater number of cases, excluding those dependent upon traumatism or hemorrhagic diseases, the blood effused in the brain has its origin in one of these aneurisms. The presence of these aneurisms has been abundantly established by other observers, and the fact that they are not usually demonstrated proves nothing except the amount of care and time necessary to find them. One does, however, find occasionally noted that they were sought for and not found. The statements of Charcot and Bouchard relate, so far as their own observations are concerned, and as they themselves remark, chiefly to aged persons, but in their first series of 66 cases there is found 1 of twenty and 1 of forty years of age. The patient of twenty was a semi-imbecile and a drunkard. Extensive cerebral hemorrhage, with atheroma, in the circle of Willis has been found in an apparently healthy and well-nourished boy of fifteen.¹

Larger aneurisms, often multiple, are not very infrequent upon the arteries at the base of the brain. They may before their rupture give rise to symptoms of pressure like any other tumor, and may also be the source of hemorrhage, which is usually meningeal. They are not infrequently symmetrical, and a place of election is one of the early bifurcations of the middle cerebral.

Coats² states that aneurism of the larger arteries is the most frequent source of hemorrhage in persons under fifty. They may be due to embolism, producing, when the occlusion is not complete, mechanical injury to the walls of the vessels by the constant hammering upon them of the embolus under the impulse of the blood. If this etiology is a common one, it accounts for the frequent situation of these aneurisms in the middle cerebral arteries.

Small vessels in a condition of fatty degeneration are often found in the neighborhood of a cerebral hemorrhage. In some cases, undoubtedly, the degeneration is a consequence of the injury to which the cerebral substance has been subjected, but they have also been found too soon

¹ Baker, *Annals of Anat. and Surg. Soc. Brooklyn*, 1879, p. 40.

² *Glasgow Med. Journ.*, 1882, xvii. 109.

after the hemorrhage for this explanation to hold; and in cases where no aneurisms are present the older supposition, that hemorrhage results from this kind of degeneration, seems to have a certain foundation, even if only in a minimum of cases.

In several cases of cerebral hemorrhage in purpura, where the general character of the disease was shown by hemorrhages in other organs, fatty degeneration of the cerebral vessels has been found, together with extensive steatosis of the liver, kidneys, muscles, and heart.¹ In a cerebral hemorrhage found in the brain of a girl of eleven the walls of the vessels were dotted with fat-globules and dark granules, and several of them studded with round and oval nuclei closely resembling the nuclei (small cells?) commonly found in tubercle. There was no trace of tubercle in any part of the body.²

There is no possible means of determining in which way any given bleeding has arisen, except a very minute search, and this may fail to show the actual point of rupture. It seems highly probable, from the connection of some cases of hemorrhage with valvular disease of the heart, that embolism may give rise to effusions of blood, especially capillary and multiple ones. In such cases the emboli may be deposited in arteries far too small to be obvious in the ordinary process of dissection. (See Capillary Embolism.)

Hemorrhage arises in some rare cases from the backing up of blood in the veins when they are obstructed by thrombosis. A case has been described where meningeal and ventricular hemorrhage resulted from a rupture of the straight sinus at its juncture with the torcular Herophili.³

In many diseases like purpura, idiopathic anæmia, and leucocythæmia many hemorrhages may take place in the brain as well as elsewhere throughout the body. Their importance under these circumstances is usually not great.

The usual localities of cerebral hemorrhage are stated with much minuteness in the following table from Durand-Fardel, which, although not very recent (1854), is not the less accurate on that account. No subsequent statistics have essentially altered its most important conclusions. In 139 cases the hemorrhage was situated in the hemispheres 119 times; in the protuberance (pons), 21; in the cerebellum, 13; total, 153.

I have placed beside these a small number of cases from the records of the Boston City Hospital and my own practice, and, to avoid the multiplication of headings, have entered some multiple hemorrhages under two or more heads, so that from the whole number of cases (46) there are 81 entries:

| | Durand-Fardel. B. C. H. | |
|--|-------------------------|----|
| Corpus striatum and optic thalamus, together | 22 | 4 |
| Corpus striatum | 13 | 10 |
| Optic thalamus | 5 | 3 |
| Corpus striatum, optic thalamus, and middle lobe | 2 | 1 |
| Corpus striatum, optic thalamus, and a considerable portion, not well defined, of the hemisphere | 12 | 2 |
| Corpus striatum, optic thalamus, with posterior lobe | 1 | |
| Corpus striatum and middle lobe | 3 | 3 |
| Corpus striatum, with a considerable portion of hemisphere | 5 | 1 |
| Corpus striatum, with an extended portion of base of ventricle | 1 | |
| Optic thalamus with middle lobe | 2 | 1 |

| " " middle lobe | 2 | |
| In the protuberance (pons) | 13 | 4 |
| Protuberance and brain | 8 | |
| Protuberance, crus cerebri, crus cerebelli, external capsule, fourth ventricle | ... | 1 |

It would not have been very difficult to increase these figures from the large number of recorded cases, but there is nothing in later statistics to invalidate the statement that the corpus striatum, including both its nuclei, but especially the nucleus lentiformis, the optic thalamus, and the white substance in their neighborhood, are the portions of the brain by far the most frequently affected by hemorrhage, and especially by hemorrhages of considerable size.

There is no essential difference in the frequency of hemorrhage on the two sides. It may occur on both sides at once. Hughlings-Jackson says that he saw a patient who escaped with life from the effects of a clot which had paralyzed both sides of the face as well as all four limbs. Charcot and Bouchard give the following localities as containing in decreasing frequency the miliary aneurisms: optic thalami, corpora striata, the convolutions, the protuberance, the cerebellum, the centrum ovale, the middle peduncles of the cerebellum, the cerebral peduncles, and the bulb. The close correspondence of this list with the table of Durand-Fardel is in itself a strong argument in favor of the importance of the miliary aneurisms as the principal factors in determining cerebral hemorrhage.

The arteries supplying the nucleus lenticularis and external capsule are small branches arising chiefly from the middle cerebral a short distance from its origin, with some assistance from the anterior and posterior cerebral. One of the larger of them runs along the outer side of the nucleus lenticularis where it is covered by the external capsule—a disposition which may have something to do with the occurrence of the larger hemorrhages so likely to take place just outside this nucleus and into the substance of the hemispheres.

The arteries of the optic thalamus arise from the posterior communicating or the posterior cerebral. Why these two groups should furnish, as they do, so large a part of cerebral hemorrhages it is impossible to state, unless it be that from their origin so near to the larger trunks before their division they are exposed to more pressure, and hence a greater tendency to form aneurisms. The functional activity of these regions is another possible reason. The largest hemorrhages also seem to spring from these sources, and if a table of large effusions were compiled

it would probably show a greater predilection for this locality than even the general one given above, which includes those of all sizes.¹

Before proceeding to a minute account of the symptoms accompanying cerebral hemorrhage, a consideration of the relation between extensive lesions and the most fully-developed clinical phenomena will be of value—in other words, the pathology of hemorrhagic or sanguineous apoplexy. This will naturally demand a reference to the cases where the same symptoms are present with a different lesion.

The most marked symptom, one which is essential to the definition of apoplexy, is the sudden, or more frequently rapid, loss of consciousness, and next, in a great proportion of cases, a unilateral paralysis or paresis. The latter, in many cases, finds a sufficient explanation in the rupture of fibres connecting the motor centres in the brain with the spinal cord; but this does not cover all cases, for it is well known that we may have paralysis without any laceration. In fact, in many cases paralysis may disappear so rapidly as to put aside at once any such explanation. Sufficient pressure upon contracting fibres is entirely competent to arrest their conductivity, and this pressure may be diffused over a considerably wider area than that where total destruction of tissue has taken place. Meningeal hemorrhage, where, of course, no laceration takes place, may be attended by a well-marked hemiplegia when the effusion is wholly or chiefly on one side.

The writer recalls a case of a man, of whose history little or nothing was known, found unconscious with a very distinct difference in the amount of motion to be provoked by irritation of the two sides. The diagnosis naturally inclined to the more common causes of hemiplegia, but the autopsy showed a purulent meningitis of the vertex, with a layer of pus considerably thicker on the side opposed to the paralysis.

A very similar statement may be made in regard to the symptom of unconsciousness, which seldom occurs more rapidly and completely than in cases of meningeal hemorrhage (not from injury), where, of course, there is no question of laceration.

F. Pagenstecher² succeeded in producing phenomena closely allied to apoplexy by injecting at a known pressure, between the skull and dura mater in dogs, masses of melted wax and tallow. In the first group of cases the result was somnolence, great depression of the psychical capacity, and general muscular weakness. The second group showed, besides the condition of sopor, unilateral paralysis; and the third contained cases in a part of which death followed in a few hours after the setting in of coma, and in another part partial recovery took place after scooping out the waxy mass. The symptoms in these cases are referred to the pressure upon the vessels; and it is stated that in order to destroy life the pressure had to be equal to that of the blood. Convulsions were present in some cases where the pressure was not steady. The temperature showed a notable peculiarity in that, after the initial fall, in which it resembles the course in human apoplexy, it kept on falling in the fatal cases, instead of rapidly rising, as in man. After injection into the brain of animals

¹ A very careful study of the form and size of foci of bleeding arising from the various nutrient arteries of the brain will be found in the well-known elaborate papers of Duret (*Archives de Physiologie*, 1874).

² *Centralblatt f. d. Med. Wiss.*, 1871, p. 706.

of sufficient quantities of water to produce great tension of the occipito-atlantoid membrane, Duret¹ found the respiration to cease and the heart to be slowed. On tearing the membrane so as to allow the water to escape, respiration began again, and the animals gradually recovered consciousness. Similar effects could, however, be produced by blows on the head.

Several cases are reported by P. R. Hoy² where pressure upon the brain produced an arrest of function, which was resumed when the pressure was removed. In the first of these a piece of bone had been removed, but the dura was intact. If the patient were asked a question and the finger immediately pressed upon the dura, no answer was made, but as soon as the finger was removed the reply came. In two other cases, which are not without their parallels, the patients resumed after trephining the mental attitude in which they had been surprised by the injury—in one case hours, and in the other years, before.

The natural generalization to be made from these cases and experiments is, that pressure upon the brain-tissue suspends, for the time, its function; but when we find exactly the same symptoms arising from either sudden or gradual occlusion of the vessels where we can hardly imagine increased pressure to exist, except perhaps over a very small area of collateral hyperæmia, we must go a step farther for a common factor; and it seems possible to find one which will not only explain the several conditions spoken of, but also others which closely resemble them. Simple anæmia will cover the cases of hemorrhage and embolism, but certainly not narcotic poisoning and certain other conditions where characteristic apoplectic symptoms exist without discoverable lesion. If, however, we say that a deprivation of a considerable portion of gray matter of its due supply of arterialized and healthy blood suspends for a time its functional activity, we can explain the similarity of results arising from very different causes.

In a case of cerebral hemorrhage of considerable size the pressure is distributed over a space much exceeding the area of the clot itself, and renders a large part of at least one hemisphere anæmic. If the blood finds its way into the ventricles, the conditions are most favorable for compressing nearly the whole brain. The anæmic appearance of the cerebral surface is often remarked at autopsies.

When an embolus lodges in an artery and produces complete occlusion, the portion of brain supplied thereby becomes at once entirely anæmic, since the arteries on the surface have so slight anastomoses that they are entirely unable to supply the deficiency, except to a slight extent around the edges of the vascular territory involved. The anæmia, however, does not extend beyond the territory originally affected, and consequently we may have extensive paralysis from embolism without a marked apoplectic attack. In extreme congestion of the brain the reverse may seem to be the case.

In reality, the hindrance to the proper functions is nearly the same, since blood which is not duly renovated and contains the products of metamorphosis of tissue in excess is worth as little for healthy nutrition as no blood at all. There is no reason to suppose that blood in circula-

¹ *Centralblatt f. d. Med. Wiss.*, 1878, p. 454.

² *Journ. Nerv. and Ment. Dis.*, vol. iv. p. 288.

tion, no matter in how great quantity, gives rise to unconsciousness. It may cause over-action or disordered action, as in mania, but not arrest of action.

The narcotic poisons also deprive the nerve-tissue of its healthy food; whether by interference with oxygenation and depuration, or by a direct action of the substance itself on the nerve-cells, it is not easy to say. The fact that the completeness and duration of the unconsciousness are not in proportion to the paralysis or anæsthesia shows that they are to some extent independent of each other; and, although it is possible to locate with some precision the lesion which abolishes motor power and conscious sensation, yet we cannot say how much or what part of the brain must be deprived of its function in order to produce that cutting off of all conscious relation with the external world and reduction of a feeling, thinking, remembering, and acting organism to the level of a mere automatic breathing-machine, which we designate as loss of consciousness.

In fact, in the present state of our knowledge as to what consciousness is, any speculation as to its seat would be a waste of time, and we must content ourselves with recognizing that experience seems to show that a large part, rather than any particular part of the brain, must be involved, not necessarily in the primary lesion, but in the resulting pressure or anæmia.

Another theory of unconsciousness is simply that it is due to shock—that the sudden irruption of blood acts like a blow, as it were, and abolishes for a time the function of the nervous structure. This is substituting something indefinite for something comparatively definite; and it is certainly not true that the more sudden the shock the more complete the unconsciousness. It may come on after the paralysis is apparent, and in fact is more commonly gradual than sudden in its onset. The classical instantaneous shock is the rare exception. In the celebrated case where a tamping-iron was driven completely through a man's skull and brain, he himself was able to give a clear description of the accident to the surgeon who first attended him. Several other instances of severe and sudden injury to the brain without loss of consciousness have been recorded.

ETIOLOGY.—As regards the greater number of cases and the most common pathology, the existence of so specific and peculiar lesion as aneurism enables us to distinguish between predisposing and exciting causes, or, in other words, the conditions which lead to the localized periarteritis with its resulting aneurisms and those which cause their rupture. Unfortunately, the aneurisms are not usually looked for, and in the collection of statistics we are obliged to group together cases the pathology of which is not always the same, and which are usually collected under the name of apoplexy.

Age, however, is well known, both on clinical and anatomical grounds, to be the most important factor. Among the predisposing causes of apoplexy, all statistics, both of recent and older date, agree in assigning the period of life beyond forty-five or fifty as that in which the liability to apoplexy is greatly increased. There is no age, however, below this, even to infancy, in which true cerebral hemorrhage may not occur, although the intracranial hemorrhage of children is more usually men-

ingeal. It is probable, however, that in many of these the rupture of the vessel does not depend upon a previous aneurism, but on other lesions. The youngest case in which aneurisms were found by Charcot and Bouchard was twenty.

If we speak of cerebral hemorrhage in general, without reference to the presence of aneurisms, as we unfortunately are obliged to do in the great majority of cases, we may often go much below this point. In youth and childhood, however, it is possible, and often almost proved, that other conditions must have been of greater importance in determining the hemorrhage than aneurism.

In our own small series we find cases of eighteen, twenty-three, twenty-five, twenty-six, twenty-seven years of age, and quite a number from thirty to forty-five. A little further examination shows many of them not to have been of the ordinary kind; thus the patient of eighteen had valvular disease of the heart and advanced parenchymatous nephritis; the one of twenty was, so far as could be seen, typical, but no search was made for aneurisms; that of twenty-five had many small hemorrhages and was a marked case of idiopathic anæmia; that of twenty-six had valvular disease of the heart, an embolus in the middle cerebral artery, which was not in the immediate neighborhood of any hemorrhage, several old hemorrhages, and hemorrhagic infarction in other organs. The case aged twenty-seven had a very large clot in one hemisphere and advanced interstitial nephritis.

Cayley¹ describes the case of a girl of eleven with a large cavity in the left middle cerebral lobe, where nothing was discovered abnormal upon the left middle cerebral artery, but when the cerebral matter was washed away with a stream of water, the walls of the vessels were found to be dotted with oil-globules, and in several places studded with round and oval nuclei. This was before miliary aneurisms were known, but the process of preparation was exactly suited to bring them to light had they been present, and they could hardly have escaped observation and mention. Other cases of boys have been reported where the hemorrhage was of the typical kind.

Meigs and Pepper speak of nine cases of hemorrhage into the substance of the brain in children, but give none of their own. Of the two cases mentioned by West as coming within his own observation, in one the source of the blood was in the cerebral veins obstructed by the formation of clots in the longitudinal sinus.

C. W. Dulles² describes a case occurring in his own practice in a child of six months, where a considerable amount of blood was found in the lateral, third, and fourth ventricles. Nothing is said of aneurisms in particular, but the brain was carefully examined without the source of the hemorrhage being found, although it seemed to be in some of the vessels of the velum interpositum. Dulles mentions further a case reported in the books of the Philadelphia Hospital by Joseph Berens, where in the brain of a child ten days old there were found, besides a large meningeal hemorrhage, many points of subarachnoid extravasation, a clot filling all the ventricles, and a clot the size of a pea in the anterior portion of both corpora striata. In addition to these there were scattered points of hemorrhage throughout the brain-substance.

¹ *Trans. Path. Soc.*, vol. xx.

² *Philada. Med. Times*, vol. vi. p. 507.

Cerebellar hemorrhage seems to show a certain preference for younger ages than the more usual forms. In a list of 25' cases from various sources I find the ages given thirty-two, twenty, nineteen, sixteen, thirteen and a half, eight. In the seven cases detailed by Hillairet there were two aged fifteen and twenty-six respectively.

These exceptions, however, do not invalidate the rule that cerebral hemorrhage of the ordinary type is pre-eminently a disease of later middle or advanced life.

The male sex is more liable than the female. Durand-Fardel gives 54 cases of men, 37 of women (old persons); our own list, 31 men, 15 women. Falret, cited by Rochoux and Durand-Fardel, gives 1670 cases of apoplexy among men and 627 among women. This, however, is only a rough approximation as regards cerebral hemorrhage, as it undoubtedly includes many cases not dependent upon this lesion. The same remark applies to Lidell's statement that there died in New York during three years, of apoplexy, 598 males and 440 females. This moderate predominance is ascribable to greater muscular effort, and probably also to the greater prevalence of alcoholic intoxication. Greenhow, in a Parliamentary report,¹ states that in England and Wales the number of deaths from apoplexy in 100,000 of population is 46 males to 44 females. From paralysis the figures are 42 and 44, so that the total from the diseases registered under these two heads is alike for the two sexes—viz. 88 to 88. In London alone the discrepancy is a little greater on the male side—108 to 101; but in certain districts of England the excess is on the other side. Race is of little influence. High altitudes (7000 feet) favor the prevalence of apoplexy in the population,² as in Peru and Mexico. Warm climates are somewhat, but less markedly, opposed to it.

Heredity seems to play an important part in the same sense as in tuberculosis; that is, in the establishment of a tendency, which of course means, anatomically speaking, periarteritis. Many deaths from cerebral hemorrhage may sometimes be found among the members of a single family. Dieulafoy has been able to trace this disposition through several generations. Among several instances, Mme. G—— died in three hours of paraplegia with loss of consciousness. Her mother had hemiplegia at the age of fifty-two, and two uncles and an aunt were also paralyzed at ages not stated. A commercial traveller, aged thirty-nine, was in the hospital with left hemiplegia, second attack; his mother, aged sixty-six, had an attack a few weeks before, and his grandmother died at seventy-five of fulminating apoplexy. A woman aged forty-six was hemiplegic for two months. Her mother, her maternal aunt, and uncle are all hemiplegic, and her son had a left hemiplegia at the age of seventeen. According to the cases of Dieulafoy, it is especially through the female side that the hemorrhagic disease is transmitted. Of course, the tendency may remain, and usually does so, latent until the age at which in the average of cases it becomes manifest by an apoplectic or paralytic attack; but the last two series given above show that it may develop at an earlier period of life in the younger than in the older generation.

Alcohol is universally stated by authorities to be one of the most potent factors in different races in establishing the hemorrhagic tendency;

¹ *Results of Inquiries into Different Proportions of Deaths, etc.*

² Hirsch, *Handbuch der Hist. Geogr. Pathologie*, vol. ii.

but it is not easy to get exact facts on this point, as so large a share of hospital patients are more or less alcoholic, and in private practice observations of this kind accumulate so slowly as not to be readily available. The greater frequency of this affection among the male sex may point in this direction. Two of the usual effects produced by the long-continued use of alcoholic drinks in excess probably combine to produce this result: first, the degeneration of tissues and tendency to low forms of inflammation of the tissues in general and arteries in particular; and secondly, the repeated dilatations of vessels under its paralyzing influence on the vaso-motor nerves, resulting in chronic congestion. This preparatory influence is distinct from the effect an occasional debauch may have in precipitating the attack.

Another highly important cause of cerebral hemorrhage is Bright's disease of the kidneys, in the form known as chronic interstitial nephritis, contracted, granular, cirrhotic, or atrophied kidney; or, as it would be perhaps more correct to say, cerebral hemorrhage is one of the results of the arterial lesion which almost invariably accompanies interstitial nephritis. As to the supposed or possible identity or relation of the arterio-capillary fibrosis of Gull and Sutton with the periarteritis of Charcot and Bouchard, the writer does not feel competent to express an opinion.

The connection between cerebral hemorrhage and hypertrophy of the heart was noticed and commented on long before it was known that the great majority of cases of hypertrophy, where no lesion of valves or of the aorta was present, were really cases of Bright's disease. The influence which might be exerted by the high arterial tension in the rupture of an aneurism is obvious enough theoretically, but it is far from certain that the effect of the renal disease, or rather the common cause of renal and cerebral disease, is not a more subtle one than this, and prepares the way for, as well as hastens along, the impending catastrophe.

This result, however, is not an extremely common one. Among 43 fatal cases of interstitial nephritis, well-marked cerebral hemorrhage was found in 4; in another, cysts and brownish indurations of small size were found which might have been partly the results of embolism. This patient had had a distinct paralytic attack. In a fifth the symptoms pointed unequivocally to a large rapid hemorrhage, although it was not demonstrated by an autopsy.

Looking at it from the other side, it was found that (in another series) of 48 cases of cerebral hemorrhage with autopsy, contracted kidneys were present in 17; and the writer is of the opinion, although he has not at his command a sufficient number of facts to make such an opinion conclusive, that if a series of cases were taken of persons under forty or fifty, excluding those where a hemorrhagic disease or a valvular disease of the heart might be present, the proportion of interstitial nephritis to cerebral hemorrhage would be greatly increased; and especially so if large hemorrhages into the great ganglia or the interior of the cerebral lobes were alone considered.

The so-called apoplectic constitution should be mentioned here; that is, the stout, thick-set build with short neck and florid complexion. The popular notions as to the peculiar dangers of this condition seem to have arisen rather from suppositions as to what might be supposed to take place, from inferring a similar state of things to exist in the brain to

what exists in the countenance, than from any observation as to what has actually occurred. Cerebral hemorrhage may take place with any sort of complexion or any figure, and there is no sufficient evidence that persons of the physique above described are specially liable to it. Many recent writers distinctly deny any such connection.

Intellectual pursuits have been considered a disposing cause—a theory which it would be difficult to substantiate. It is not, of course, the quality of the work, but its relation to the capacity of the individual brain, which makes any amount of thought a special strain. The cases of Dieulafoy, in which the hereditary tendency was so strongly marked, were mostly hospital cases, among which class the so-called intellectual occupations do not specially preponderate. A life of constant cerebral excitement, like that of a speculator or stockbroker, certainly seems more likely to give rise to overstrain of the vessels than the more quiet and regular, but certainly more intellectual, labor of the professional or literary man.

Thackrah¹ speaks of affections of the head as frequent among professional men, but does not advert to cerebral hemorrhage in particular. He evidently considers a want of sufficient exercise in the open air a far more potent factor than mental excitement.

It is very difficult to get statistics which bear upon the influence of mental labor on the brain, since the recorded occupation of an individual furnishes but a very rough estimate of the amount of thought evolved from his brain, and a very much less accurate one of what is probably of far greater importance—the amount of friction and anxiety with which it is done.

Hemorrhagic diseases may, for the sake of completeness, be once more mentioned as among the predisposing causes.

The exciting causes of cerebral hemorrhage are those which give rise to rupture of the fragile walls either of the aneurisms or fatty degenerated arterioles. They are to be found chiefly among such conditions as increase the pressure in the cerebral vessels, chiefly, though not wholly, from the arterial side. The connection of an attack of apoplexy with hypertrophy of the heart means, as has already been shown, in a great many cases, their mutual dependence upon arterial disease, as in chronic interstitial nephritis, but it seems probable also that an unusually powerful action of such a heart might be the immediate cause of the rupture. An excited action of the heart, connected with a dilatation of the cerebral vessels, naturally increases the strain on the weak portions, and we have thus the explanation of those instances where sudden or great excitement brings on the attack.

Apoplexy is less frequent in summer than in the other seasons, and it is especially remarked that sudden changes of temperature are likely to be accompanied by an unusual number of cases. Changes in the arterial tension consequent upon the varying amount of blood circulating in the skin are the probable connecting link.

Obstruction to the venous outflow, either alone or in conjunction with the preceding condition, has undoubtedly a marked effect. In addition to the cases of hemorrhage from veins obstructed by thrombi, already mentioned, instances of this method of production are to be found in

¹ *Health and Longevity*, p. 183.

the effects of severe muscular effort, as in lifting, in straining at stool, or, as has occasionally happened, in coitu. It has been objected to the congestion theory of apoplexy that even in severe paroxysms of whooping cough, where the face becomes cyanosed and congested, nothing like unconsciousness or paralysis occurs; but cases have been reported where aphasia and cerebral hemorrhage into the optic thalamus and cortex have accompanied whooping cough. Violent convulsions may be the cause of cerebral hemorrhage, as in puerperal eclampsia.

Obstruction to the circulation in the neck by tight clothing may be a means of increasing the back pressure from the veins. It is said that deaths from apoplexy have been unusually frequent among soldiers who have been obliged to wear tight stocks for the sake of imparting what was supposed to be a more military bearing. Probably some of the hemorrhages found with valvular disease of the heart are to be explained by venous congestion, although others are due to embolism.

Blows and shocks to the head, not producing fractures, are occasional causes of cerebral and ventricular as well as of meningeal hemorrhage. Important medico-legal questions are likely to arise where both bruises externally and internal hemorrhage are found. It is important to recollect that ecchymoses of the pericranium¹ have been found in cases of apoplexy where no violence has been used. These may occur with occlusion of the cerebral vessels, as well as with hemorrhage, and are most likely to be situated on the paralyzed side, being sometimes distinctly limited at the median line. They have been supposed to be due to the general tendency of the blood toward the head, and to be of the same pathological origin as the cerebral lesion they accompany; but the fact that they may not be associated with hemorrhage proves that this explanation is inadequate. Another explanation attributes their causation to vaso-motor paralysis, together with some unknown factor present in only a certain number of cases. They may be compared to the subconjunctival hemorrhages seen after violent convulsions.

Cerebral hemorrhage depending upon a blow is likely to be accompanied by meningeal bleeding; to be situated at some point of the cortex, and not in the regions more frequently affected; and to consist of the effusion of no great amount of blood, mixed with cerebral substance. There are also very often more than one. All the circumstances should be carefully weighed when, as not infrequently happens, there is doubt as to whether a blow was the cause of a hemorrhage, or whether a person found insensible, with a bruise upon his head, may have fallen down suddenly from an apoplectic attack. In the following case it would be difficult to be sure of the sequence: A negro man aged fifty fell backward from the first step of a ladder. He got up and went to work again, but soon became unconscious. He became partially conscious again in the accident-room of the hospital, but died in a few hours. There was no sign of injury to the head, but there was a rupture of an aneurism (not miliary) of the left middle cerebral artery, and hemorrhage into the meninges and all the ventricles. If the first fall had occurred in a scuffle, and the autopsy had been made in such way as not to disclose the aneurism, it might have been considered a case of homicide.

¹ Lepine, *Archives de Physiologie*, tome ii., 1869, p. 667.

Alcohol, besides not infrequently counterfeiting apoplexy, and besides acting as one of the predisposing causes, is occasionally an exciting cause. The dilatation of cerebral vessels, perhaps present as an habitual condition, is added to by the effect of the temporary narcotism and produces the rupture. In many cases these factors have their activity much increased by heavy sleep, very likely in a constrained posture, causing pressure on the veins of the neck and consequent venous congestion, which is in its turn intensified by the confined air of a station-house or the cold of the weather. The man who has possibly a vessel ready to burst in his brain should have, even if demonstrably drunk, the advantage at least of good air and an unconstrained position.

Other poisons, less frequently taken, may perhaps have a similar influence. In one case under the observation of the writer a number of small hemorrhages were found in various parts of the brain of a man who was found in his room some forty-eight hours after taking a quantity of opium, and having had, of course, no treatment during that time. He was aroused in the hospital without great difficulty, but died after a day or two with his brain in the condition above described, and bronchitis with inhalation pneumonia. There had been no paralysis, and the hemorrhages were probably not the immediate cause of death.

Durand-Fardel gives a table of supposed causes in 21 cases of persons over fifty: 8 of these were connected with either habitual use of liquor or a debauch; 9 had an attack immediately after a meal.

After naming all these causes, it must be said that in many cases it is impossible to find any reason for the occurrence of the hemorrhage at the particular moment it comes. A person may go to bed in apparent health, and be found some hours afterward unconscious and comatose, or unable to stir hand or foot on one side, or to speak. Gendrin, as quoted by Aitken, states that of 176 cases, 97 were attacked during sleep. The attack may come on when the patient is making no special muscular effort and under no special excitement. It is simply the gradual progress of the lesion, which has reached its limit.

SYMPTOMATOLOGY.—If we take as a point of departure the fully-developed attack, such as most frequently is found with a large and rapid hemorrhage into the cerebral hemispheres, pons, or cerebellum, the symptoms are those usually spoken of as an apoplectic attack, shock, or stroke, or, as the Germans say, Hemorrhagische Insult. Trousseau quotes as a satisfactory definition the words of Boerhaave: "*Apoplexia dicitur adesse, quando repente actio quinque sensuum externorum, tum internorum, omnesque motus voluntarii abolentur, superstite pulsu plerumque forti, et respiratione difficili, magna, stertente, una cum imagine profundi perpetuque somni.*"

Loss of consciousness, abolition of voluntary motion and sensation, and usually stertor, the appearance of the patient being that of one in deep sleep, are found in the extreme cases. In others the loss of consciousness and sensation are not complete; the patient can be aroused enough to utter a grunt or raise a hand to his face in order to brush away a fly or the hand of the physician who is trying to raise his eyelids, or can make a grimace to show that he is hurt, the face returning to its indifferent expression as soon as the cause of irritation is removed. Although the grade of action, both sensitive and motor, seems to be a little above the

purely reflex, it is but very slightly so, and probably is not sufficient to remain an instant in the memory.

The rapidity with which this condition comes on varies widely, from a very few minutes, or even seconds, to some hours. It may even diminish for a time and return. The cases in which unconsciousness is most rapidly produced are apt to be meningeal and ventricular, and presumably depend upon the rupture of vessels of considerable size, although the location among the deeper ganglia, where the conductors of a large number of nervous impulses are gathered into a small space, will, of course, make the presence of a smaller clot more widely felt. Even in these, however, the onset is not absolutely instantaneous, and the very sudden attack is rather among the exceptions. Trousseau denies having seen, during fifteen years of hospital and consulting practice, a single case in which a patient was suddenly attacked as if knocked down with a hammer, and that since he had been giving lectures at the Hôtel Dieu he had seen but two men and one woman in whom cerebral hemorrhage presented itself from the beginning with apoplectiform phenomena. In each of these the hemorrhage had taken place largely into the ventricles.

Lidell gives the following case: A colored woman, aged forty-nine, was engaged in rinsing clothes, and while in a stooping posture suddenly fell down upon her left side as if she had been struck down by a powerful blow. She was picked up insensible, and died in ten or fifteen minutes. The hemorrhage was chiefly meningeal, and especially abundant about her pons and medulla oblongata. The fourth ventricle was full of blood, and there were clots in the lateral ventricles.

A woman, aged about forty, had been hanging out clothes in an August sun. She was observed to run out of the house screaming, and fell to the ground unconscious. This was at 1 P. M., and she died at 3.30 P. M. Her temperature just after death was 107.2°. The neighborhood of the posterior surface of the pons Varolii was occupied by a broken-down-looking mass, appearing like an aggregation of small apoplexies (hemorrhages), involving and breaking down the middle crura of the cerebellum. There was no fatty degeneration nor any miliary aneurism. (I do not know upon how thorough an examination this last statement rests.)

In a large number of cases it is difficult to say, in the absence of any observation, intelligent or otherwise, exactly how rapid the onset of the symptoms may have been, but in those which occur where the patient is watched or is in the company of observant persons it is almost invariable to meet with symptoms less than unconsciousness which denote the actual beginning of the hemorrhage. From the nature of the lesion it can rarely give rise to symptoms which justify the epithet of fulminating in the sense of struck with a thunderbolt. The unconsciousness, so far as can be known, does not depend on the injury of any one special small point of the brain in which consciousness resides, but upon the compression of a considerable portion, which must necessarily take place gradually, but with a rapidity proportioned to the size of the current which issues from the ruptured vessel and the ease with which pressure can diffuse itself over a large area. It is undoubtedly the greater facility offered to such diffusion by the communication of the hemorrhage with the so-called cavity of the arachnoid and the ventricles which gives to

these forms a peculiar severity. The difference between a hemorrhage spreading through all the ventricles or over a large surface of the brain, and one which is limited to a focus in the substance of one hemisphere, being restrained by more or less firm tissue, may be illustrated by the gain in power in the hydraulic press from the transfer of the stream of water from a small cylinder to a larger one.

Vomiting is a symptom of some importance in diagnosis, being not very common in cerebral hemorrhage, but very frequent in cerebellar.

Whether of sudden, rapid, or slow development, the apoplectic attack is, in its main features, described in the aphorism of Boerhaave given above. The muscular relaxation of the face imparts to it an expressionless, mask-like character; the limbs lie motionless by the side, unless they can be excited to some slight movement by some painful irritation or are agitated by convulsions, or in a condition of rigid spasm; the face may be pale or flushed; the cheeks flap nervelessly—*le malade fume la pipe*.

Swallowing, in the deepest coma, is not attempted. The fluid poured into the mouth remains, and distributes itself according to the laws of gravity without exciting reflex movements of the pharynx. When the depression is less profound, it may excite coughing or be swallowed. An attempt to swallow when the spoon touches the lips indicates a considerably higher degree of nervous activity. Respiration may be slow, but when the case is to terminate fatally rises with the pulse and temperature. It is often stertorous and difficult, the obstruction consisting partly in the gravitation backward of the soft palate and tongue, and partly in the accumulation of fluids in the pharynx. Hence stertor is in some cases only an accidental phenomenon, depending upon the position of the patient on the back, and can be relieved by turning him on his side and wiping out the mouth as far back as can be reached. Cheyne-Stokes respiration occurs in severe cases, though not confined to necessarily fatal ones.

The general temperature in cerebral hemorrhage has been studied enough to make it of considerable value, especially in prognosis. In a case which extends over a sufficiently long time several stages can be distinguished which in shorter ones may be wanting. An initial period of depression is described by Bourneville¹ as occurring immediately after an attack, in which the temperature falls a degree or two below the normal, and, according to his view, continues depressed if death takes place rapidly. He gives the case of a man who died very shortly after an attack (his second one), where the temperature, taken in the rectum at the moment of death, was 35.8°. In cases which survive longer this initial fall passes either into a stage where it oscillates within the neighborhood of the normal or immediately begins to rise; the latter occurrence indicates an impending fatal termination (unless, of course, something else can be found to account for it). In the former condition we find patients whose life may be indefinitely prolonged for days or weeks, when, if a fatal termination is to result, the thermometer again indicates a rise.

The initial fall of temperature is not so likely to be observed except in institutions like the Salpêtrière, where large numbers of old persons are collected and under close medical surveillance; and, indeed, it

¹ *Études cliniques et thermométriques sur les Maladies du Système nerveux*, 1872.

Fig. 37.

may be doubted, even from Bourneville's own table, whether the rule is one without exceptions. At any rate, the rise is a more important phenomenon than the fall. When the rise of temperature is interrupted by a fall, and then continues again, it is due, according to the author already quoted, to a renewal of the hemorrhage.

These changes of temperature may be noted with various locations of the lesion, but it seems probable that further study might make them useful in diagnosis as well as prognosis. Hale White reports the case of a boy aged six and a half years, who was found unconscious with right hemiplegia, and who afterward had many and various paralyzes with hyperpyrexia, the highest temperature being 107° . He lived long enough for secondary degeneration to extend down the crura and into the anterior cornua. A small soft patch a quarter of an inch in diameter existed at the anterior part of each corpus striatum.¹

The chart W. H. (Fig. 37) is from a man aged fifty who fell in the street while returning from work at noon, and whose axillary temperature was taken at 5 P. M. and every two hours thereafter until death. The hemiplegia was not very marked, but the hemorrhage was extensive, involving the pons and left crus cerebri, the external capsule, left crus cerebelli, and medulla, bursting through into the fourth ventricle.

The chart M. M. (Fig. 38), as taken from Bourneville, represents the course of the temperature in a rapid case: each perpendicular line denotes an hour.

The difference in the temperature of the two sides has been variously stated, and probably depends on a number of factors besides the length of time that has elapsed since the first attack. There is probably, however, a tendency to excess of heat on the paralyzed side soon after the attack, owing to vaso-motor paralysis; and this difference will be more marked in the hands than in the axillæ. After a length of time which may be from days to months the temperature becomes equalized, or more frequently the relation is reversed, the paralyzed side being colder as atrophy takes place. Lepine² gives a case where the axillary temperatures of the two sides continued the same within a small fraction of a degree for three days, and then

FIG. 38.

separated very slowly, until at death the

¹ *Guy's Hosp. Rep.*, 1882.

² *Mémoires de Société de Biol.*, 1867.

paralyzed side was six-tenths of a degree (Cent.) hotter than the other, in both being inferior to the rectal (107° Cent.).¹

The chart C. M. (Fig. 39) shows the excess of temperature in a case of meningeal hemorrhage. The dotted line is from the paralyzed side. The first observation was made two and a half hours after the attack.

Fig. 39.

A very interesting case is reported by Johnson² of crossed hemiplegia, where the temperature was about a degree higher on the paralyzed side of the body, and, corresponding to this, the sphygmograph showed a great diminution of tension; the lesion is supposed to have been a hemorrhage in the pons. Johnson, in commenting on the statement of Lorrain that in all cases of hemiplegia the pulse is more full on the paralyzed side, says that it is incorrect for ordinary cases of hemorrhage into the corpus striatum, though true in his own case.

The most marked differences of temperature have been observed where the lesion has been in the

neighborhood of the pons, crus cerebri, or medulla oblongata. In a case reported by Allbutt there was a difference of 1.6° ; the radial pulse was softer and fuller on the paralyzed side, and the cheek upon that side was flushed.³ The pulmonary hemorrhages which have been noticed by Brown-Séquard and others in animals after cerebral lesions, and the extravasation, congestion, subpleural ecchymoses noted by Ollivier⁴ in cerebral apoplexy, are probably to be referred to vaso-motor disturbances.

Much more attention has been paid to the pulse than to the temperature, but it is less easy to lay down definite rules in regard to it. It may vary in either direction. When the case is approaching a fatal termination the pulse is apt to accompany the temperature in a general way in its rise, though not necessarily following exactly, as is seen in the chart in Fig. 38.

The throbbing or bounding of the arteries often described may indicate increased activity of heart, but means at the same time vaso-motor relaxation. The urine and feces are often passed involuntarily.

In some rare cases symptoms closely resembling those produced in animals by section of the sympathetic have been seen. These are false ptosis, narrowing of the palpebral opening and sinking of the globe of the eye

¹ The chart in the original, and as reproduced by Bourneville, is wrongly lettered. The text says that the left side was the hotter.

² *Brit. Med. Journ.*, Jan. 6, 1877.

³ *Med. Times and Gaz.*, Dec. 4, 1869.

⁴ *Archives générales*, 1873, 167.

into the orbit, diminution in the size of the pupil, higher temperature on the paralyzed side of the face and the corresponding ear, abnormal secretion of the eye, nose, and mouth on the same side.¹ They are supposed to indicate a paralysis of the sympathetic.

The condition of general relaxation may be so profound as to cover up everything else, but in many cases true paralytic symptoms may be discovered or provoked, which even at an early period give us information as to the locality and nature of the lesion.

A greater degree of muscular relaxation may be manifest on one side of the face than the other; the forehead may be a little smoother on one side, the corner of the mouth drooping, the downward line from the ala of the nose flattened, and the cheek flapping. There may be a little greater resistance to passive motion of the limbs on one side; one hand on being raised may drop helplessly back to the bed, while the other is laid slowly down; the right hand when pinched lies motionless and without power to escape the pain until the left comes to its assistance. Irregularity of the pupils, if present, is an important sign, but its absence signifies nothing.

One of the most significant signs is the conjugate deviation of the eyes, both eyes and the head being turned strongly to one side or the other. When the lesion is above the pons and is irritative, as in the early stage of hemorrhage, the deviation is toward the side of the body affected and away from the lesion; when paralysis is established, away from the paralysis and toward the lesion. Below the pons the rule is reversed. The spastic stage of conjugate deviation may coincide with stiffness (early rigidity) of the paralyzed limbs. This deviation must not be mistaken for an accidental position of the head. The patient should be addressed from the side away from which he is looking. Sometimes the eyes can be brought to the median line, and not beyond. An attempt to turn the head forcibly beyond the median line occasionally causes pain. The value of this symptom in diagnosis has been denied, but a part at least of the apparent contradictions have arisen from the neglect to notice whether it were of a paralytic or spastic character.

As the condition of unconsciousness gradually passes off, the face regaining, at least in part, its natural and more intelligent expression, the eyes trying to follow the movements of surrounding persons, an attempt being made, perhaps only by an unintelligible sound or by a nod, to answer questions, the tongue being protruded, or at least an attempt toward it made, and some motions being made with the limbs,—the exact extent and intensity of the paralysis become more apparent. Conjugate deviation, if it have existed, may disappear before the other symptoms, or, if it has been of the rigid form depending on an irritative lesion, it may become paralytic, and is then in the opposite direction. The patient is then usually found to be in a condition of hemiplegia, and at this point the history of hemorrhagic apoplexy becomes identical with that of paralysis from hemorrhage where no truly apoplectic condition has been present.

Lidell states that in more than one-third of all cases of cerebral hemorrhage hemiplegia is developed without loss of consciousness or coma. In some, the paralysis precedes unconsciousness, which then slowly supervenes.

¹ Nothnagel, quoted by Grasset.

Hemiplegia ($\zeta\mu$, half, $\pi\lambda\gamma\gamma$, blow) is a paralysis or paresis of a part of the voluntary muscles of one side of the body, and a few, in some cases, on the other, and is undoubtedly to be referred to a lesion interrupting the nervous communication between the cortical centres of motion and the nuclei of the motor nerves, cerebral and spinal; the conductors passing through the corpora striata, the internal capsule, the peduncles, and crossing in great part to the other side above or at the lower border of the medulla oblongata, and passing down the crossed pyramidal tracts of the cord, to be finally connected with the anterior gray columns of the cord. The portion which does not decussate passes down the inner border of the anterior columns under the name of columns of Türek. The amount of decussation which takes place varies somewhat, and the suggestion has been made, in order to explain certain cases of paralysis occurring on the same side with the lesion, that possibly in some rare cases there may be no decussation. It has never been shown, however, that this condition, highly exceptional if even it ever occurs, is present in such cases.

It may be said in a general way, although exceptions to the rule can be found, that it is those muscles trained to separate, specialized, or non-associated movements which are chiefly affected, while those which are habitually associated in function with those of the other side are less or not at all so. It would not, however, be in the least correct to say that specialized or educated movements of any set of muscles are alone paralyzed, since the fingers, which are trained to the most independent movements, are often just as incapable of making the slightest movement of simple flexion as of writing or sewing.

We have in ordinary hemiplegia more or less paralysis of the upper facial, the patient not being able to close his eye or to wink quite so well as on the paralyzed side. The forehead may be smoother on the paralyzed side. This condition is usually slight and of short duration, but varies in different cases. Paralysis of the lower facial angle of the mouth and cheek is usually better marked, but not absolute. The corner of the mouth droops, perhaps permits the saliva to escape; the naso-labial fold is less deep, and the glabella deviated away from the paralyzed side. The cheek flaps with respiration. The difference between this facial paralysis connected with hemiplegia and that dependent upon a lesion of the trunk or distribution of the nerve (Bell's), as in caries of the temporal bone or the so-called rheumatic paralysis, is very striking, the latter being so much more complete, and, by affecting the orbicularis palpebrarum so as to prevent closure of the eye, giving a very peculiar expression to the countenance. This distinction between the two portions of the facial seems to make an exception to the rule stated above, since in most persons the movements of the corner of the mouth and of the cheek are quite as closely bilaterally associated as those of the eyelids.

Paralyses of the third, fourth, and sixth pairs upon one side of the body are comparatively rare in hemiplegia, and when present are usually referable to localized lesions in the pons. They are to be looked upon as something superadded to the ordinary hemiplegia. These nerves, however, are affected in the peculiar way already spoken of as conjugate deviation, which phenomenon would seem to denote that muscles accomplishing combined movements in either lateral direction of both eyes,

rather than all the muscles of each, are innervated from opposite sides—*i. e.* that the right rectus externus and the left rectus internus are innervated from the left motor centres, and vice versa. Exactly the same remark will apply to the muscles of the neck which cause the rotation of the head seen together with the deviation of the eyes. The muscles controlling deviation to one side, although situated upon both sides of the median line, are apparently innervated from the side of the brain toward which the head is turned in paralysis.

The tongue is usually protruded with its point toward the paralyzed side; and this is simply for the reason that it is pushed out instead of pulled, and the stronger muscle thrusts the tongue away from it. The motor portion of the fifth is, according to Broadbent, affected to a certain extent, the bite upon the paralyzed side being less strong.

The hand and the foot are the parts most frequently and most completely affected, but one or the other may be partially or wholly spared, though the latter is rare. The muscles of the limbs nearer the trunk may be less affected, so that the patient may make shoulder or pelvis movements when asked to move hand or foot. In severe cases even the scapular movements may be paralyzed. The muscles of the trunk are but slightly affected, though Broadbent states that a difference in the abdominal muscles on the two sides may be perceived as the patient rises from a chair. The respiratory movements are alike on the two sides. A woman in the hospital service of the writer had a quite complete left hemiplegia at about the seventh month of pregnancy. There was some return of motion at the time of her confinement. None of the attendants could perceive any difference in the action of the abdominal muscles of the two sides, although, of course, the usual bracing of the hand and foot upon the left side was wanting. The pains were, however; generally inefficient, and she was delivered by turning. Muscular weakness often exists, and in some cases the non-paralyzed side shows a diminution of power.

The sphincters of the bladder and rectum frequently, and in severe cases almost invariably, lose their activity for a time. It is possible, however, that in some cases of alleged inability to retain urine and feces the defect is really mental, and akin to the dirty habits of the demented. The involuntary muscles probably take no part in hemiplegia, with the very important exception of the muscular coats of the arteries, which apparently share to a certain extent, and sometimes the iris.

Speech may be attempted, and the words be correct, so far as they can be understood, though the patient is apt to confine his remarks to the shortest possible answering of questions. It is, however, thick and indistinct, since the muscles of the tongue and lips are but imperfectly under the control of the will. This condition may be connected with paralysis of either side, and is to be sharply distinguished from aphasia or mental inability to select the proper word or to determine the necessary movements for its pronunciation. Aphasia is almost invariably connected with paralysis of the right side, and will be minutely spoken of hereafter. There is, of course, nothing to prevent the coexistence of the two conditions, but aphasia cannot well be shown to exist until we have reason to suppose, first, that the patient has ideas to express, and secondly, that the paralysis of the muscles of the lips and tongue has more or less completely disappeared. The patient may indistinctly mumble a word which, how-

ever, can be understood to be appropriate to the occasion (defective articulation, glosso-labial paralysis), or, on the other hand, pronounce with distinctness an entire wrong word or a number of sounds without meaning (aphasia).

Sensibility—that is, ordinary cutaneous sensation—and, so far as we can judge, the special senses, are not greatly affected after the deep coma has passed off, but exceptions to this rule will be noted later.

Having described this most typical but not most common form of cerebral hemorrhage—that is, the form in which both lesion and symptoms are most distinct and can be most clearly connected—we have a point of departure for conditions less clearly marked and less easily explained.

It is probable that cerebral hemorrhage is much less likely than cerebral embolism to take place without any disturbance of consciousness or abnormal sensations; but there can also be little doubt that a certain amount of paralysis is often accompanied by no other symptoms, and post-mortem appearances often show the remains of small hemorrhages which have passed unnoticed or are lightly estimated. It is highly probable that small hemorrhages may give rise to symptoms which pass for only a little accidental vertigo or a slight feeling of faintness, until a later and more serious attack gives a more definite explanation.

On the other hand, we have a set of cases in which all the symptoms of cerebral hemorrhage may be present without the lesion. Many of these are of course due to embolism, which will be considered later; but besides this condition, recognized as softening for many years, we find described under the head of simple, congestive, serous, and nervous apoplexy cases where sudden or rapid loss of consciousness occurs with general muscular relaxation, which, when fatal, show nothing beyond changes in the circulation—*i. e.* in the amount of blood in the cerebral vessels or of serum in the meshes of the pia or at the base of the brain.

Besides these, there are cases of temporary unconsciousness with complete recovery—the coup de sang of the French, or rush of blood to the head, which are attributed to congestion of the brain—a theory difficult to prove or disprove, but not in itself unreasonable. Trousseau, without denying the possibility, or even probability, of such a condition, says that which has been called apoplectiform cerebral congestion is in the greater number of cases an epileptic or eclamptic accident, sometimes a syncope. Simple epileptic vertigoes, vertigoes connected with a bad condition of the stomach or diseases of the ear, are wrongly considered as congestions of the brain. He speaks of various conditions, such as violent attacks of whooping cough, the expulsive efforts of women in labor, the congested faces of laborers under heavy burdens, to show that cerebral congestion does not give rise to an apoplectiform attack; and it is undoubtedly true that, as a rule, no long-continued attack is the result; but it must be within the personal experience of almost every one that decided cerebral disturbance is produced for a few moments by such efforts, as, for instance, blowing a fire with the head down. Besides this, a laborer under a heavy load is presumably healthy and accustomed to his work, so that his arteries may be supposed capable of maintaining a due balance between arterial and venous blood in the brain; and, again, although the ordinary efforts of women in labor do not cause unconsciousness, puerperal convul-

sions, involving a longer period of violent muscular action, may do so, and even give rise to hemiplegia.

Whatever name we may adopt for the temporary cases which recover, there are others, and fatal ones, which are not explained by any change in nomenclature. Epilepsy may, it is true, occur under such circumstances that no convulsion is observed, but, on the other hand, convulsions may accompany not only an attack of unconsciousness, but actual cerebral hemorrhage.

Cases of sudden death with no discoverable lesion furnish abundant opportunity and temptation for conjecture, and it is well known that too much dependence must not be placed upon the post-mortem appearances as to the amount of blood in the brain before death, and probably just as little upon the amount of serum, except as indicating a condition of atrophy.

Syncope, either from over-stimulation of the pneumogastric or from simple failure of the heart, may be put forward to explain some cases of sudden death, but seems to have no advantage as a universal theory over the older one, which meets with so little favor. Lidell gives no less than seventeen cases which he classifies as congestive or serous apoplexy. They are not all equally conclusive, and were almost all of alcoholics. In some of these there were absolutely no appearances which could account for death. The two most characteristic of congestive apoplexy were, first, a young negress who experienced a violent fit of passion, became unconscious, with stertorous breathing, and died, having had some tonic spasms. The brain contained a large amount of blood in the vessels, but no effusion. Second, a semi-intoxicated woman, aged thirty, became very angry, fell insensible, and expired almost immediately. The brain contained an excess of blood, with no effusion. In both these cases the patients were subject to fits under the influence of strong excitement, but in both the author took pains to inquire into and negative the probability of epilepsy of the ordinary kind; and a change of name does not go far toward clearing up the pathology.

Lidell's case (XXII.) was that of a man accustomed to alcohol, thin and pale, who had an apoplectic fit with coma and hemiplegia. He regained consciousness on the second day, and the hemiplegia disappeared in a fortnight. This rapid and complete recovery, exceptional to be sure, cannot be regarded as proof of the absence of hemorrhage or embolism. In fact, the latter is highly probable. It is possible that the clot may have been partially dislodged, so as to allow some blood to pass by it, or that an exceptionally favorable anastomosis allowed a better collateral circulation than usual to be established.

The following case occurred in the service of the writer: An elderly negress, who had extensive anasarca and signs of enfeebled action of the heart without any valvular lesion being detected, after washing her face was heard to groan, and found speechless and unable to swallow, with complete right hemiplegia. There was a slight improvement in a few hours, but she died two days later. The autopsy disclosed some hypertrophy and dilatation of the heart without valvular lesion. A careful search failed to discover any change in the brain or obstruction in its vessels, although there was chronic endarteritis.

The relations between epilepsy, apoplexy, and syncope are interesting

and important, but are certainly far from clear. Little is gained by shifting obscure cases from one category to the other. If sudden deaths be synonymous with apoplexy, we shall certainly have to admit that apoplexy does not always demand for its cause cerebral changes sufficiently marked to be recognizable after death. If, on the other hand, we refer them to heart disease, we shall have to admit that a heart without valvular disease or extensive changes in its muscular substance may cease to beat under influences as yet not well understood.

Since the paralysis arising from hemorrhage resembles so closely in its progress that dependent upon occlusion of the cerebral vessels, a further description will be deferred until the latter lesion has been described; but this remark does not apply to the premonitory and initiative symptoms, which may be of great importance, and which are not always the same with the two or three sets of lesions. There are many of them, but, unfortunately, no one among them taken alone can be considered of high significance, unless we except what are sometimes called premonitory attacks, which are in all probability frequently genuine hemorrhages of so slight extent that they produce no unconsciousness, and but slight paralysis easily overlooked. A little indistinctness of speech or a forgetfulness of words, a droop of one angle of the mouth, or heaviness in the movement of a foot or hand, lasting but a few moments, may be real but slight attacks, which may be followed either by a much more severe one, by others of the same kind, or by nothing at all for a long time. They are sufficient to awaken apprehension, and to show in what direction danger lies, but they give little information as to the time of any future attack.

Retinal hemorrhage is admitted by all modern authors to be connected with disease of the vascular system, and hence also with renal inflammation and cerebral lesions. The writer is greatly indebted to Hasket Derby for the following facts: Out of 21 patients who had retinal hemorrhage, and of whose subsequent career he had information, 9 had some sort of apoplectic or paralytic attack; 1 had had such an attack before she was examined; 3 died of heart disease, 1 suddenly, the cause being variously assigned to heart disease or apoplexy; and 6 were alive when heard from, one of these, a man of forty-eight, being alive and well fourteen years after.

Bull¹ describes four cases of his own where retinal hemorrhage was followed by cerebral hemorrhage, demonstrated or supposed in three, while in the fourth other symptoms rendered a similar termination by no means improbable. He quotes others of a similar character. The total number of cases which were kept under observation for some years is, unfortunately, not given. In a case under the observation of the writer a female patient, aged fifty-seven, who had irregularity of the pulse with some cardiac hypertrophy, was found to have a retinal hemorrhage two and a half years before an attack of hemiplegia. The hemorrhage was not accompanied by the white spots which often accompany retinitis albuminuria.

In a case reported by Amidon² retinal and cerebral hemorrhages seem to have been nearly simultaneous a few hours before death. There was diffuse neuro-retinitis and old hemorrhages besides the recent one.

¹ *Am. Journ. Med. Sci.*, July, 1879.

² *N. Y. Med. Rec.*, 1878, xiv. 13.

The highly interesting observation has been made by Lionville¹ that when miliary aneurisms are present in the brain, they may often be found in the retina also. In one case where they were very numerous in the cerebrum, cerebellum, pons, and meninges, aneurismal dilatations were found also in the pericardium, mesentery, cervical region, and carotids (the latter not being more minutely described). There was very general atheroma and numerous points of arteritis. The retinal aneurisms varied in size from those requiring a power of ten or twenty diameters to be examined up to the size of a pin's head or a millet-seed. He thinks they might have been recognized by the ophthalmoscope.

The hemorrhages accompanying idiopathic anæmia and other diseases with a similar tendency are not to be taken into this account. Hemorrhage accompanying optic neuritis is likely to be due to some disease of the brain other than the one under consideration.

Mental disturbances of various kinds have been considered as significant, and Forbes Winslow gives a great many instances of different forms, but they are to be looked upon rather as indicating chronic cerebral changes which may result in various conditions, of which hemorrhage may be one, than as furnishing any definite indication of what is to be expected. Loss of memory should be regarded in this way. Some acute or temporary conditions of depression may affect the nutrition of the brain in such a way, without having anything to do with hemorrhage actual or anticipated.

Aberrations of the special senses are often observed, such as noises in the ears more or less definite, the sight of colors (red), or being unable to see more than a portion of an object. The fact to which these testify is probably a localized disturbance of the circulation which may not precede rupture of the vessels.

Distinct hallucinations of hearing, followed by those of smell and succeeding irritability, sleeplessness, were observed by Savage² in a case which terminated soon after in apoplexy.

There are few symptoms which are more likely to excite alarm and apprehension of a stroke of paralysis than vertigo or attacks of dizziness, but it is too common under a great variety of circumstances to have much value, and is, as a matter of fact, rarely a distant precursor of intracranial hemorrhage, although it frequently appears among the almost initiatory symptoms, especially when the lesion is in the cerebellum, so that, if continuous, it is not likely to mean that anything worse is coming. It has been said to be strongly significant if occurring without the digestive derangements or circulatory disturbances likely to cause it, and be unconnected with disease of the ear. Unfortunately for diagnosis, but fortunately for the patients, the so-called vertigo a stomacho læso, may arise in cases where the stomach trouble is very difficult or impossible to detect, and it often continues for weeks or months after the most careful regulation of the diet, and yet is followed by no cerebral lesion. Although a vertigo for which every other cause can be excluded certainly justifies a suspicion of cerebral trouble, the tendency to exaggerate its prognostic importance should not be encouraged by the physician, as it may exist a long time, and disappear without another sign of the catastrophe which has been keeping the patient in dread.

¹ *Comptes Rendus de l'Acad. des Sci.*, 1870.

² *Journ. Ment. Sci.*, 1883, xxix. 90.

Among the more significant and immediate symptoms are to be reckoned paræsthesiæ of the side about to be paralyzed, such as numbness or tickling. Headache of great severity is often, but not invariably, present. It has nothing characteristic about it, except that it may be different from those the patient has been in the habit of having, or may be of unusual severity, so that the patient says it is going to kill him. Such a headache in a person in whom there is good reason, from age, interstitial nephritis, or other symptoms, to suspect the existence of vascular lesions is likely to be an immediate precursor of a hemorrhage. Persistent early waking with a slight headache, which passes off soon after rising, is said by Thompson¹ to be a somewhat frequent premonition. Vomiting is hardly a premonitory, but may be an initial, symptom, especially in hemorrhage of the cerebellum.

Reference is had in these statements chiefly to the ordinary form of cerebral hemorrhage. Of course if, during a leucocythæmia or purpura, large hemorrhages occur elsewhere, it may be taken as a hint that possibly the same thing may take place in the brain.

These signs of arterial disease must be considered as of the highest importance among the (possibly remoter) premonitory signs, not only of cerebral hemorrhage, but of the other lesions treated in this article. Atheroma and calcification of the tangible arteries place the existence of peri-endarteritis among the not remote possibilities. High arterial tension has already been spoken of in connection with etiology, and its presence should be sought for. An irregular and enfeebled cutaneous circulation has been spoken of as an indication of value.

OCCCLUSION OF THE CEREBRAL ARTERIES may take place from several causes other than those which concern us here, as from the pressure of tumors or endarteritis, usually syphilitic. Thrombosis and embolism are grouped together from their great anatomical resemblance and their frequent coexistence, but the symptoms produced, although ultimately the same, are often different enough to make it necessary to bear in mind the fact that there is a distinction—that is, that embolism is rapid and thrombosis is slow.

A cerebral artery may be occluded from the presence of a plug of fibrin more or less intermixed with the other elements of the blood. This plug may have been formed in situ, and is then somewhat firmly attached to the walls of the vessel, and partly decolorized at its oldest portion, while on each side of it, but especially on the side away from the heart, it is prolonged by a looser and darker clot of more recent origin. This is a thrombus.

When the plug has been transported from elsewhere it is embolus.² It may consist of various substances, as described in the article on General Pathology, but is usually of fibrin which has formed a thrombus or vegetation elsewhere, and, having been broken off, is carried by the blood until it comes to a place too narrow for it to pass, or where it lodges at the bifurcation of a vessel. The piece of fibrin thus lodged has a strong

¹ *N. Y. Med. Record*, 1878, ii. p. 381.

² The Greek word *εμβολος* (*en*, in, and *βαλλω*, to throw) signifies the beak or rostrum of a ship of war. *Εμβολον* signifies wedge or stopper, and would certainly seem the appropriate form to be adopted for anatomical purposes. As uniformity of nomenclature, however, seems more to be desired than etymological accuracy, the writer has conformed in this article to the general usage.

tendency to cause a still further deposition—that is, a secondary thrombus—which may progress until it comes to a place where the blood-current is too strong for the process to go on any farther. It may in such cases not be obvious at the first glance whether the whole process is thrombosis or whether it started from an embolus.

It is probable that a thrombus forming at one point in a cerebral vessel may break to pieces and its fragments be carried farther along, forming a number of small emboli. (See Capillary Embolism.) Embolism or thrombosis may take place anywhere in the brain or body generally, but has certain points of preference. Of these, the most usual in the brain is in the neighborhood where the internal carotid divides into the anterior and middle cerebral, or in either of these arteries, especially the middle, beyond this point. The plug may be situated in the carotid just before this point, or even as low down as its origin from the common trunk. Emboli lodge in this region, somewhat more often upon the left side. The brain is said to be third in the order of frequency with which the different organs are affected by embolism, the kidneys and spleen preceding it. It has been found that small emboli experimentally introduced into the carotids are found in much larger numbers in the middle cerebral than elsewhere. It is the largest branch, and most nearly in the direct line of the carotid. Position undoubtedly influences the point at which an embolus lodges, as it probably moves slowly along the vessels and along their lower side. It has been remarked that, on account of this course of the embolus, it is doubtful whether it can get into the carotid when the patient is standing, but it certainly can do so when he is sitting up; which, so far as the direction of the carotids is concerned, is the same thing. The frequency with which a hemiplegia is observed when a patient awakes in the morning may perhaps be accounted for by the position favoring the passage of an embolus into the carotid, which otherwise would reach organs more remote.

The vertebrals and basilar are not infrequently affected.

The sources whence cerebral emboli may spring are various, but cannot be found outside a certain range. They may, in the first place, be torn off from vegetations upon either the mitral or aortic valves; and this source is probably the most common. The appendix of the left auricle may furnish a plug from the thrombi formed among its trabeculæ, or the aorta from an aneurism or from parietal thrombi formed upon spots roughened by atheroma. The pulmonary veins are occasionally the source of the embolus, though this is not very common.

It is rather doubtful whether an embolus can find its way from the systemic veins through the lungs to the brain, but it is possible that small emboli may do so, and increase in size from the addition of fresh fibrin when floating in the blood-current. The occurrence of pyæmic abscesses in the brain would suggest the possibility of this, though it is, on the other hand, possible that the brain abscesses are secondary to older ones in the lungs. In some cases, however, a careful examination does not disclose the source of the embolus.

In the blood-current the embolus may give rise to no symptoms whatever, and even after its arrival in the cerebral circulation it may lodge in such a way as not entirely to obstruct the current. In most instances, however, it does not stop until it plugs the vessel completely and arrests

the current of blood beyond it for a moment. Whether it shall completely deprive the portion of brain to which it is distributed depends upon its situation as regards anastomoses and upon the formation of secondary thrombus. Hence the knowledge of the distribution of the arteries supplying the brain—that is, the two carotids and two vertebrals—is of more importance in reference to embolism and thrombosis than to cerebral hemorrhage, where the effusion takes place from quite small branches.

The anterior portion of the brain, including the anterior and posterior central convolutions and the first temporal, are supplied with blood by the two terminal branches of the internal carotid, the anterior and middle cerebral, the ganglia underlying these portions of the cortex being supplied, as already stated, by small branches arising near the origin of these two trunks, and principally the second. The anterior cerebrals of the two sides are connected by the anterior communicating, which is a short and usually wide vessel. Sometimes one anterior cerebral branches in the longitudinal fissure, and supplies a part of both sides. Hence in plugging of one internal carotid which does not reach its bifurcation a collateral supply may be received from the other side. If, however, an embolus or thrombus has penetrated beyond the origin of the middle cerebral, this vessel can no longer receive a supply from the anterior.

The posterior communicating arteries are two small vessels which connect on each side the posterior cerebrals and either the carotid, just as it gives off its two chief cerebral branches, or else the middle cerebral close to its origin. These arteries may be of quite unequal size, that upon the right usually being the larger, and sometimes so large as to give the appearance of being the principal origin of the posterior cerebral. When this happens the part of the posterior cerebral which arises from the basilar may be reduced to a minute arteriole, and the basilar, almost entire, goes to supply the left side of the brain. This condition of the posterior communicating may exist to some extent on both sides in the same brain. It is probable that in many cases these arteries are too small to be of great value in re-establishing the circulation in the anterior portion of the brain when it is suddenly interrupted by an embolus.

When the large trunks leave the circle of Willis to be distributed upon the surface of the brain, after giving off from the first centimeter or two of their course the nutrient arteries for the deep-seated ganglia, they break up into several branches which ramify upon the surface, but, as Duret has shown, undergo very few anastomoses. Instead of forming, as was once supposed, a richly inosculating network, small branches penetrate into the brain-substance perpendicularly from the superficial vessels, but these do not communicate freely with each other by vessels larger than capillaries.

From these anatomical conditions it happens that when a vascular territory is deprived of its normal supply by an embolus, it cannot be supplied with blood from surrounding districts. A certain limited amount of collateral supply is possible through the capillaries and the rare anastomoses, but it is only around the edges, and the centre of the territory becomes destitute of circulating blood. Thus an embolus does not in the brain produce, as it does in other organs with more abundant collateral supply, a large hemorrhagic infarction.

Small hemorrhages may, however, take place around the edges of the softening, and when a number of small emboli are present, so as to afford a number of overlapping areas with their borders of congestion, a red softening may be the result. When the emboli are very small, and at the same time not numerous enough to occlude all the ultimate ramifications of a trunk, the vascular compensation may be rapidly completed.

The change produced in the cerebral substance from cutting off its supply of blood is known as anæmic necrosis, and includes what has been known as white softening, with probably some yellow, and possibly a little red softening, the latter in case where simple softening has been complicated by hemorrhage.

When the circulation ceases the substance that should have been nourished loses its firmness and acquires a custard-like consistency. The gray and white substances are no longer so distinct in appearance, the latter losing its milky-white color, the whole surface of a section becoming of a dirty yellowish-white, somewhat shining, and looking as if it contained more moisture than normal. When a considerable portion of the interior of the hemisphere is thus affected, the brain outside, with its membranes, bags down, looks swollen, and feels to the fingers as if there were present a sacful of fluid. The boundaries of such an area of softening are marked off from the healthy substance with some distinctness, though less than that of a hemorrhage. There may be some hemorrhage around the edges or into the cavity, so that the presence of a little blood-pigment is no proof that the original lesion was not softening from occlusion. In the further progress the contents of the cavity become more fluid, and finally a somewhat distinct cyst is formed, not unlike that from a hemorrhage, with an internal areolar structure from the remains of connective tissue, and contents of a slightly yellowish or brownish color, or often of a chalky white. These cysts have little to distinguish them, when old, from similar ones left by hemorrhage, except the much greater amount of pigment in the latter. The smaller spots of softening may after a time lose their fluidity, and remain as yellowish patches as firm as, or firmer than, the surrounding brain. The region of the brain involved becomes atrophied, the convolutions shrink, and the membranes become filled with serous fluid, to compensate for the sinking of the surface.

The microscope shows gradually increasing fatty degeneration, disorganization of the nervous tissue, and degeneration of its elements. The pyramidal cells are sometimes distinctly recognizable by their form, and show gradual transition into the indeterminate round granulation-corpuscles. The vessels exhibit fatty degeneration of their coats, as well as accumulation of fatty granules between the vessel and the lymphatic sheath. The clot which blocks the artery becomes adherent to its walls, and the vessel with its contents forms a round solid cord.

In a few instances the thrombi have become perforated through the centre, so that a channel is formed for a renewal of the circulation. There is no reason to suppose that this takes place soon enough to be of any advantage in restoring the nutrition of the necrosed portions of brain.

The region involved in softening depends upon the artery which is plugged and the location of the obstructing body. The place of election seems to be the carotid near its separation into its large branches, or these

branches after the separation, especially the middle cerebral, this being peculiarly liable because it is the largest branch and is the continuation in a direct line of the carotid. It is more frequent upon the left side. Cases have been observed where the whole of one hemisphere was softened from obstruction of the carotid at its bifurcation; which may be accounted for, as Charcot suggests, by an unusual distribution of the arteries, as described above, the posterior cerebral as well as the other two being derived almost entirely from the carotid. In a case recently observed by the writer the whole right cerebral hemisphere, with the exception of the tip of the frontal and tip of the occipital lobes, was softened to the consistency of custard, a thrombus extending from the bifurcation of the common carotid into all the ramifications of the middle cerebral. The most common form, however, is where more or less of the brain around the fissure of Rolando and fissure of Sylvius, with or without the underlying ganglia, is softened. This happens from a lodgment of the embolus in the middle cerebral. If the obstruction be close to the origin of the artery, the corpus striatum suffers, from the mouths of its small nutrient arteries arising in this part of its course being stopped; while if it have passed along a little farther, these remain open, and the cortex, to which the larger branches are distributed, alone is softened.

The anterior cerebral is not infrequently affected, either alone or with the middle, and in these arteries as well as the posterior the embolus, if of small size originally, may penetrate so far as to give rise only to quite a limited anæmia. The basilar is an artery not very rarely occluded, though more commonly by thrombus than embolus. This occlusion may be so limited as to affect only the nutrient arteries of the pons and cause a very limited softening, the parts before and behind it being supplied by the unobstructed portion or by collateral circulation from the carotids. Occlusion of the cerebellar arteries and softening of the cerebellum are among the rarer forms. The vertebrals themselves are sometimes plugged. A thrombosis has been observed in the only inferior cerebellar artery which existed, causing softening in both lobes. There was atheroma of the heart and arteries, and a thick calcareous plate in that which was occluded.¹

In a general way, it may be said, with many exceptions on both sides, that thrombosis and embolism tend to affect the cortex, and hemorrhage the central ganglia.

What has just been written applies to the simple mechanical action of emboli. If, however, they have a septic origin, as notably in cases of ulcerative endocarditis, the region in which they lodge becomes, instead of a simple spot of necrosis, a septic focus or abscess, with its results of compression or irritation. In such a case there are likely to be abscesses of similar origin in other organs, and the cerebral lesion is only a part of the general pyæmic condition.

ETIOLOGY.—So far as the lodgment of an embolus in an artery is concerned, it can hardly be said that there is any etiology, for the detachment of the plug from its place of origin is purely a matter of accident, and may take place at any time. As to its origin in the form of fibrinous deposit on the valves of the heart or a roughened spot on the aorta, we must refer to the article on General Pathology. The most important

¹ *Progrès méd.*, 1876, 373.

condition for embolism is disease of the valves of the heart, rheumatic or otherwise. Next comes arterial disease, producing roughening of the inner coat and subsequent deposition of fibrin. So far as we can tell, the causes leading to endarteritis or atheroma are essentially the same as those which produce the periarteritis described in connection with cerebral hemorrhage, and we may therefore put down old age, alcohol, and strain as among the causes of cerebral embolism. Injuries of the lungs leading to thrombosis of the veins may be considered as possible sources for the formation of an embolus, and we might suppose that phthisis and pneumonia would furnish plugs which would lodge in the brain, though as a matter of fact they seldom do so.

Experience shows that embolism, unlike hemorrhage, is not specially a disease of advanced life, but is distributed over different periods, with preference for old age less marked than with hemorrhage. Andral gives the ages of patients with softening—which, however, includes thrombosis as well as embolism—as follows: the average would undoubtedly be displaced in the direction of youth if thrombosis could be taken out of the list:

| Andral: Beginning of softening in 27 cases. | | Andral: Death with softening in 153 cases. | | Cases (with autopsies) of embo- lism, thrombosis, and soften- ing—25 cases. | |
|---|---|--|----|---|---|
| 17-20 | 4 | 15-20 | 10 | 20-30 | 4 |
| 27 | 2 | 20-30 | 18 | 30-40 | 3 |
| 30-37 | 2 | 30-40 | 11 | 40-50 | 3 |
| 43-45 | 2 | 40-50 | 19 | 50-60 | 1 |
| 53-59 | 4 | 50-60 | 27 | 60-70 | 5 |
| 63-69 | 7 | 60-70 | 34 | 70-80 | 2 |
| 76-78 | 6 | 70-80 | 30 | Young | 1 |
| | | 80-89 | 4 | Middle-aged | 1 |
| | | | | Old | 5 |

In the etiology of cerebral arterial thrombus there seem to be two factors of prime importance, although there are cases which seem to demand a third, and Charcot¹ suggests the possibility of some hæmic dyscrasia favoring the formation of a thrombus, and relates a case of thrombosis of the middle cerebral, with three others of the same process in other arteries, occurring in patients with uterine cancer, where all the usual sources of emboli were explored with negative results. The first of the two is disease of the cerebral arteries, not necessarily extensive, but sufficient to form a starting-point on the inner wall for the deposit of fibrin. In this respect the etiology of thrombosis may be various. Syphilitic endarteritis, for instance, may very easily give rise to this lesion, but it is likely to be accompanied by others, and has a symptomatology more or less peculiar to itself. It is not, of course, to be included with the form we are considering.

The second factor—one which is perhaps capable of giving rise to coagulation of the blood or deposit of fibrin without any arterial disease—is weakness of the heart, connected or not with anæmia. The causes of this condition may be manifold, and are likely to lead to many other consequences than cerebral thrombosis. A thrombus may form upon a very small basis of atheroma. Several of these points are illustrated in the fol-

¹ *Comptes Rendus Soc. de Biol.*, 1865, p. 24.

lowing case: A lady, aged about sixty-five, had had for many months vague symptoms of want of strength, fatigue, want of appetite, and so on, with complaints of distress and fulness in the abdomen, for which no special cause could be found. On one occasion she was unusually long in dressing, and her expression was noticed to be changed and her voice altered for a few moments. The pulse was habitually 60 or less, and at times irregular, but nothing abnormal could be detected in the sounds or position of the heart. Fatty degeneration was suspected. One morning, after going to bed in her usual health, she was found on the floor of her room unconscious and with left hemiplegia. She lived about thirty-six hours. The autopsy showed nothing abnormal in the abdomen except a considerable accumulation of fat; and in the thorax the heart appeared normal, and was not fatty. There was very little atheroma. In the end of the internal carotid artery was a thrombus, of which the lower and firmest part was connected with a very small spot of roughening just at the point where the artery comes through the base of the skull. It extended just beyond the origin of the middle cerebral artery, which was of course occluded. The corresponding region of the brain was converted into a vast mass of softened tissue.

The SYMPTOMS of the lodgment of an embolus in the brain may closely resemble, or even be precisely the same as, those of hemorrhage. Unless, however, an embolus makes a pause on its journey, giving rise to a partial obstruction before there is a complete one, or unless the obstruction is not absolute until after the formation of a secondary thrombus, the attack may be absolutely sudden.

A thrombus, however, is slower in its formation, and may produce gradually increasing anæmia of the region of brain supplied before it is absolutely complete, with a gradually increasing paralysis and loss of consciousness slowly approaching. Thus we may have the early symptoms in the form of headache, vertigo, heaviness, and drowsiness, peculiar sensations in the limbs about to be paralyzed or in the head, delirium of various kinds, or hysterical manifestations. Prévost and Cotard¹ lay special stress upon the importance of severe vertigo (*étourdissement*) as a prodrome or warning of softening, especially in the aged. It is dependent upon anæmia of the brain, and this, in its turn, upon atheroma of the arteries, and sometimes at least upon feebleness of the circulation, both of these being conditions likely to cause the deposit of a thrombus. As, however, the thrombus does not necessarily result from these conditions, and as the vertigo may arise from other sources, as stated under the head of Cerebral Hemorrhage, it is to be looked upon with special suspicion chiefly in those cases where other symptoms might lead in the same direction, and when other causes can be excluded.

The same authors also speak of less defined symptoms, like delirium and stupor, occurring among the inhabitants of the Salpêtrière (old women), with intervals of comparative health, as being premonitory.

It is possible, however, for the symptoms of thrombus to be developed rapidly when, as in the case last described, the thrombus begins to form in a place which does not entirely interrupt the current, but afterward reaches the mouth of a large vessel, which it closes.

The loss of consciousness, coma, and all the phenomena of the apo-

¹ *Mémoires de la Soc. de Biol.*, 1865, p. 171.

vent the structure from being disorganized. In others a specially favorable anastomosis may preserve even a larger area, but in others still it is not easy to account on entirely anatomical grounds for the amount of improvement which takes place.

From this point onward the history of hemorrhagic and of embolic and thrombotic paralysis is essentially the same, and the description of the principal phenomena and progress of hemiplegia will apply to all.

SYMPTOMS AND PROGRESS OF HEMIPLEGIA DEPENDING ON CEREBRAL HEMORRHAGE OR OCCLUSION OF THE CEREBRAL VESSELS.—The cerebral cortex represents the centres for many of the higher nervous functions, spread out in such a way that they may be more or less separately affected, while the corpora striata and internal capsules are the regions where the various conductors are crowded together, so that embolism, when affecting small vessels and limited areas of the cortex, more frequently gives rise to narrowly-defined groups of symptoms than hemorrhage, which, taking place oftener in the central ganglia, is able to cut off the communication from large masses of cerebral tissue at once. This is a general remark, tending to explain why aphasia, for instance, is often spoken of as especially a symptom of embolism, while it is in reality common to all the lesions that affect the proper locality.

The motor paralysis, more or less complete, which has been described under the head of Hemorrhage continues indefinitely. It may disappear rapidly, so that motion begins to return in a day or two, and goes on to complete recovery in a short time. On the other hand, it may be months before the flexion of a finger or a toe gives the slightest token of the will resuming its control. The face often recovers its symmetry before the limbs are fully restored, but the leg may be used in locomotion before the complete recovery from paralysis, since the tone of the muscles is sufficient to keep the knee straight enough for support, as if the leg were all in one piece, while it is swung around at each step by the pelvic muscles. We may meet with all degrees of recovery—from that which is absolutely complete and comparatively rare, through the case where a little want of play upon one side of the face, a little thickness of speech, a feeble or awkward grasp of the hand, betrays what has happened, or that of the man so often seen in the streets with a mournful or stolid face, the arm in a sling or dangling straight down by the side, and swinging one leg awkwardly around, to the helpless paralytic lifted in and out of his chair or lying almost motionless in bed, and living only to be fed and be kept clean.

Involuntary movements may take place in limbs entirely incapable of voluntary ones, and may occur under conditions of excitement or with other involuntary movements, such as gaping. On the other hand, the patient often moves the well hand while making utterly ineffectual attempts on the paralyzed side. Involuntary twitching of the feet may be annoying. Reflex movements, especially of the feet, are often exaggerated, and in fact the twitching just spoken of is often excited by some trifling, perhaps unperceived, irritation. A touch with the point of a penknife upon the sole of the foot may call out a movement which the patient is utterly incapable of executing by the force of the will, and the appearance of volition is often increased by the grimace or exclamation of pain or annoyance.

Epileptiform attacks may be a sequence of hemiplegia, occurring at irregular intervals, and not of great severity. Sometimes the patient seems depressed or less talkative for a day or two previously, and relieved after the fit has occurred, as in true epilepsy.

Comparatively little attention has been given to the condition of sensation in hemiplegia. In the more complete apoplectic stupor it is apparently abolished, like nearly all the functions above those of respiration and circulation, but it often happens when the patient is unable or unwilling to make any voluntary response to the voice, and lies apparently perfectly indifferent, that any moderate irritation like a pinch will bring out evidence of sensation. It is often stated that in hemiplegia the sensation is not at all affected; and this is probably true of many cases, but a more attentive examination will often disclose a decided diminution on the affected side. Broadbent, who has tested with pricking, touch, the compasses, and hot substances, says that it is frequently diminished, and often greatly so, and not only in the limbs, but in the face, chest, and abdomen. Tripier¹ says that a lesion of the larger part of the fronto-parietal region determines at the same time a paralysis of motion and a diminution of sensibility; and one may conclude that this region holds under its dependence sensitive as well as motor phenomena intimately connected with each other. The zone called motor, of which the limits are difficult to fix, may with more reason be called sensorimotor.

Anæsthesia probably in most instances disappears more rapidly than motor paralysis, which accounts for its being frequently overlooked. The more common location of lesions causing motor paralysis—*i. e.* the corpus striatum and the motor portion of the cortex—is one not likely, unless extensive, to concern sensation; but there are cases where a very complete hemianæsthesia, including the special senses, may be found; and when, in such cases, the motor paralysis is slight, a picture is presented almost identical with that of hysterical hemianæsthesia with great diminution or abolition of the special senses, hearing, taste, smell, with concentric diminution of the field of vision and of the color-field, or complete color-blindness on the affected side.

A man aged thirty-five while at work suddenly felt a prickling sensation upon his left side, and became unconscious. The bystanders say he was convulsed. On returning to consciousness after three hours he had lost his speech, which, however, was rapidly recovered, and his left side was not so strong as his right, though there was no distinct history of paralysis. Two or three days afterward it was noticed that sensation was much diminished upon the left side, two sharp points of the æsthesiometer being felt as one at two inches on the forearm and three-quarters of an inch on the tongue. He could feel the touch of a spoon, but could not tell whether it was cold or hot. Odors were not recognized upon the left side of the nose, except faintly ammonia and chloroform, and a watch was heard on that side only when in contact with the ear. The field of vision was much diminished and color-blindness was almost complete. A few days later the field of vision had increased, and there was color-sense, the field of perception for the different colors being arranged almost exactly as laid down by Charcot, vision for red being largest, but not so

¹ *Revue mensuelle de Méd. et Chir.*, 1880, p. 18.

large as for simple perception of objects; those for blue, green, and yellow nearly the same and smaller; and that for violet limited to a small space in the centre of the field.

Less regular forms of anæsthesia may be met with, as well as hyperæsthesia. These are said to be especially connected with various lesions of the pons.¹ A case is recorded² of complete hemianæsthesia in a man, coming on like a blow. There was no loss of motor power; the face was symmetrical, sight and hearing unimpaired. Taste was lost and smell doubtful. There was aortic and mitral disease. Hughlings-Jackson speaks of a man who experienced a severe apoplectiform attack which it was thought would be fatal in a few hours. He recovered, however, with almost complete loss of hearing.

Neuralgic pains of long continuance are not infrequent accompaniments of hemiplegia, and may be lasting even after nearly complete recovery from the paralysis. A peculiar restlessness, a constant desire for change of position, has been referred to derangement of the muscle-sense. It is sometimes very distressing, and causes much annoyance to attendants as well as to the sufferer, as the patient is no sooner placed in one position, no matter how comfortable, than he desires to change it.

The mental condition seldom fails to suffer more or less in cases of hemiplegia, but the limits are very wide between a slight emotional excitability on the one hand and almost dementia on the other. This is, of course, applicable to cases where the lesion is a single or limited one, and not where a hemorrhage or thrombus is merely a part of a general vascular degenerative change with chronic meningitis or atrophy of the brain, where the mental decay can hardly be called the result of any single lesion. In cases of aphasia the mental condition is harder to make out, from the peculiar inability to communicate ideas if present. It is very safe to say, however, that many such patients possess much greater intelligence than would appear to a casual observer, and yet the apathy with which they often bear the deprivation of speech and consequent isolation speaks more strongly in favor of some blunting of the perceptions than of Christian resignation. A patient whose general appearance is that of tolerable comfort is likely to cry when attention is called to the helpless condition of the hand. It is probable that memory suffers in such cases, if not the reasoning faculties.

Trousseau cites the case of Lordat, who became aphasic, and after recovery described his own case. The learned professor claims to have been in full possession of his faculties, and to have arranged a lecture with the divisions and subdivisions of the subject, and all this without the thought of a single word passing through his mind. Trousseau ventures to doubt the possibility of carrying on complicated mental processes without words, and thinks Lordat may have overestimated the precision of his mental processes. It appears in confirmation of this view that after his attack he always read his lectures, whereas before he had been distinguished as an extempore speaker.

McCready, in an excellent article in the *New York Journal of Medicine* (September, 1857), discusses this subject at length, and details a number of cases where it was evident that paralytics and aphasics (who, however,

¹ Couty, *Centralblatt f. d. Med. Wiss.*, 1878, 571.

² *Med. Times and Gaz.*, 1871, i. 246.

he did not know by that name, nor the special lesion connected with their condition) possessed not only ordinary intelligence, but excellent business judgment and ability. He says that the confusion of mind and difficulty in pursuing a train of thought of which apoplectics are apt to complain is, to a great extent, the mere result of diminished nervous energy—that they comprehend well and judge correctly. It is fair to say that while the mind is almost certainly impaired, it is not necessarily in exact proportion to the severity of other symptoms, aphasia included. The memory, either special or general, is most apt to be impaired.

The testamentary capacity of a person who has had an apoplectic fit or who is paralyzed at the time of making a will may be called in question. The only general remark to be made is that these facts alone are not sufficient to prove incapacity; neither should the presence of aphasia or agraphia do so without further evidence of want of comprehension of the meaning of language used by others; so that if, for instance, a person were seized with hemiplegia and aphasia between the drawing up of a will and its signature, it should not be invalidated unless there be further evidence to show that the testator was incapable of understanding it when read over to him. In cases of word-blindness, a patient, like one described by Magnan, may be able to draw up a will with full comprehension of what he is doing, and yet be unable to read it understandingly. Inability to signify intelligibly assent or dissent would, of course, entirely disqualify one from signing a will.

It is seldom that a paralytic attack fails to leave its mark, though perhaps slight, for years, if not for the remainder of life. An extreme ease of shedding tears is a very common symptom, and sometimes laughter comes on very slight provocation.

Among the most interesting groups of phenomena connected with hemiplegia, and sometimes the sole representative of this condition—that is, existing alone without any motor paralysis—is that embracing the means of communicating with the outer world by means of language spoken or written. Corresponding to, and usually but not always connected with, right motor paralysis we have the inability to use words in speaking, known as aphasia, aphemia, alalia, and others. The first of these names is the one most frequently used. Agraphia is the inability to use words in writing.

On the receptive side we have the inability to understand language as presented to the eye (word- or psychic blindness) or to the ear (word- or psychic deafness). A case of the former condition has already been spoken of. One still more singular was reported by Mdlle. Skwortzoff,¹ where the patient, not being blind, could not understand letters presented to the eye, but could read with the fingers and understand raised letters like those used by the blind. In a case of the latter kind a man whose ears were normal, and who could distinguish different sounds, answered questions, but entirely at random, though he could read and understand what was written. All these defects are manifestly connected with a peculiar loss of memory, and hence the word amnesia is used sometimes to cover part of the group, and amnesic as an adjective to qualify aphasia.

It should, of course, be understood that the muscles are not paralyzed, so that glottis, lips, tongue, and fingers are capable of making the neces-

¹ *Comptes Rendus de la Société de Biologie*, 1883, p. 319.

sary movements to produce words, and, on the other hand, that the senses of sight and hearing are intact. Aphasia was confounded by some of the older writers with paralysis of these organs, and the whole grouped together under the name of alalia. Even now the distinction is not always clearly observed.

The act of speaking, according to Kussmaul,¹ consists in three stages or processes: the preparation in the intelligence and feelings of the matter to be uttered; the diction, or the formation of the words internally, together with their syntax; the articulation, or formation of words outwardly, irrespective of their connection with one another in the matter spoken. Defects in the first condition have already been spoken of. In the entire absence of mind, as in the deepest apoplexy, aphasia can hardly be said to exist, and it is only later that it becomes manifest. If the second stage is defective, amnesic aphasia exists, and if the third, ataxic. In the great majority of cases of aphasia the loss of memory is the most important factor; and as this exists whatever be the mode in which it is desired to express the idea, amnesic aphasia is accompanied by agraphia. In those cases, however, in which the patient retains a few words, they are not always the same for speech and writing. Occasionally an instance is found where a person can write perfectly well and possesses complete intelligence, but is unable to speak a word. This is pure ataxic aphasia, and is certainly rare. An ataxic agraphia is less easy to detect, since the aphasic patient is likely to be paralyzed upon the right side, and thus unable to write, even if he remembers the words, until educated upon the left side.

There are many degrees and kinds of amnesic aphasia, and, in fact, every case is a study by itself. The slightest might be called physiological; at any rate, it is sufficiently common among people supposed to be well, and consists in the failure to recollect in time for use the name, most frequently of a person, but sometimes of a thing, which is really well known, is recognized at once if suggested, and perhaps returns spontaneously at a later period. Another person may forget only some words which are not recalled at any time, or parts of words. A man appeared among the out-patients at St. Bartholomew's Hospital who had his name written on a piece of paper, because he could not say it, but could carry on a long conversation. There were a few other words he could not say. The more complete cases have no vocabulary at all, or only a few words or syllables applied to all purposes, and perhaps an exclamation or two. In these cases the patient may know perfectly well that he is not expressing his ideas, and he may recognize perfectly well the word when it is told to him or reject a wrong one. If he be, as happens in nearly all cases, unable to pronounce the word after he has recognized it as the one he wished for, there is a combination of ataxic and amnesic aphasia. Incorrect or deficient words may be corrected or supplemented by gestures or intonation. "Yes" may do duty without confusion for "yes" or "no," according to the tone.

Oaths may be retained, and sometimes an exclamation may be uttered with perfect propriety of application which cannot be repeated deliberately a moment afterward. This emotional use of words may be considered akin to the movement executed by paralyzed limbs under the stim-

¹ Ziemssen's *Cyclopædia*.

ulus of a movement taking place elsewhere, and may lead to an erroneous prognosis of recovery. This curious fact, that more or less automatic expressions are possible when deliberately-willed pronunciation is not, is a probable explanation for the observation which has occasionally been made that an aphasic patient is able to sing words which he cannot speak.

Paraphasia is the use of the wrong words, or of phrases which carry an entirely different meaning from that intended, as when Trousseau's patient receives a guest with politeness and invites her to be seated with the words "cochon, animal, fichue bête," or an old paralytic, when a lady declines to drive with him, answers with great suavity, "It don't make any damnation to me whether you go or not."

Word-blindness is more common than word-deafness, and is a frequent accompaniment of aphasia. Rostan, the well-known author of the work on softening of the brain, experienced an attack of aphasia lasting a few hours. The symptom which first attracted his attention was the inability to understand the book, by no means abstruse, which he was reading. He was, however, able carefully to observe his own symptoms, and made signs to be bled, which operation was followed by relief.

Gouty aphasia has been described in a man aged thirty-seven who on several occasions became aphasic, with recovery in a short time. This condition was connected with localized paralysis, and once with entire right hemiplegia. Afterward it was accompanied by convulsions. In the intervals the patient was in fair health.¹ It is difficult to imagine the lesion in this case. The reporter speaks of "sudden blocking by a gouty thrombus," but nothing is known of any thrombus which can disappear so rapidly. Ball² describes twelve attacks of aphasia occurring within nine months, and accompanied by slight paresis and convulsive movements in the right hand. The patient suffered habitually from migraine. He supposes the cause to have been a temporary anæmia.

Aphasia may be entirely unconnected with motor paralysis, and is then likely to be of shorter duration, though just as complete. Most of these cases probably do not depend upon a lesion of the same kind as when aphasia is only one of several severe symptoms. It shows how delicate a function of the brain memory for words may be, and is possibly the result of a temporary malnutrition or a change in the vascular supply. It has been observed in various conditions of debility and after acute disease. Rostan was diabetic. It has been seen after chloroform narcosis, after santonin (5 cgr.), after fright, and is said to be one of the ordinary symptoms after the bite of venomous serpents. Aphasia and paraphasia may be met with in thorough bromization, and, naturally enough, may be part of the symptomatology of general paralysis. In other cases, even when it is the principal symptom, it depends upon an organic lesion, and is not infrequently the precursor of a more fully-developed attack. The diagnosis is of great importance, and other traces of paralysis should be carefully sought for. This symptom is far more common with occlusion of the vessels than with hemorrhage, though not unknown with the latter.³

By far the most common situation of the softening or hemorrhage which gives rise to aphasia is in the third left frontal convolution (con-

¹ *Brit. Med. Journ.*, Aug. 28, 1880.

² *L'Encephale*, 1883, 2.

³ *Lancet*, Oct. 11, 1884, p. 655.

volution of Broca) or the white substance immediately underlying it. The island of Reil may be involved in some cases where but little damage is done to the third frontal.

In a respectable minority of cases aphasia may be associated with left hemiplegia. A case where a tumor in the third right frontal convolution was found in a case of aphasia is reported by Habershon.¹ It is not stated whether the patient was left-handed. Some of these cases constitute those exceptions which prove the rule, inasmuch as the patient is left-handed, and Hughlings-Jackson has shown that the relationship of aphasia to the side which is congenitally pre-eminent, and which is in the vast majority of human beings the right side, is not destroyed by a partial education of the other side to such acts as writing or using a knife.

A lesion in the pons may give rise to aphasia or something closely resembling it, but it is probable that a careful distinction of true aphasia, both amnesic and aphasic, from paralysis or inco-ordination of the muscles of speech, would reduce the number of these cases, and bring the symptom into closer relations with the usual cortical lesions.

A case of congenital aphasia with right hemiplegia has been described.² When six years old the boy was well developed, though less so on the paralyzed side; intelligent; heard well, but could say only a few words, and those badly. Whatever the lesion, which is thought by the author to have been in the speech-centre, but which may not improbably have been in the pons, it is interesting, as showing that the development of the speech-centre is certainly not accomplished by education.

Post-paralytic chorea is an affection the nature of which is indicated by its name. As the hemiplegia disappears, irregular movements are developed in the paralyzed limbs, sometimes closely resembling ordinary chorea, and at others consisting of irregular movements, as closing and spreading of the fingers, with curious and bizarre stiffenings, extensions, and contractions, sometimes known as athetosis, or in others still a tremor resembling paralysis agitans. These usually cease during sleep. It is very apt to be associated with hemianæsthesia more or less complete, though this may be represented by only a certain amount of numbness. A hemiathetosis has been observed to be gradually developed from a post-hemiplegic hemichorea of the more ordinary form.³

This affection is not a common one, and Weir Mitchell states that it is common in inverse proportion to the age. He thinks it possible that some of the congenital choreas may be the result of, or at least closely connected with, intra-uterine cerebral paralysis. It remains for years or for life. In the absence of history such a case might present difficulties of diagnosis from the more usual hemichorea, which is not infrequently accompanied by considerable weakness of the affected side.

The temperature in the early days of both hemorrhage and embolism has been described. At a later period of the hemiplegia it remains in the neighborhood of normal. The temperature of the affected side is often higher than that of the sound one for an indefinite period, but in many cases sinks below if atrophy takes place. The time at which the change occurs is extremely variable. Out of ten cases reported by Folet,⁴ in two of them for three years and one year after the attack the paralyzed

¹ *Med. Times and Gaz.*, 1881, i.

² *Centralblatt f. d. Med. Wiss.*, 1873, p. 299.

³ *Archiv für Psychiatrie*, xii. 516.

⁴ *Gaz. hebdomadaire*, 1867.

side was eight-tenths and six-tenths of a degree respectively the warmer. In three others, of twenty months, four and six years, it was the same on both sides, and in the remaining five the paralyzed limb was a little the cooler. In the last eight there was more or less atrophy.

The coincidence of rise of temperature with vascular relaxation has already been noted under the head of Cerebral Hemorrhage. It is not difficult to explain why a vascular paralysis in a comparatively well-nourished limb, especially when the heart is vigorous, may, by allowing a larger amount of warm blood to circulate, raise the temperature, when the same paralysis with atrophied muscles, weak heart, and impaired general health, merely furnishes a larger reservoir in which the slowly-moving blood may be cooled. The accompanying charts represent the difference of temperature between the two sides in two cases of hemiplegia, the first, O. G. T. (Fig. 41), from embolism, and the second, J. B. (Fig. 42), from hemorrhage, the observation being made within two or

FIG. 41.

Fig. 42.

three weeks of the attack. The dotted line is from the paralyzed side. A subjective feeling of coldness is not uncommon in paralyzed limbs.

The modifications undergone by the urine in a case of cerebral hemorrhage are increase of quantity amounting to polyuria, the urine becoming limpid and afterward returning to the usual color; a diminution in the quantity of urea coinciding with the fall of temperature, and afterward a return to the normal or even above it. When this augmentation is considerable, it constitutes at the same time with a marked elevation of temperature an unfavorable prognostic sign.¹ In a case under the observation of the writer, probably of thrombosis, the acid urine has been

¹Ollivier, *Archives de Physiol.*, 1876.

remarkable for the amount of mucus contained in it, so that it pours from one vessel to another like white of egg. There is a small amount of pus, but no vesical irritation whatever.

Since the trophic centres for the muscles are situated in the spinal cord, cerebral hemiplegia, which does not cut off their connection, does not produce the rapid wasting seen in some cases of spinal paralysis, unless descending degeneration involves the anterior gray columns. The limbs preserve their fulness for a time, although the muscular masses become flabby and slowly atrophy for want of use. This atrophy, however, seldom becomes extreme. The skin of the hands becomes dry, the folds at the knuckles disappear, and the hand loses its expression, looking more like a stuffed glove. The change, however, is not much greater than may be seen in a hand kept for a long time in a bandage. The growth of the nails is retarded, as may be seen by staining them with nitric acid.

If there is any tendency to œdema, as when nephritis is complicated with hemiplegia, the swelling is likely to be much greater upon the paralyzed side. In the adult, of course, there can be no question of the growth of limbs, but when a child becomes hemiplegic from cerebral disease, the limbs grow more slowly and remain smaller, as in a case of ordinary infantile palsy or anterior poliomyelitis.

Much importance has been attached to the fact that large sloughs form with great rapidity upon the nates of the paralyzed side, and Charcot says that this tendency is greater than can be accounted for in any mechanical way. He therefore thinks that a direct trophic influence of the brain upon nutrition is shown. At the very most, however, that can only be a contributory cause, and the freedom of other portions from a similar condition—and that, too, in regions farther removed from the centres of circulation—makes it highly improbable that anything more is necessary to account for it than the less sensitiveness of that side to irritation from urine, roughnesses in the bed, or pressure, and hence neglect. The writer, among a very considerable number of hemiplegias, fatal and otherwise, does not remember to have seen a well-marked case of the kind. Scrupulous cleanliness and changing the position sufficiently often make the preference for the paralyzed side a very slight one.

Arthropathies, consisting in a vegetating, and sometimes an exudative, synovitis, and accompanied by swelling, redness, and pain, are sometimes observed, especially in the upper extremity. They do not appear until fifteen days or a month after the attack.

The most significant change which occurs in the course of a hemiplegia is the development of increased reflexes and rigidity and contracture. After some weeks or months, during which the aspect of the case has not essentially changed, the limbs remaining in the same condition, it will be found on examination that the patellar reflex has become quite energetic, and ankle clonus developed upon the paralyzed side; the arm reflexes from the triceps, biceps, and supinator longus are much exaggerated. This has the same meaning as when similar phenomena are found with spinal disease, and signifies descending degeneration of the postero-lateral columns of the spinal cord, the crossed peduncular tracts. This degeneration may sometimes be traced completely down from the situation of the lesion in the cortical motor centres through the basal ganglia, crura, decussation, and cord. The fuller development of this condition is the

contracture or rigidity, which was at one time referred to secondary changes taking place in the neighborhood of the original lesion, as well as to a purely reflex action having no relation to the degeneration of the cord.

The arms are usually flexed at the elbow, the wrists on the arm, and the fingers in the hand. Sometimes, however, the arm is straight. The leg, which is not always affected to the same extent, is generally in extension, though the toes are likely to be flexed. Attempts to move the limbs are resisted strongly, and in such a way as to show the reflex nature of the phenomenon. If an attempt be made to open the fingers of a contracted hand slowly and carefully, it can be often accomplished and the hand held open with but little pressure, but if it is twitched the fingers resist like a spring. The violent attempt to overcome rigidity is often painful.

In some rare cases rapid atrophy of the muscles of one limb may take place. This has been found to coincide with extension of degenerative changes in the cord to the anterior gray columns.

Late rigidity is an unfortunately clear symptom. There is little if any hope of complete recovery of the use of the limb after it has made its appearance, though it does not prevent walking. After long-continued contracture the activity of the muscles diminishes, but the increase of connective tissue and changes in the joints hold the limb in its fixed position, and the contracture is a more passive one. The electrical reactions of the muscles and their nerves in cerebral hemiplegia are not materially altered, but the neuro-muscular irritability may be somewhat increased for a time by the irritating influence of the cerebral lesion.

In most cases of flaccid cerebral hemiplegia the electrical irritability is somewhat decreased, though retaining the normal character with both currents. Since the muscles and their nerves retain their connection with the spinal nuclei which are their trophic centres, and these nuclei are uninjured, their nutrition does not undergo the changes which affect electric excitability.

When descending degeneration takes place there may be found, coinciding with increased reflex activity and contracture, increased sensitiveness to the electric currents. If the degeneration extend to the anterior columns, as happens in rare cases, the muscles waste rapidly and exhibit the reactions of anterior poliomyelitis—*i. e.* degenerative.

What has just been said applies to the muscles paralyzed by a central lesion. If, however, with or without a complete hemiplegia, a limited lesion, as in the pons, affects the nucleus of a nerve, the peripheral distribution of that nerve is cut off from its nutritive centre, and it undergoes the usual changes which lead to the reaction of degeneration, so that, in some unusual forms of paralysis, the two kinds of reaction, normal and degenerative, may be present in different sets of muscles.

DIAGNOSIS.—The apoplectic form attack due to hemorrhage or occlusion of the cerebral arteries is to be distinguished from narcotic poisoning, especially by opium or alcohol, or by coal gas; epilepsy with its succeeding coma; uræmia (so called) or cerebral symptoms connected with renal disease; comatose form of pernicious intermittent; diabetic coma; sun-stroke; hysteria, and various other forms of intracranial disease, especially meningitis; concussion and compression of the brain, which often

involve hemorrhage; the apoplectic form attacks of intracranial syphilis and of general paralysis, as well as the congestive attacks (*coup de sang*, rush of blood to the head).

The first of these distinctions is, in a practical point of view, among the most important and often the most difficult, so that distinguished authorities insist not only on the difficulty, but impossibility, of making a positive diagnosis in every case. The physician who is most familiar with all the different conditions which may cause coma is least likely to jump at a conclusion.

Persons are constantly being picked up in the street partially or wholly unconscious, or found alone in a room without history and away from friends. The physician must then form his opinion from the present condition, which without a history may be very obscure, though with one it might present no difficulty. An empty laudanum- or whiskey-bottle may be of assistance, the former of much, but the latter of less. The smell of the breath may give a hint, but even if the smell of alcohol be detected, considering the widespread belief in its virtues as a panacea, it may be as well the result of amateur therapeutic attempts as an indication of the cause of the attack. Neither does it follow that because a man has been or is drunk he has no organic disease in his brain. Alcohol should simply make us more careful to examine for possible injuries. In regard to both these poisons—and in fact in the diagnosis of these conditions generally—the first thing to be sought for, after assuring one's self that the patient can breathe and is likely to do so for a few minutes, is some evidence of hemiplegia. This is not so easy as it might appear at first sight, since the general muscular relaxation may be so complete as to cover up local manifestations. The face, however, may show inequality in its lines or one cheek flap more loosely than the other. The patient is not likely to undertake voluntary movements at the request of the physician, but he may make semi-voluntary ones if annoyed by the examination. The flaccidity of the arms may vary. Irregularity of the pupils is a piece of evidence to be received with some caution, as it may be habitual or the result of disease in the eye. Conjugate deviation of the eyes and head is a form of paralysis, or sometimes of unilateral spasm, which when present is of great significance. In opium-poisoning—and to a less extent in alcoholic coma—the pupils are much contracted, while they are not always so in apoplexy. Respiration is usually much more rapid in apoplexy than in opium-poisoning, and this, in the absence of distinct signs of hemiplegia, would be one of the most important means of distinction. The pulse is more nearly normal in frequency, while that of opium is either slow and hard or more often frequent and feeble.

After the time for the initial depression has passed, rapidly-rising temperature is very strong evidence in favor of apoplexy. If the patient be only partially unconscious and able to protest against being handled, to make some short answers, or even be inclined to be combative, this is not to be taken as evidence of alcohol. Hemiplegia may then be noticed. This condition of excitement may be observed in the early stage of an apoplectic attack before it deepens into coma. Unfortunately, when the lesion is situated in certain portions of the brain, as in the extremities of either the frontal or occipital lobes, there may be no paralysis, but then also there is less likelihood of the extreme symptoms we are supposing

to be present. In the cerebellum, however, the symptoms may be very severe without hemiplegia, and the diagnosis correspondingly difficult. Vomiting, not caused by the presence of large quantities of food or liquor, and persisting after the stomach is once emptied, would be of some value in this case, but it would often be necessary to wait for a diagnosis. Cerebellar hemorrhage is, however, a very rare accident, and cerebellar embolism sufficiently large to cause apoplecticiform symptoms still more so. A limited lesion in the pons may cause gradually-increasing stupor without distinct paralysis.

Chloroform, especially if swallowed, and chloral might possibly give rise to difficulties in the way of diagnosis, and would have to be distinguished on the same general principles as alcohol and opium.

The poisonous gases arising from burning coal, consisting chiefly of carbonic oxide and dioxide, or illuminating gas, consisting of carburetted hydrogen with a little carbonic oxide, cause unconsciousness, coma, and sometimes convulsions and vomiting. In case of a person found unconscious in bed the possibility of poisoning by one of these should not be lost sight of, nor, on the contrary, assumed to be a cause without investigation. A case has been reported where, after acute poisoning by coal gas, there occurred, presumably as the result of local anæmia, alternate paralysis, convulsions, and aphasia.¹ The new water-gas process is said to furnish a product considerably richer in the poisonous carbonic oxide than that now most in use.

The stupor succeeding an epileptic convulsion resembles apoplexy, and the fact that cerebral hemorrhage may be accompanied by some convulsions increases the possible similarity, but it requires only a short time for epilepsy to make itself manifest, either by a renewal of the convulsions or a rapid recovery without paralysis. According to Trousseau, however, many attacks of so-called congestion of the brain are really epilepsy. Puerperal eclampsia comes under the same head, but when convulsions are violent they may give rise to actual hemorrhage. Unilateral epileptiform convulsions are likely to be dependent on organic disease of the brain, usually not of the kind at present under consideration, but more frequently of a tumor.

Among the cerebral symptoms connected with renal disease, and not involving organic change in the brain, may be found unconsciousness, deep coma, and convulsions. It is obvious that the presence of a few hyaline casts and a little albumen will not decide the matter, since these may be present from many causes, and especially the changes in the circulation accompanying apoplexy. Neither will the most indubitable evidence of Bright's disease, such as dropsy, hypertrophy of the heart, rigid arteries, with fatty and waxy casts in the urine, do so, for, as we have already seen, not only is there nothing in the presence of nephritis to exclude apoplexy, but the very form, the interstitial, which, from the supervention of coma not preceded by other very severe symptoms, most nearly counterfeits apoplexy, is also the most likely to give rise to actual cerebral hemorrhage. The extreme and frequent cephalalgia which is so distressing a symptom in cases where there is no cerebral lesion may also be the precursors of hemorrhage.

If we have a history, the gradual onset of the symptoms, deepening

¹ *Boston Med. and Surg. Journal*, Nov. 26, 1885.

unconsciousness without any paralytic or unilateral symptoms, especially if accompanied by a diminution in the amount of urine or contained urea or a marked change in the character of the casts, renders it probable that we are dealing with so-called uræmia alone. In the absence of history hemiplegia must be the chief dependence, but it would not be difficult to imagine a case of embolism of the basilar artery with softening of the pons which would defy a positive diagnosis.

Pernicious intermittent fever appears in a so-called comatose form, which, if it were to be accompanied, as in a case related by Bemiss in the second volume of this work, by paralysis of one arm, might present difficulties of diagnosis. If it were known that the attack had been only of short duration, the elevation of temperature would, as in the case of sunstroke, decide in favor of the fever, but if it had lasted some hours, this symptom would be of no value, as the temperature may rise to an equal height in apoplexy.

Diabetic coma is a much less common affection than apoplexy. The peculiar odor (aceton) of the breath, if present—which is not always the case—might be diagnostic. The peculiar long and deep respirations would awaken suspicion which would be confirmed by an examination of the urine.

Sunstroke, with its sudden onset, complete unconsciousness, and rapidly rising temperature, may present a very close resemblance for a while to apoplexy, and in fact has been known as heat apoplexy. Age, temperature, and surroundings would give strong probabilities one way or the other, and if the temperature of the patient were at first below the normal and did not rise for an hour or two, it would certainly not be sunstroke and would be apoplexy, while if the temperature were very high a few minutes after the patient had been observed to cease work or become unconscious, the evidence in favor of sunstroke would be equally strong.

It might appear that hysteria need hardly enter into our consideration, and could hardly be mistaken for apoplexy, but most experienced physicians could relate instances where serious organic disease has been made light of under the name of hysteria, and many inexperienced ones could tell of the opposite and safer mistake. An occasional case of deep coma presents itself where, although the age and sex of the patient awaken strong suspicion, we cannot at once be sure that no organic lesion is present; and if, in addition, the patient should be affected with hemiplegia—a combination which, although rare, is by no means beyond the limits attainable by this perplexing disease—an immediate positive diagnosis would be difficult. Absence of facial paralysis, which might be made manifest by some irritation like pinching or an attempt to raise the eyelids, would be of much value under these circumstances. The hysterical physiognomy might be well enough marked to be almost conclusive by itself. The urine and feces are not likely to be passed involuntarily in hysteria, as they are in apoplexy.

Injuries to the head should be carefully looked for in any case with unknown history. Actual fracture, which perhaps leads to no depression of bone, may give rise to hemorrhage, probably meningeal, which will cause the usual symptoms, and a shock which is not accompanied by fracture may cause considerable laceration of the brain with consequent hemorrhage. In the latter case, however, unless the brain be already

predisposed by arterial disease, the laceration and hemorrhage will not be extreme and the symptoms will be those of concussion. The diagnosis can hardly be said to be between hemorrhage and concussion, but whether the hemorrhage be the result of concussion—a question which can hardly be answered without the history and observation of the further progress. Cuts and bruises may result from a fall caused by the shock, and pericranial ecchymoses may result from cerebral hemorrhage through the vaso-motor system without the intervention of accident.

Rapid meningitis of the vertex, with predominance of the effusion upon one side, may closely simulate compression from hemorrhage. At the base, by the time it has become severe enough to cause unconsciousness, it is likely to have affected the ocular muscles, and perhaps given rise to other paralyses less regular in their distribution than the ordinary hemiplegia. Ophthalmoscopic examination would be of value in these cases if—which is not very likely to happen—there is no history. The temperature in meningitis is more likely to be irregular and less rapidly and uniformly rising than in a severe hemorrhage or occlusion. In many cases emaciation, dry tongue, and constipation with sunken abdomen will testify to a previous illness, while after a few hours' observation the progress of the case will make the diagnosis more clear.

In differentiating cerebral hemorrhage or ordinary embolism from the apoplectiform attacks met with in syphilitic intracranial disease, it is rather a question of etiology than of diagnosis in the narrower sense, since unconsciousness and hemiplegia coming on with syphilis are often dependent upon a condition of the vessels closely resembling that which gives rise to the ordinary forms; that is, we are dealing in either case with an endarteritis which has furnished the basis for the deposit of a thrombus, and the question is, Of what nature is the endarteritis? It is obvious that this is only to be answered by a knowledge of the history, not necessarily of a primary or secondary lesion, but of previous disease. The syphilitic taint may often be suspected from the irregularity of the paralysis, the cranial nerves, for instance—especially the ocular—being much more frequently affected in syphilitic than in ordinary hemiplegia. After partial recovery or amendment the characteristics of irregularity and changeableness will be more strongly marked.

The pathology of hemiplegia and apoplectiform attacks, often transitory, in the course of general paralysis is not certain, but it is probable that they are due to sudden congestions of regions of some extent already in a condition of chronic periencephalitis or to cerebral oedema. The question of the existence of the previous disease can only be settled after the return of the patient to consciousness. Usually, these attacks are not of the severest kind, and are not necessarily attended with loss of consciousness, which, when it occurs, is usually not of long duration. An apoplectiform attack occurring in a young or middle-aged person who has neither cardiac nor renal disease, rapidly recovered from or changing its character, should awaken strong suspicions of either general paralysis or syphilis, or both.

The characteristic of the so-called congestion of the brain, or coup de sang, is a close resemblance to ordinary apoplexy, but without hemiplegia and usually with a rapid and complete recovery. A diagnosis from apoplexy cannot be made at once, except so far as hemiplegia can be shown to be either distinctly present or absent.

As has already been stated, the doctrine of the dependence of real apoplectic attacks upon cerebral congestion alone has been vigorously combated by distinguished clinicians; and certainly the diagnosis of congestive (and the same may be stated even more strongly of so-called serous) apoplexy should never be made until after the rigorous exclusion of every other possibility.

After the severer apoplectic symptoms have passed off, and in cases where they have never been present, the diagnosis, so far as most of the conditions mentioned above is concerned, is divested of many of its difficulties when we are dealing with cases of well-marked hemiplegia. The chief points left are the distinctions from the apoplectic attacks of general paralysis, cerebral syphilis, and cerebral tumor, which are to be made as every other possibility.

Slighter and more localized paralyses, such as may occur with limited lesion of the pons or where a hemorrhage having a large focus in the substance has escaped under the membranes and presses on some cranial nerve, would present more difficulties. Paralyses which are very limited, and at the same time complete, are not likely to arise from hemorrhage or embolism, though it is possible that they may do so, but the diagnosis is to be considered rather under the head of local palsies than of cerebral disease. General rules cannot be laid down for slighter cases, and each case must be diagnosticated for itself. In many of them the electrical diagnosis would be of great value and often decisive.

Hysteria remains, as always, ready to counterfeit anything, but the following case shows that the error is not always on that side: F. S——, a young woman, was brought to the hospital, apparently conscious and understanding what was going on, but unable or unwilling to speak or to protrude her tongue. There was no history except that she had probably been in the same condition for thirty-six hours. There was paralysis of the right side, including the face, and marked anæsthesia of the same side, quite distinctly limited at the median line; temperature 97.8°, pulse 60, respiration 20. The next day she seemed perfectly conscious, but did not speak. The faradic brush to her face caused loud outcries, and the facial paralysis was diminished. This condition remained nearly the same, the patient appearing half conscious, but passing urine in bed. Four days later there was marked diminution of sensation and motion on the left (previously sound) side, as well as the right. The note two days later was, "Shuts and opens her eyes when told, and moves eyeballs in every direction, but there is apparently no voluntary motion except slight of the head. Incontinence of urine and feces." A week later the temperature rose to 100.4°, pulse 140, and she died. The autopsy showed red adherent thrombus in the left carotid, extending into the cerebrals, with extensive anæmic necrosis of the cortex and a part of the corpus striatum. On the right there was a grayish thrombus and softening of the cortex, while the great ganglia were not affected.

A woman of thirty-two had repeated attacks of loss of consciousness and somnolence lasting several hours, but leaving her apparently well. The case was considered hysteria, but the patient died in a similar attack. Degeneration of the cerebral arteries and hemorrhage were found.¹

Post-paralytic chorea might present difficulties of diagnosis from hys-

¹ Christian, *Centralblatt f. d. Med. Wiss.*, 1873, 864.

teria or malingering, though the difficulty is quite as likely to be on the other side.

The diagnosis, however, is not complete until the lesion is located with some precision and its nature determined, although it must be confessed that when we have got as far as this the diagnosis in most cases is of more interest to the physician than to anybody else, except to a slight extent for prognosis, so that the event may be anticipated by a few hours. As to the localization of the lesion, recent experiments and observations, involving not only lesions of the kind we are here discussing, but tumors and injuries as well, permit this to be done with a reasonable degree of certainty. The general article on Cerebral Localization may be referred to by the reader for the minuter points, but certain groups of symptoms may be indicated here which are available to some extent before the complete return of the patient to consciousness.

In the vast majority of cases the lesion is situated upon the side of the brain opposite to the paralysis, except in some instances of cerebellar lesion, while in the peculiar form known as alternate paralysis due to lesion of the pons it is on the opposite side to the paralysis of the limbs and on the same side with the facial. It should be distinctly stated, however, that there are exceptions which are inexplicable on the present basis of cerebral anatomy. It is well known that only a part of the motor tracts cross to the other side of the cord at the decussation, and also that the proportion between the fibres which do and those which do not cross is a variable one. It has been suggested, in some cases of the kind mentioned, that all the motor fibres, instead of only a minority, as is usual, pass down on the same side of the cord as their origin. This has not been demonstrated. The number of such cases are so small that it need not be taken into account in diagnosis, and if the practitioner should make a mistake on this basis, he will have the recompense of knowing that he has assisted in a very rare case, in which it was next to impossible for him to be right. This condition is said to be found more frequently when the brain lesion and paralysis are on the right side.

Severe pain in the head, followed by gradually but rapidly deepening coma and paralysis of one side, becoming more and more complete, probably means a hemorrhage into or just outside of the great ganglia and involving a large extent of one of the hemispheres.

If there have been moderate loss of power or complete paralysis lasting some hours, with, afterward, sudden loss of consciousness and general muscular relaxation, with sudden fall, soon followed by rapid rise, of temperature, it is very probable that a hemorrhage has broken through into the ventricles or beneath the membranes, and is still going on.

Rapidly-deepening unconsciousness, with general muscular relaxation and gradual manifestations of more paralysis on one side than the other, may come from meningeal hemorrhage.

Very sudden and complete hemiplegia without prodromata, with deep unconsciousness coming on rapidly or suddenly, but a little after the paralysis, is likely to denote the occlusion of the middle (and perhaps anterior cerebral) artery of the opposite side at a point sufficiently low down to produce extensive anæmia of the motor centres along the fissure of Rolando as well as the underlying great ganglia.

Aphasia with hemiplegia, often without the slightest disturbance of consciousness, is in a considerable proportion of cases connected with a lesion of the third left frontal convolution, and in a somewhat larger proportion with the frontal lobes in general and the island of Reil. This lesion is in a great majority of cases occlusion of the artery. Difficulty of speech, connected with difficulty of swallowing and associated with a certain amount of amnesic aphasia, has been found with lesions of the pons. As aphasia, however, may occur without any fatal lesions at all, it is not certain in all these cases that the obvious lesion of the pons is a direct cause of all the symptoms.

Word-blindness is associated, according to a case reported by Skworzoff and a few others,¹ with a lesion of the angular gyrus, pli courbe (P_2 of Ecker), and word-deafness with a lesion of the first temporal (T_1). These localizations agree with those experimentally determined.

Conjugate deviation is of importance as a localizing symptom, chiefly because it may be manifest when other signs of hemiplegia are difficult to elicit. I do not find it mentioned in twenty-seven cases of cerebellar hemorrhage not included in the table of Hillairet, but it is not infrequent with lesions of the pons; and when the lesion is in the lower third, it is in the opposite direction to that described as usual with lesions of the hemispheres.

Hemianæsthesia involving the organs of special sense, unilateral amblyopia, and color-blindness is supposed to be connected with a lesion of the posterior third of the internal capsule, or the thalamus in its immediate vicinity, sometimes also with a lesion of the pons. Bilateral hemiopia—blindness of the corresponding sides of both eyes—is apt to be connected with a lesion of the occipital lobe of the opposite side. Rendu and Gombault remark that hemianæsthesia of the limbs and face may be met with in certain lesions of the cerebral peduncles, but in this case the higher special senses (sight, smell) remain unaltered. Hemichorea points to the same localization as the more complete hemianæsthesia.

Alternate hemiplegia is due to a lesion of the pons upon the side of the facial paralysis, and opposed to the paralysis of the limbs and in the posterior or lower half. Care should be taken not to confound this with the accidental addition of a facial paralysis to a hemiplegia of the other side.

Irregular ocular paralyses are very likely to be due to lesion of the same region. In some of these forms an investigation of the electrical condition with reference to the presence of the degeneration reaction may be of great assistance.

With extensive lesions profound coma and relaxation without distinct hemiplegia are likely to be due to injury of the pons. A thrombus of the basilar artery may lead not only to rapid, but even to sudden, death. A phthisical patient died suddenly while eating his supper, and a thrombosis of the basilar artery, with softening of the pons, was found. Of course the lesion must have been of older date.² Bright³ thought that when symptoms pointing to disease of the intracranial vessels were present the diagnosis was confirmed, and the location of the lesion in the vertebral arteries rendered highly probable, by a persistent occipital

¹ West, *Brit. Med. Journ.*, June 20, 1885.

² *Bull. de Société anatomique*, 1875.

³ *Guy's Hospital Reports*, 1836.

pain. In the upper part of one side of the pons the hemiplegia is not alternate, but of the ordinary form.

Any extensive lesion of the medulla must cause death so rapidly as almost to defy diagnosis, but such rarely occurs. The very rapid termination of certain cases of hemorrhage into the pons and cerebellum is due to the escape of blood into the fourth ventricle and consequent compression of the medulla.

Lesions of the lower and inner part of the crus are indicated by paralysis of the third nerve of the same, and hemiplegia of the opposite side of the body.

Obstinate vomiting, severe occipital headache, and vertigo, with or without a distinct paralysis, render a cerebellar hemorrhage probable, though no one of these symptoms is necessarily present or pathognomonic. Vomiting is very much more common with cerebellar hemorrhage than with cerebral. Ocular symptoms, like nystagmus and strabismus, accompany cerebellar lesions.

A difference in the temperature of the paralyzed and non-paralyzed sides, when amounting to one and a half to two degrees and lasting for a long time, is thought by Bastian to indicate a lesion of the optic thalamus.

The severe and rapid sloughing of the nates sometimes seen in rapidly-fatal cases is stated by Joffroy to be most frequently connected with a lesion of the occipital lobes.¹

It is plain, from what has been said about the symptoms of the different kinds of lesion, that a distinction may be often very difficult, and at times impossible; and in this connection all observers are agreed, the apoplectiform shock, the hemiplegia, and the slighter attacks being common to two or three lesions. The diagnosis can be made, if at all, only by the consideration of more or less secondary symptoms and the careful weighing of the various probabilities against each other. Most of the statements of differences of symptoms are only relatively true.

A glance at the nature of the pathological processes involved may serve to systematize our observations.

Hemorrhage is a sudden accident, with a severity increasing as the amount of effusion increases. It has been prepared for by arterial disease, but this disease is one which may have no previous symptoms. It is at first an irritative lesion.

Embolism is a sudden attack which may be as severe at first as even a few minutes afterward. It is also prepared for by disease of other organs, which may or may not have symptoms according to the origin of the embolus. As embolism affects especially those regions where the motor centres are spread out, while hemorrhage attacks more frequently the conductors in their locality of concentration, the paralyses arising from the former affection may be more narrowly limited.

Thrombosis is a gradual affection, which may, however, manifest itself suddenly, from the obstruction reaching a certain point and suddenly cutting off the supply of blood. This also depends on previous disease which has more or less definite symptoms.

The severity of the attack is not conclusive, though the completely developed apoplectic attack is more frequent with hemorrhage. Rapidly

¹ *Arch. gén.*, Jan., 1876.

increasing severity, especially if there have been prodromata, is in favor of hemorrhage. Convulsions, early rigidity, and conjugate deviation of the eyes of the spastic form, especially if afterward becoming paralytic, are strongly in favor of hemorrhage, and the latter possibly conclusive. Hughlings-Jackson states that he cannot call to mind a single case of hemiplegia from clot in a young person in which there were not convulsions.

Sudden paralysis without cerebral prodromata, unconsciousness, or pain can hardly be anything else than embolism; but, unfortunately for diagnosis, the initial paralysis from the embolus may be slight, and afterward added to by the secondary thrombus, so as to put on the appearance of more gradual approach.

Aphasia, and especially aphasia associated with but little or no paralysis, is very much more frequent with embolism than with hemorrhage.

The temperature, if we could always have it recorded from the very beginning, might be of value, as the initial depression is said to be less with embolism than with hemorrhage, but Bourneville¹, who lays down this rule, gives so many cases where no great depression occurred with hemorrhage that it cannot be considered decisive. Besides this, we are not likely to get the information at the time it is of the most value.

Etiological information may have a very practical bearing on this part of the diagnosis. Age gives a slight amount of predominance to the chances of hemorrhage, and youth a considerably greater one to the chances of embolism. Interstitial nephritis with hypertrophy of the heart, after the exclusion of uræmia, gives a strong probability in favor of hemorrhage. Valvular disease of the heart, especially a more or less recent endocarditis, is strongly in favor of embolism. A feeble action of the heart, slow and irregular pulse, are more likely to be connected with thrombosis.

Atheroma and calcification, as detected by examination of the visible and tangible arteries like the radial and temporal, is a condition either connected with the periarteritis aneurysmatica which gives rise to hemorrhage, or one which furnishes a suitable spot for the deposition of a thrombus; hence it can be considered conclusive in neither direction.

Arcus senilis, even of the fatty variety, can only show some probability of arterial degeneration.

Retinal hemorrhage, if present, favors the presence of a similar cerebral lesion, but nothing can be argued from its absence. Landesberg² has reported a case in which embolism of the central artery of the retina, easily diagnosticated by the ophthalmoscope, preceded by a few days a similar accident in the middle cerebral; and Gowers³ another in which the two arteries were occluded simultaneously.

If a sudden paralysis arises in connection with a septic process, we may diagnosticate an embolus with a good deal of confidence; but it is not unusual to meet with small abscesses of septic origin which have given rise to no special symptoms whatever, or only to such as are covered up by the more general constitutional ones.

PROGNOSIS.—The prognosis *quoad vitam* of cases of apoplexy still in the unconscious state is based upon the general severity of the symptoms

¹ *Op. cit.*

³ *Lancet*, Dec. 4, 1875.

² *Archiv für Ophthalmologie*, xv. p. 214.

as indicated by general muscular relaxation, or, at a later period, the extent of the paralysis, the amount of affection of the heart and respiration, and especially the progress during the first few hours. Too much weight should not be placed upon a very slight improvement at first, since this often takes place in cases soon to prove fatal.

Stertorous respiration with perfect tolerance of mucus in the throat, absolute loss of the reflexes, and immobility of the pupils signifies profound depression of the organic nervous centres, and is consequently of unfavorable augury.

The temperature is a valuable guide. In proportion as it moves steadily and rapidly upward is the prospect of an early fatal result. A person may die during the initial fall of temperature, but in such a case there would hardly be need of a prognosis.

In general, the prognosis from hemorrhage, supposing the symptoms to increase in severity for an hour or two, is worse than that from occlusion.

Age, aside from the fact that it makes hemorrhage more probable than occlusion, is not of great importance in prognosis, certainly not out of proportion to the general impairment of vigor in advanced years.

A renewal of the hemorrhage within a few hours cannot be predicted. It may be indicated by another fall of the temperature, which, if it have been previously on the rise, renders, of course, the prognosis more unfavorable.

After recovery, more or less complete, from the apoplectic condition the prognosis is favorable, for a time at least, except so far as one attack may be looked upon as the forerunner of another. After the temperature has reached a sort of standstill in the neighborhood of normal, its subsequent rise will furnish among the earliest indications of an approaching fatal termination.

Urinary trouble, retention, incontinence, or, much more, cystitis, is to be looked upon as a complication which materially increases the gravity of the situation. Bed-sores or abrasions may be placed in the same class, except that the early and extensive sloughing of the nates described by Charcot is of almost absolutely fatal significance.

After some days or weeks the progress of the paralysis either toward better or worse may be exceedingly slow, and as time goes on the danger to be apprehended from the latter becomes less and less.

When paralysis takes place in young persons and the primary attack is recovered from, it is doubtful if the chances of a long life are materially diminished. A case has already been referred to in this article where the consequences of a cerebral hemorrhage occurring in infancy were found in a woman of eighty-three in the form of atrophied limbs and an old pigmentary deposit in the brain.

Hemorrhage into the cerebellum would appear, from statistics, to be exceedingly fatal, but it is certain from old lesions occasionally found that it is not absolutely so, and its apparent severity is partly caused by the fact that it is very seldom diagnosticated except at the autopsy.

The prognosis *quoad restitutionem ad integrum* cannot be made to advantage at an early period. After the immediate danger to life has passed it is safe to say, if pressed for an answer, that it is highly probable that some recovery from paralysis may take place, but that it is

highly improbable that it will be absolutely complete, and just how far improvement may go it is impossible to predict with accuracy at first. Time must be given, in the first place, for pressure to subside, compressed nerve-fibres to be restored, and for such collateral circulation as is possible to be established. How recovery takes place beyond this it is not easy to say. It is hardly supposable that any considerable portion of nerve-structure is renewed. A certain amount of substitution, by which one part of the brain takes up the functions of another part, is among the most plausible suppositions; but how this is accomplished it is hardly worth while in the present condition of cerebral physiology to speculate.

Practically, it may be said that physicians are apt to consider a paralysis absolute at too early a period, while the patient and his friends continue to hope for a complete restoration after it is evident that no really useful increase of power is to be looked for. Weeks, and even months, may elapse before any return of motion can be perceived in cases which are really susceptible of considerable improvement, and a year most certainly does not cover the limit of the time during which it may go on.

The most unfavorable symptom, one which probably precludes all hope of useful recovery in the limbs affected, is contracture, heralded for a time by increase of the deep reflexes, indicating degeneration of the motor tract in the white substance of the cord. Until this begins, certainly for many weeks, the patient may be fairly encouraged that some improvement is possible, though after a few weeks the chances diminish as time goes on. In the rare cases where the muscles undergo rapid wasting the prognosis is, if possible, worse still. The localization of the lesion after the early symptoms are passed does not greatly influence the prognosis.

A rapid recovery taking place in either hand or foot, and especially of the hand first, without corresponding improvement in the other limb, is of unfavorable import for the latter, and, in general, the prognosis is not exactly the same for both limbs involved. In the rare cases of hemiplegia from acute brain disease occurring in children the nutritive disturbances in the form of arrest of growth should be taken into the account in prognosis, since the result may be nearly or quite the same as is found after infantile paralysis from disease of the cord.

In regard to the slighter forms of paralysis, it may be said that the less extensive the original paralysis is, and the sooner improvement begins, the better is the chance of complete recovery.

TREATMENT, INCLUDING PROPHYLAXIS.—Cerebral Hemorrhage.—As the condition upon which the usual form of cerebral hemorrhage depends is so frequently aneurism, and probably nearly always some arterial disease, the prophylaxis must evidently consist in such a mode of life as will least tend to this degeneration, or at least put it off as long as possible. This, of course, means the avoidance of all the special causes described under the head of Etiology. It is a disease of old age, but in a pathological sense old age begins in different persons after a different number of years. Fortunately for rules of hygiene, there is little that is contradictory in those to be given for most chronic and degenerative diseases. Abstinence from alcohol, as an agent tending at once to paralysis and dilatation of the vessels, is one of the most important rules and insisted upon by nearly all writers. The avoidance of over-eating, and especially of

nitrogenous food as tending to lithæmia—a generally recognized cause of arterial degeneration—is perhaps the next. Over-eating is of course to be understood as a relative term, and to be estimated with reference to the habits of exercise of each person. Practically, it will be decided by its effects; that is, if careful thought be given to the matter and the statements of the gourmand as to his immunity from all risk of trouble are not accepted as of scientific value. On the other hand, insufficient food, producing anæmia, may be a factor in arterial degeneration. Keeping one's self free from anxiety, and getting through the world with as little experience of its roughnesses as possible, might be, properly enough, added in a purely theoretical point of view if any one ever asked a physician's advice in youth as to avoidance of the diseases of age, or if any one could or would profit by this advice if it were given.

Intellectual pursuits have been credited with a special tendency to apoplexy, but there is no good reason to suppose that healthy exercise of the mind is otherwise than beneficial to its organ. Hurry, over-anxiety, and mental tension are undoubtedly potent factors in general breakdown, but do not necessarily lead to this form. They are certainly not to be found by preference in those persons who lead an intellectual life.

Syphilis, one of the most important of the causes of organic cerebral disease, and that too in the form of thrombosis, is not specially concerned in the etiology of the forms here under consideration.

If symptoms have occurred that justify the apprehension of apoplexy or paralysis, such as frequent headaches in an elderly person, hemiopia, temporary aphasia, or slight and temporary paralyses, or if one have reached a time of life at which the risk of cerebral hemorrhage becomes considerable, a stricter attention to the rules laid down above, and even to some to which but little heed would be given in health, is not out of place. A certain amount of limitation of diet, moderate and regular but not violent exercise, clothing suitable to the season, and especially warm enough in winter, and, most of all, rest if the patient be doing wearing and anxious work, should be enjoined. Finally, it should be said that the real prophylaxis of cerebral hemorrhage is to be begun in early life.

Among the exciting causes to be avoided are those which obstruct the flow of blood from the head, like tight clothing around the neck. Increase of the arterial pressure by severe or prolonged muscular effort, as in lifting or straining at stool, is to be avoided, as well as violent fits of passion. The condition of the bowels should be regulated by mild laxatives.

When the apoplectic attack has actually occurred, treatment, though apparently urgently demanded, is really of little avail. If a patient is about to die in an hour or two from rapidly increasing pressure, nothing within the reach of medical science can stop him.

There is one danger, however, easily avoided, but probably often overlooked. A patient may die from suffocation. The stertor is often a result of the paralysis of the tongue and palate and of the amount of fluids collecting in the pharynx from the almost invariable position of the patient on his back; that is, if he have been seen by some one who wished to do something for him, but did not know what. Insensibility and paralysis combine to favor this accumulation, which obstructs the respiration, and which may find its way to the lungs, together with brandy and milk, and set up an inhalation-pneumonia. The simple and obvious thing

to do is to place the patient sufficiently on his side, with the face somewhat downward, for the tongue and palate and secretions to fall forward, instead of backward into the pharynx. Swabbing out the pharynx may be of some use, but cannot be so thorough. An easy position and proper ventilation should be secured in all cases of unconsciousness, even at the risk of treating a drunkard with undue consideration. Police-stations should be provided with rooms where these conditions can be secured, and the necessity avoided of placing persons picked up in the streets in the narrow, close, and perhaps distant cells provided for malefactors. The writer recalls the cases of two young men—one who had been drinking some time before, and the second roaring drunk—who were locked up in a suburban station-house in the evening, and found the next morning—one dying and the other dead.

Artificial respiration may be used to prolong life in some cases until the nervous centres have sufficiently recovered their functions to carry on the process without assistance. The condition of the bladder should be ascertained, and the urine drawn if necessary, though it is more frequently passed involuntarily.

Although it is manifestly impossible to remove the clot from the interior of the brain, it may appear that the further flow of blood may be stopped and the amount of damage done limited. For this purpose two remedies are proposed—namely, bleeding and purgatives. Both of these act to diminish arterial pressure, which is forcing the blood out of the rupture. Though the treatment seems reasonable, it would not be difficult to imagine a condition where sudden and premature diminution of pressure in the brain, which of course exists outside of the arteries as well as inside, would tend to set going again the flow which has ceased from the very force of the pressure it itself exerts, very much as if a tampon were prematurely removed from a bleeding cavity elsewhere. As the conditions are somewhat complicated, and at the same time only remotely to be estimated, it is safer to be guided by experience in the use of these remedies than by abstract reasoning. In some of the cases of temporary aphasia, as notably that of Rostan narrated by Trousseau, bleeding seems to have given immediate relief. Trousseau, however, is no advocate of that method of treatment. Most modern authors speak of venesection as to be used in cases where the pulse is strong and full and the face red, but not to be thought of in the opposite class. When a case presents the appearances of plethora and an attack has come on suddenly, the loss of a few ounces of blood can certainly do no harm. Other forms of bleeding, such as cups and leeches, are not rapid enough to be of great value, though a large number of leeches about the head might be useful. Some French writers recommend leeches to the anus as revulsives. Cathartics may be more freely used, although they should be given cautiously when there is any tendency to cardiac depression. It can be clearly shown that a brisk purgative lowers the arterial tension decidedly. In case of cerebral tumor or injury with occasional so-called congestive attacks, the relief afforded by cathartics is very great, and, although the conditions are not exactly parallel, it is fair to assume a similar action in the congestion accompanying cerebral hemorrhage. From one to three drops of croton oil may be placed far back on the tongue or it may be diluted with a neutral oil. An enema may be desirable for the unloading of the bowels,

but has a much less marked effect on the tension of the cerebral circulation.

In most cases of apoplectiform cerebral hemorrhage, and probably in all of simple paralysis, no very active treatment is called for. Measures directed to the prevention of another hemorrhage, and to allay any irritation that may supervene during the changes taking place about the clot and the formation of its capsule, are of the simplest, and consist in keeping the head high and cool, the clothing sufficient for warmth, and offering no obstruction to respiration or circulation, laxatives sufficient to keep the bowels in good order, and a diet not highly nitrogenous, but sufficient and digestible.

That which will tax most severely, however, the care and patience of attendants is the scrupulous and minute attention to cleanliness and pressure over the bony prominences which is necessary when a patient is helpless and unable to control the discharges from the rectum and bladder. Frequent change of clothing, bathing, change of position, and avoidance of wrinkles and roughnesses in the bed may be successful in keeping the patient free from bed-sores. Bathing with alcohol hardens the skin and makes it less susceptible to pressure.

Surgical interference may perhaps be of value in cases where the portion of the clot outside the brain can be clearly demonstrated; and this would apply with special force where the hemorrhage arises from injury.

Trephining and removal of the clot has been done in a few cases of meningeal hemorrhage, though with indifferent success (3 cases—2 deaths, 1 unknown.)¹ An intracerebral clot is obviously a step beyond, though possibly in some cases not absolutely without, the reach of the surgeon.

Treatment of Cerebral Embolism.—The prophylaxis is in the avoidance of such conditions as give rise to the formation of detachable vegetations or clots. Unfortunately, these are numerous, not completely known, and not always avoidable. Arterial disease is to be looked upon as of some importance, but cardiac valvular lesions of much greater, and the causes of these, like rheumatism, scarlet fever, and the puerperal condition, are not always to be escaped. The presence of a detachable piece of fibrin in the pulmonary veins, heart, or aorta being granted, nobody can possibly say what will prevent its being loosened and lodging in one of the cerebral arteries; so that, practically, the prophylaxis of embolism consists in the judicious treatment of acute rheumatism and the other conditions just mentioned. The treatment of the first attack must consist solely in the relief of respiration, bladder, and bowels, if they have not taken care of themselves. Stimulants may be of use for a short time, but there cannot be any call for even the slight amount of depletion suggested for some cases of hemorrhage. Bed-sores are to be looked out for, just as in hemorrhage, and the subsequent treatment conducted on the same principles. As regards the primary lesion, we can do nothing about it either in the way of removal of the embolus or restoration of the necrosed brain-tissue.

Treatment of Cerebral Thrombosis.—There being two factors in this affection, both of which are to a certain extent under control, something may be done toward diminishing the risk of its occurrence. Arterial disease and its prophylaxis have already been spoken of. The other con-

¹ *Med. Press and Circular*, Oct. 11, 1885.

dition which is necessary to the production of thrombosis—namely, an enfeebled circulation—is to some extent under the control of general hygienic rules: a nutritious, not too highly nitrogenous, diet, and especially sufficient exercise and the avoidance of completely sedentary habits. If there is a crisis which predisposes to the formation of coagula in the vessels, it is not known that there is any special treatment, medical or otherwise, which can prevent it. The attack is to be treated exactly on the principles already laid down. Bleeding is about the last thing to be thought of. Stimulants, though they cannot dislodge the clot, may be of use for a time to sustain the heart under the shock. The secretions and the condition of the skin are to be looked out for.

After a few weeks of waiting the patient and his friends not unnaturally feel as if something ought to be done to hasten recovery, and certain measures may be taken, in addition to careful hygiene, which have this object in view. It is very doubtful, however, whether anything really shortens the time necessary for such repair as is possible or diminishes the amount of damage which is to be permanent. As has already been said, improvement may go on slowly for months. In the first place, it is sometimes considered desirable to practise shampooing and massage of the affected muscles in order to keep them in as good a condition of nutrition as possible. This, as well as the regular use of the faradic battery if it be not begun too early, will prevent a certain moderate amount of atrophy, but could not have any influence in those rare cases where rapid wasting depends upon secondary degeneration of the anterior gray columns. It may be doubted, however, whether it is necessary to pay much attention to the condition of the muscles, as they do not ordinarily atrophy to the extent of becoming unsusceptible to the nervous stimulus from the brain so soon as it shall be transmitted to them. Faradism, like many other agencies, such as magnets, metals, pieces of wood, and so forth, is said to produce a transfer of sensibility in cases of hemianæsthesia.

There is no sufficient reason to suppose that any drug is of any value in the restoration of the nervous structure. Iodide of potassium may possibly prove to have some effect as a sorbefacient. Very favorable results have been claimed for ammonia salts in the restoration of aged persons to a nearly complete use of paralyzed limbs. Phosphorus has been spoken of as assisting in repair, but the writer is not aware upon how wide a basis of facts. Silver and gold have been said to counteract the sclerosing myelitis. Strychnia is certainly useless, and probably worse. It may make the paralyzed limbs twitch, but this does just as little good as the involuntary spasmodic movements, which have never been considered desirable, except as awakening in the patient false notions of immediate recovery, and which are frequently a very annoying symptom. The galvanic current has been applied with a view to a sorbefacient or restorative action directly to the brain, or rather to the pericranium.

Something can be done for the comfort of such patients: the rubbing and kneading of the paralyzed limbs, if they do not hasten the recovery of motion, relieve many of the painful and unpleasant feelings. Since we do not know how far one part of the brain may supplement another, attempts at motion after it has once appeared to ever so slight a degree should not be abandoned by the patient. He should walk

with crutches frequently as soon as he can, though not to the point of fatigue.

There is one faculty which seems capable of re-education to some extent: that is of speech in cases of ataxic aphasia, and even in others the attempt should be made to teach the patient the names of things. A very interesting case has been reported by Bristowe¹ of a man who came under his observation after an attack which may have been anterior poliomyelitis with extensive paralysis, able to write well and intelligently, but unable to say anything. By gradual education, first in the sound and formation of letters and afterward of words, he reacquired the use of language. It is obvious that in this case there could have been no loss of memory for the words themselves, but simply the loss of the knowledge of how to produce them. When his speech returned he spoke with his original American accent.

In short, the therapeutics of hemiplegia from arterial disease in the brain is good nursing and attention to symptoms, with a moderate amount of care of the paralyzed muscles.

Capillary Embolism.

It may be remarked, in the first place, that the lesions known by this name are not necessarily strictly capillary, but are situated in the very small arteries. The microscope marks the transition from the larger to these smaller embolisms.

More is known about very small embolisms experimentally than clinically, since they have been produced by the injection of small seeds and insoluble particles of various kinds. Embolisms arising from natural causes and deposited in the minutest arteries may have very similar origin to the larger ones already described, but there are also other conditions which give rise to particles which pass through larger arteries without any disturbance, and are arrested in smaller ones. The softening of thrombi is undoubtedly one source. The same thrombus which, if detached en masse, would block the carotid artery, may, if broken up into a number of minute fragments of fibrin and fat, pass into the ultimate distribution of the cerebrals. The same thing may of course happen if the thrombus have already undergone one transportation.

Cases of localized softening are seen where no cause has been found, except perhaps a thrombus in the heart, which has discharged its softened and puriform contents; and it is probable that the connecting links exist in the form of embolisms so minute as to escape ordinary observation.

The consequences of capillary emboli if they block every minute ramification of an arterial branch must be essentially the same as if the branch itself were stopped; but if only a part are thus affected, the resulting anæmia is not so complete, since the zones of capillary congestion surrounding the part the supply of which is cut off may be sufficient entirely to cover it and make more or less complete compensation. The experimental emboli, in the form of tobacco-seed and other insoluble substances, which have been traced into the brain in considerable numbers,

¹ *Clin. Soc. Trans.*, iii. p. 92.

often give rise to no distinct lesions in the cases where the immediate effects are recovered from.

Among the other sources, ulcerative endocarditis may be mentioned as of special importance, not from the size but the character of detached emboli, which will give rise, not to simple anæmia, nor, on the other hand, to merely negative results, but to septic changes at the place of lodgment.

Aside from these conditions, which are almost the same on a small scale as we find with the large emboli, we have several peculiar substances formed in the body and floating in the blood which lodge in the capillaries of the brain. These are pigment, fat, lime salts, and white corpuscles. Every one of these, however, is much better known anatomically than clinically.

Pigment scales, flakes, granules, or cells containing them, are formed in the course of severe malarial fever, and deposits consisting of this pigment are found in the spleen, liver, kidneys, heart, lungs, and lymphatic glands, as well as the brain and spinal cord. The brain, when a deposit of pigment has taken place, is of a slaty-grayish or chocolate color, which is marked only in the cortical substance, the white being unaffected. The pigment is found in the capillaries, and, according to Frerichs, fibrinous coagula are often associated. Punctiform hemorrhages in the brain have been seen, as well as meningeal hemorrhages, in connection with this degeneration.

The point at which these masses are formed is still a matter of theory. If the liver, as has been supposed, is one of the places of formation, or if they originate in the blood, it is of course easy to see how they reach the brain. If in the spleen, they must pass through the wide portal capillaries before they are arrested in the narrower ones of the brain.

It is by no means certain, however, that pigment reaches the brain in the form of emboli. It is quite as probable that it is found in many organs which undergo repeated congestions from the local destruction of blood-corpuscles and changes in their pigment. The very general deposition seems to point to a process of this kind rather than to a local origin and a distribution through the blood. The punctiform extravasations which may be found with deposits of pigment are also found without it.

Minute particles of fat have been found in cerebral capillaries, but are much less common here than in the lungs. They may be derived from the decomposition of a thrombus, as described above, or they may come from a fractured bone, when, of course, only particles fine enough to pass through the pulmonary capillaries can reach the brain. This form of embolism has an interest in connection with diabetic coma.

Collections of white corpuscles in considerable number have been observed to form an embolus. These cannot be considered to differ very widely in character from the ordinary fibrinous embolus, which contains white corpuscles. It is, however, not certain that such emboli are deposited during life.

Calcareous masses formed from the decomposition of bone have been seen in cerebral arteries.

About the symptomatology of such emboli little is known. An array

of minute emboli from the breaking up of a thrombus in the left auricle, carotid, or even aorta, might possibly so block up large numbers of arterial twigs as to give rise to the ordinary symptoms of embolism; but considering the possibility of the re-establishment of circulation, provided a certain proportion of the minutest vessels escape, complete anæmia of a large tract produced in this way must be rare. It is possible that some of the slighter and more transitory attacks of hemiplegia or of more or less vague cerebral symptoms may be referred to a lesion of this kind, the first action of a large number of emboli being to cause an anæmia, which is compensated for much more rapidly and thoroughly than would be the case if a single considerable vessel were obliterated.

Various attempts have been made to connect definite and peculiar diseases with capillary embolisms. Chorea in particular has been said to depend upon a lesion of this kind, but, although cases have been observed where the symptoms and lesion coexisted, yet they are very far from being the rule, or even from constituting a respectable minority of cases. The lesion of chorea in the great majority of cases is not known, although attention has been directed to this theory long enough to have established its truth.

The same may be said of the relationship between pernicious attacks of intermittent and pigment embolism. There is occasional coexistence, but far from invariable. Cerebral symptoms of the same kind and severity occur without as with the pigment deposit. If pigment embolism is the cause of coma, delirium, etc. in pernicious fever, it is difficult to see why such cases can recover so rapidly, and why no symptoms referable to a localized cerebral lesion are observed after the primary unconsciousness.

Even less proof can be adduced as to any connection between leukæmic embolisms and the cerebral symptoms occurring toward the end of severe acute disease.

Calcareous embolism is a pathological curiosity.

DIAGNOSIS.—In the case of multiple capillary embolism it would be impossible, if it were complete, to distinguish it from a blocking of the main branch.

Cerebral symptoms arising in the course of ulcerative endocarditis might be referred, with a high degree of probability, to an embolus, but if they were distinct enough to be referred to a localized lesion, the probability of a single embolus would be much greater than that of a multitude of capillary ones occluding the same vascular territory. The diagnosis of pigment embolism might be a probable, or at any rate a possible, one if in a long-continued case of paludal fever, where the liver and spleen were enlarged and the skin had the slaty hue marking the deposit of pigment, there were decisive cerebral symptoms. It could not, however, be a positive one.

Fatty embolism might be suspected in a case of diabetic coma, though even if the condition were found it would not establish the relation of causation.

PROGNOSIS AND TREATMENT can hardly have a definite basis in the absence of all ground for a satisfactory diagnosis, but do not differ essentially from those of the larger occlusions.

Thrombosis of the Cerebral Veins and Sinuses.

It has for centuries been known that coagulation of the blood might take place in the sinuses in a way different from the ordinary post-mortem clots, but this was looked upon rather as an anatomical curiosity than as a fact of practical importance and clinical significance, and it is chiefly among observers of the present century that we find a growing knowledge of the conditions under which it occurs and the symptoms to which it gives rise.

Thrombi in the cerebral sinuses are not essentially different from those formed elsewhere, and the reader is referred to the account given in the article on General Pathology for a history of their formation, growth, appearances, and transformations. For our purposes it is sufficient to recall that they may be white, red, or striated, either partly or wholly obstructing, and that they may become degenerated and partly or wholly washed away. The most important distinction of all, however, is that into two classes, of which the first consists of those which are simply depositions of fibrin in a comparatively healthy vessel, and the second of those which are dependent on a phlebitis.

In order that a thrombus may form it is necessary that there should be, in the first place, a special condition of the walls of the veins—not necessarily, however, inflammation, though this is one of the most frequent and probably the most active form; second, a slackening of the blood-current; and, third, perhaps a peculiar state of the blood, though this latter is not certain. A thrombus tends strongly to grow, and when already formed furnishes a most favorable point for the deposition of more fibrin.

The cerebral veins furnish a very suitable place for the coagulation of the blood for several reasons: they are roomy in proportion to the amount of blood they carry; they are tortuous and abundantly anastomosing, so that the current of blood is almost reversed at some points, and can easily stagnate; the veins of the diploë are held open by their bony walls, and the sinuses by their stiff membranous ones, so that they cannot collapse and thus limit the extension of a thrombus once formed.

The sinuses most frequently affected, though none are free from the liability, are the cavernous, superior longitudinal, and lateral.

The results of thrombosis of the sinuses and veins are not equivalent to those of a similar process in the arteries, and they may be said in a general way to be more diffused, as might be expected from the much greater freedom of anastomosis. Limited softening is rarely a consequence of occlusion even of a considerable number of veins, but it has been observed. A large area of softening of one hemisphere, not involving the temporal and occipital lobes, has been seen with thrombosis of the parietal veins¹ (the internal capsule and ganglia were not affected).

Passive congestion in the brain, as elsewhere, although apparently entirely incompatible with the normal function, seems to be able to sustain a low form of structural integrity.

Bleeding may take place from the congested veins behind the obstruction, constituting a distinct form of cerebral hemorrhage which does not depend upon an arteritis, although if miliary aneurisms were present the

¹ *Gaz. des Hôp.*, 1880, 1066.

occurrence of thrombosis would undoubtedly tend to their rupture. The writer, however, is not aware of such a coincidence having been actually observed. Hemorrhages are usually diffuse, composed of or accompanied by a number of small effusions, and situated on or near the surface of the brain or distinctly meningeal. Punctiform hemorrhages are exceedingly common.

Phlebitis of the cerebral veins is very likely to run into meningitis, and the two affections are often so closely united that it is difficult to say which was the first. Œdema is a consequence of venous obstruction in the brain as well as elsewhere, and is seen also around some of the peripheral veins connected with the sinuses.

ETIOLOGY.—Venous thrombosis in the brain depends chiefly on three sets of causes, though it must be admitted that there are a few cases where the origin cannot be distinctly traced and where no previous disease has existed. In the marantic form, occurring chiefly in the very old and in children, as well as in cases of wasting and depressing diseases in adults, a simple thrombosis without inflammation takes place. Two conditions, and sometimes three, are combined here to produce the result—feebleness of the blood-current from a corresponding state of the heart, diseased endothelium of the vessels from defective nutrition, and possibly, where profuse watery discharges have been going on for some time, an increased tendency to coagulation from the inspissation of the blood.

Rilliet and Barthez and Von Dusch¹ give the following tables of ages at which this form of thrombosis has been observed. The observations of the former were made in a children's hospital, and hence do not affect the question of its frequency in later life. Perhaps the rules of admission may account for the absence of cases under one year of age, of which Von Dusch collected several:

| | Rilliet and Barthez. | Von Dusch. | | Rilliet and Barthez. | Von Dusch. |
|------------------------|----------------------|------------|--------------------------------|----------------------|------------|
| Under 1 year | ... | 5 | 10 years | 1 | |
| 2 years | 2 | 1 | 11 " | 1 | |
| 4 " | 4 | 1 | 12 " | | 1 |
| 5 " | 1 | 1 | 14 " | | 1 |
| 6 " | 1 | | Adults (20, 23, unknown) . . . | | 3 |
| 7 " | 1 | | 53 years | | 1 |
| 9 " | 2 | | Aged women | | 2 |

The special diseases in which thrombosis is most likely to be met with are given by Bouchut as follows. The same remark is to be made about these as about those of Rilliet and Barthez. The table is given as convulsions from thrombosis of sinuses:²

| | | | |
|---------------------------------------|---|---|---|
| Chronic enteritis | 5 | Chronic albuminuria | 2 |
| Measles and catarrhal pneumonia . . . | 2 | Whooping cough and pneumonia . . . | 7 |
| Chronic pneumonia | 5 | Scrofula, tubercle of bones, etc. . . . | 1 |
| Phthisis | 8 | Gangrene of mouth | 1 |
| Anasarca without albuminuria | 1 | Diphtheritis | 2 |

Von Dusch gives a number of cases of the same kind, as do many subsequent writers, but without tabulation. Virchow³ reports a case of congenital variola with thrombosis of the sinuses of the dura mater, the superior and inferior cava, and vessels of the cord.

¹ Sydenham Society's translation.
² *Arch.*, 1859, 367.

² *Gazette des Hôpitaux*, 1879.

It is probable that simple anæmia may, here as elsewhere, either alone or with other debilitating influences, lead to thrombosis. Von Dusch remarks that quickly operating and debilitating influences lead to thrombosis, and gives as an instance a case where a puerperal peritonitis, for the cure (?) of which repeated copious abstractions of blood were made during nine days, was supposed to be the cause. The puerperal condition seems to have a tendency in this direction in a way not always to be explained by the ordinary rules of the transmission of emboli or of phlebitis. Although in those reported by Ducrest¹ phlebitis of the pelvic veins existed or was suspected, in the first of these five cases the lesion may have been, so far as the description goes, arterial instead of venous thrombosis; and in the second it is possible that the succession of events was uterine phlebitis (with the addition of a large sacral slough), lobular pneumonia surrounded and traversed by veins which were affected with phlebitis, emboli in the arteries of the cortex, and consequent venous thrombosis. In the third, fourth, and fifth the connection between the uterine phlebitis and the inflammation of the cerebral veins (in two cases meningitis) cannot easily be made out, except by the rather vague assumption of a general tendency to phlebitis, which was shown in one by a similar condition in the vein of the arm where the patient was bled. Empyema has been followed by hemiplegia, cerebral softening, and thrombosis of the lateral sinus. The venous thrombosis in such a case may be secondary.

Marantic thromboses are more likely to occur upon one side, and that the side upon which the patient habitually lies.

The second class of cases embraces those where a simple obstruction, partial or complete, of the current of the blood gives the starting-point for a thrombus in the veins. Such an obstruction may be formed by an embolus, but in the veins this cannot be considered an important factor, although a portion of a thrombus may be detached and become lodged in a narrower vessel or branch farther along. In this way the propagation of thrombosis for a short distance toward the heart may be accounted for.

A tumor or inflammatory exudation may press upon a vein or intrude into it, but most cases of obstruction-thrombosis are traumatic in origin. Thromboses arising in connection with tubercular meningitis may be looked upon as having both an obstructive and marantic cause. In many wounds of the vertex, gunshot and other, the walls of the superior longitudinal sinus are pressed upon by pieces of bone, and sometimes spiculæ have directly penetrated it. This class of injuries is also likely to cause phlebitis without any actual penetration or compression of the sinus, simply as a result of the inflammation of tissues in the neighborhood. The thrombi formed in these cases are not necessarily completely occluding. Where direct injury to the sinus or in its immediate neighborhood gives rise to phlebitis and consequent thrombosis, we have a condition closely resembling that of the third class, where disease of an inflammatory character in the tissues of the skull, neck, or face sets up a phlebitis and thrombosis which are transmitted to the intracranial veins and sinuses.

The most frequent source of this third form of inflammatory thrombosis

¹ *Archives générales*, 1847, p. 1.

is the chronic inflammation of the middle ear with the mastoid cells. The inflammation may be propagated through a carious or necrosed portion of the temporal bone to the petrosal and lateral sinuses, or may, without disease of the bone, be carried by the small veins which open into the sinuses from the petrous and mastoid portion of the temporal in this region. Abscesses in the neck may set up a phlebitis extending up the jugular to the lateral sinuses, to which a meningitis may possibly be added.

Carbuncles about the root of the nose, face, and so far down as the upper lip are very prone to give rise to thrombosis propagated through the ophthalmic vein to the cavernous sinus; and it is probably this risk which gives to carbuncles in this situation their well-known peculiar gravity. The divide or watershed between the regions which drain backward through the cranium and those which are connected with the facial vein below is apparently situated about the level of the mouth, so that a carbuncle of the lower lip is much less dangerous. Billroth, however, gives a case where a carbuncle in this situation was followed rapidly by cerebral symptoms and death, and where a thrombo-phlebitis was not improbable. He mentions another case where a carbuncle upon the side of the head set up an inflammation which travelled along a vein into the cellular tissue of the orbit, and thence through the optic foramen and superior orbital fissure into the skull.

Erysipelas of the scalp apparently causes phlebitis in some cases, and even eczema in the same situation seems to have done so. When the erysipelas is situated about the upper part of the face, the path of transmission is through the ophthalmic vein; but when upon the vertex, it may be propagated through the small veins that penetrate the bone. This result is certainly a rare one in facial erysipelas of the ordinary and superficial kind, which is a notoriously benign disease for one of such apparent severity. It may, however, be more frequent than ordinarily supposed, since cerebral symptoms occasionally appear at a date too late to be accounted for by the fever and too slight to be referred to extensive interference with the cerebral circulation; the lesion to account for which, as they do not cause death, can be only inferred, though it is not unreasonable to suppose it to be a limited thrombosis.

Dowse¹ describes the case of a robust man who fell on the back of his head, but walked home. After a few days he had a severe headache, chill, and total loss of vision. His temperature rose; he had erysipelas and partial coma, but no convulsions. There was thickening of the scalp, but no fracture of the skull and no adhesions of the membranes. The superior longitudinal lateral sinuses were free from thrombi, though there was a roughness about the latter, as if there had been a fibrinous deposit. The cavernous sinuses were almost completely occluded with adherent fibroid masses, and there was hemorrhage in the anterior lobe. There was some degeneration of the brain-structure, but no disease of the arteries.

Ulcerations in the nasal passages and ozæna have proved starting-points for thrombosis.²

Thrombosis of the jugular veins and corresponding cavernous sinus, with paralytic symptoms, has been observed in the horse.

¹ *Trans. Clin. Soc.*, 1876.

² *Med. Times and Gaz.*, 1878, i. 614.

The symptoms produced by venous thrombosis, as might be supposed from their varying location and extent, and also from the fact of their being almost invariably connected with other diseases having marked and severe symptoms of their own, are not always easy to pick out from among many others, but they are sometimes very well marked and characteristic. A distinction must obviously be made between the symptoms of simple thrombosis depending on interruption of the cerebral circulation and those of phlebitis, which give rise in addition to febrile phenomena common to phlebitis in any of the large veins.

The symptoms which indicate venous obstruction, without reference to its inflammatory or non-inflammatory character, are of two kinds: first, those dependent upon the disturbance of the functions of the brain; and, secondly, those which depend upon congestion and compression of other structures.

According to the locality and completeness of the obstruction we meet with brain symptoms.

In the marantic thrombosis of children these may be very vague, and consist either in restlessness, followed by somnolence and coma, or, most especially, in convulsions. The convulsions may be partial and involve the face only; they may affect one side only, or, what is more usually the case, be general. There is almost always strabismus. There may be conjugate deviation. This latter phenomenon is said by Bouchut to be of no value in children, as it may take place in either direction, from or toward the lesion, but possibly the distinction between the spastic and paralytic forms was not duly observed by him. The condition of the fontanelles is spoken of as yielding and depressed, with the edges of the bones overlapping. They may, however, become again tense in the course of the disease from exudation or hemorrhage taking place. Paralysis is not so marked as in adults, but may be present.

In adults delirium takes the place of convulsions, due to a disturbance of circulation over a considerable area, rather than to a total suppression in a more limited one. Paralyses are not infrequently met with, either in the form of a hemiplegia or more localized. Hemorrhage will naturally be followed by its usual consequences, according to its location. Headache, often very severe, is among the early symptoms.

It is evident that none of these symptoms can be considered highly characteristic. They can only furnish a certain amount of probability in cases where the general course of the disease has made it likely that thrombosis may take place.

There is another set, however, which, when present, offer the strongest kind of confirmation: these are due to the pressure from the veins themselves.

Œdema about the points at which the intracranial circulation is connected with that of the face and neck may give rise to protrusion of the eyeball, conjunctival ecchymoses, swelling of the upper lip, and even of the upper part of the face, which sometimes becomes slightly cyanosed from the congestion. Epistaxis has been noted. Œdema may be noticed about the mastoid process when the thrombosis is situated in the lateral sinuses, but it would be important in many cases to distinguish this from inflammatory œdema directly due to disease of the bone.

Œdema of the optic disc, as shown by obscuration of its outlines, with large and pale vessels, has been observed by Bouchut.

Veins closely connected with those within the cranium may be thrombosed, and felt as hard cords by the finger. This may occur in the facial veins about the orbit, in those around the mastoid, or in the jugulars. On the other hand, if one cavernous sinus is filled with a coagulum which does not go down into the jugular, this vein will naturally be empty or receive only a small amount of blood from other veins.

When the cavernous sinuses are affected, we are likely to have a set of phenomena due to the pressure of the clot upon the nerves which pass through it—*i. e.* the third and fourth, part of the fifth and sixth—with filaments of the sympathetic accompanying the carotid artery. Hence dilatation of the pupil, strabismus, or ptosis, and other ocular paralyses may be the symptoms observed.

It is possible that a headache upon the side of the affected sinus may be due to vascular dilatation from paralysis of the sympathetic, or to a direct pressure upon the first branch of the fifth pair.

DIAGNOSIS.—The diagnosis of venous thrombosis may be almost entirely a conjectural one in those cases where the cerebral symptoms are vague or mixed with others peculiar to the causative disease. Where wasting disease has existed, the patient is much emaciated, and profuse discharges have diminished the fluidity of the blood, the rapid supervention of coma with slight spasms or general convulsions will render it highly probably that thrombosis is taking place. Unilateral symptoms would greatly increase this probability, and if any accessible veins about the head, neck, or face could be definitely distinguished as filled with firm coagula, the diagnosis would approach certainty.

In cases of this kind the only condition likely to put on the appearance of thrombosis is the simple inanition or so-called hydro-encephaloid disease, which comes on in exactly the same sort of cases. Localized phenomena must be the chief point of difference. Fortunately, the distinction is practically not an important one.

In wounds of the vertex affecting the longitudinal sinus the question likely to arise where cerebral symptoms supervene is that of thrombosis or abscess. Here the more definite localization is likely to be upon the side of the abscess, although, as is well known, this may remain latent or nearly so for a considerable time, and in general is much more chronic in its course than thrombosis.

The swelling of the external veins, epistaxis, œdema of the lid, protrusion of the eyeball, with œdema of the optic papilla, with only moderate fever, would favor the diagnosis of thrombosis, while optic neuritis, if present, with chills, would render the abscess more probable. Unless the wound were sufficiently severe to fracture a piece of bone into the sinus, or unless the subsequent inflammation were of an unhealthy character, the abscess in a person of middle age and previous good health may be considered the more probable of the two. In the case of Dowse, already mentioned, the diagnosis between abscess and thrombus must have been very difficult, and, as it seems to the writer, would have been more likely to rest upon abscess or meningitis than upon the condition afterward found to exist.

Where inflammatory diseases exist which are known to lead to thrombosis with phlebitis, the practitioner, if on the lookout, can often make a diagnosis with a high degree of probability in its favor. The cerebral

symptoms with the venous swelling, collateral inflammatory œdema in the more immediate neighborhood of the lesion, and slight œdema and congestion at more distant points, and a febrile movement indicating a distinct inflammatory exacerbation, will point very strongly to thrombophlebitis.

An absolute distinction between such a condition of the veins and a meningitis arising under exactly the same circumstances may not always be possible, and is the less important since the two affections are likely to coexist and form a part of the same disease.

The localization of the thrombus is to be determined partly by the paralytic symptoms, if such exist, but principally by the situation of the secondary œdema and from the lesion which forms the starting-point. It has been said that the jugular vein of the side on which thrombosis exists is less full; and this point might be of value when the lateral sinus is affected.

PROGNOSIS.—From the character of the lesion itself, as well as from the diseases with which thrombosis is usually connected, it will readily be seen that the prognosis is in general a highly unfavorable one; but it is possibly regarded as too inevitably so, for the reason that a positive diagnosis may be in slighter cases a matter of considerable uncertainty, so that the practitioner, even if attempting to make an accurate anatomical explanation of obscure cerebral symptoms, is as likely to think that he has been mistaken as that his patient has recovered from so serious a disease.

Cases, however, have been reported where the diagnosis seems as clear as it can be made without an autopsy, and recovery has taken place.

A case is reported by Voorman¹ of a child aged six months who had diarrhœa and vomiting, much prostration, sunken fontanelles, overlapping cranial bones, trembling of the tongue, slight spasm of the right arm and leg, head drawn back, and strabismus. The head afterward increased in size, the temporal vein was swollen and hard, with œdema of the skin in its neighborhood. There was gradual improvement and recovery, though when the patient was four and a half years old its mental development corresponded to that of a child two years younger.

In another, by Kolb,² a child of seventeen, well nourished, had a purulent discharge from the right ear. Besides headache, delirium, hyperæsthesia, convulsions, and then sleepiness and loss of consciousness, the following symptoms pointed toward thrombosis of the sinuses: Chills, inflammatory swelling over the right mastoid, with fulness of a cutaneous vein passing over it; a purely œdematous swelling in the neighborhood of the internal jugular or temporal fossa, forehead, and both upper eyelids, with exophthalmos on the right side; photophobia, blepharospasm, and cloudy vision; nose-bleed. There was no elevation of temperature, and recovery took place.

A case of thrombo-phlebitis following otitis and terminating in recovery is reported at length by Wreden.³

The **PROGNOSIS** in any particular case can be based only on the severity of the symptoms and on the character of the preceding disease.

TREATMENT.—The prophylaxis of this affection evidently consists in

¹ *Centralb. f. d. Med. Wis.*, 1883.

² *Berl. klin. Woch.*, Nov. 13, 1876.

³ *Archives of Ophth. and Otol.*, 1874, lii. (translation).

the proper treatment of the diseases upon which it depends, and might therefore be made to embrace nearly the whole range of tonic, roborant, antiphlogistic, and antiseptic measures, to say nothing of surgery and obstetrics. The proper nourishment of infants and children, the cutting short, when possible, of their acute diseases, or preventing their debilitating effects, will reduce marantic thrombosis to a minimum. At a later period of life the proper surgical management of carbuncle, abscess in the neck, and of the puerperal condition will tend to avoid this risk.

The most important point of all, however, is undoubtedly the careful treatment of otitis media and early attention to inflammation in the mastoid cells, with incision or trephining as may be necessary.

After a thrombus has formed there is little to be done toward its removal.

It has been claimed¹ that the preparations of ammonia are capable of diminishing considerably the coagulability of the blood when it is morbidly augmented. Though this cannot be considered proved, yet since the tendency of these salts is also to quicken the blood-current, a trial in a case where other indications are wanting is, to say the least, justifiable.

In a case reported by O'Hara,² where the symptoms pointed very strongly toward thrombosis of the cavernous sinuses, recovery took place under mercurials, iodide of potassium, and purgatives. The reporter was inclined to consider the cause of trouble specific.

Considering the fact that cases with such marked and decisive symptoms as those last recorded have recovered, it is certainly the duty of the physician to prolong the life of his patient to the utmost, that absorption and condensation may go on as long as possible and collateral circulation be developed. Probably most physicians can recall cases of obscure cerebral disease going on to recovery contrary to all expectation, in which thrombosis furnishes an explanation quite as plausible as any other.

Softening of the Brain

is a name which it is yet too early to omit altogether from a systematic work, although in treating of it we have more to do with nomenclature and classification than with pathological anatomy. The phrase may be said to have both an anatomical and a clinical signification, which do not coincide at all points. Clinically and among the laity it is used to express various symptoms and groups of symptoms more or less referable to the brain, some of them connected with one and some with another lesion, and many purely functional—if the word may be used—or at any rate unconnected with any known or definite lesion.

Vertigo, dull headache, sleeplessness, or, on the other hand, drowsiness, failure of memory, failure of power of concentration, of steady application, mental depression, fatigue, and even slight aphasia or actual slight hemiplegia, may any of them be considered symptoms or forerunners of softening of the brain. As nearly as anything, the popular notion of this affection corresponds to general paralysis of the insane or senile dementia, or even mere exhaustion. Many of these symptoms may, of course, be connected with the real softening described as the result of embolism or

¹ Lidell, *Am. Journ. Med. Sci.*, July, 1874, p. 101.

² *N. Y. Med. Record*, vol. xvii, p. 617.

thrombosis, but it is hardly necessary to say that a symptomatology based on these elements alone is either too vague or else too much like that of diseases already described to be considered useful as a separate clinical grouping.

On the anatomical side softening of the brain has had a definite meaning, and for many years a part of its pathology has been well known. A general softening of the whole brain, such as seems to be the condition supposed when the phrase is used, does not and cannot exist, since a vascular lesion sufficient to cause anemic necrosis of the whole brain must cause death long before softening would have time to take place. Nearly all the works and reports on softening have been based upon cases such as are now referred to definite lesions of the blood-vessels; and a good idea of the change in nomenclature and pathological views may be obtained by noticing the dates given in the extensive literature of the subject in the *Index Catalogue* of the Surgeon-General's library, which are nearly all previous to 1860 or 1865.

Localized softening has already been described under the heads of hemorrhage, embolism, and thrombosis, venous and arterial. Whether it may occur from diseases of the cerebral vessels without actual occlusion is not certain, but, remembering the difficulty of detecting thrombi in minute vessels, and also the fact that it is not a great many years that occlusions have been systematically sought for at autopsies, it is better for the present to assume, in cases where softening is found in the usual form and the usual situations for the results of thrombosis and embolism, that one of these accidents is the cause, even if the actual point of occlusion is not found.

Softening may take place secondarily from tumors in the brain, and the name is also sometimes applied to a local encephalitis, which is an early stage of abscess. When, however, these various forms of disease are removed from the general heading of softening and referred to their proper pathological classes, there is a residuum in which the softening seems to be the primary affection, so far as the brain is concerned, though depending on other constitutional conditions.

In new-born infants softening of the brain, besides the rare cases in which it may be dependent on the same conditions which may cause it in the adult, is observed in two forms, as described by Parrot:¹ *A.* White softening in multiple foci, dependent upon fatty degeneration, of which it constitutes the last stage, is found almost exclusively in the centres of the hemispheres. *B.* Red softening, which affects the same region, but more extensively, and is accompanied by hemorrhage into the lymphatic sheaths with rupture.

These two forms may exist with each other, and with other intracranial lesions, such as thrombi of the sinuses and exudation under the arachnoid and around the veins.

Parrot compares this form of softening to that occurring in the other extreme of life, dependent on vascular lesions; but although he supposes the method of production to be unlike in the two cases, it is by no means so certain, either from his conclusions or his cases, that it is always so. In some of his cases the vessels are said not to be abnormal, but in others old thrombi are distinctly mentioned. As secondary consequences may

¹ *Arch. de Phys.*, 1873, p. 302.

be observed intracranial dropsy, with perhaps hydrocephalic cranium and degeneration of the pons, bulb, and medulla.

Two cases of red softening of the cerebellum have been reported.¹ In one of them the pia was adherent, in the other thickened and covered with exudation. The microscopic details are not given nor the state of vessels mentioned. They are probably not strictly analogous to those described by Parrot.

The occurrence of granular corpuscles in the brain of the new-born is described by Virchow, and it is thought by him to be pathological and of an irritative character (encephalitis congenita). It is somewhat doubtful if this process is characterized by any distinct symptoms.

The ETIOLOGY is impaired nutrition, deficient or improper feeding, and depressing diseases, frequently tubercle.

The SYMPTOMS and DIAGNOSIS of this form of softening are even more obscure than those of venous thrombosis in the same class of cases. Vague cerebral symptoms arising in an infant poorly nourished and suffering from acute disease may be due to this condition, but a positive diagnosis is out of the question. In the two cases of softening of the cerebellum just mentioned, in one, aged five, there was dilatation of the pupil, difficulty of hearing, and vertigo; in the other, aged six, vertigo, inclination to vomit, and clonic spasm of the left facial muscles. Parrot says that in the greater number of patients the encephalopathic troubles observed during life cannot be referred to it (softening), and in no case can it be diagnosticated.

Under these circumstances it is obvious that remarks upon the PROG-
NOSIS and TREATMENT must be purely works of the imagination.

Atheroma of the Cerebral Arteries

has already been spoken of as one of the most important factors in thrombosis, and perhaps of considerable consequence in embolism and hemorrhage. Its symptoms, when one of these accidents has taken place, are hardly to be separately considered; and if atheroma have produced complete occlusion, even without the assistance of a clot, the symptoms could not be distinguished from those of an ordinary thrombosis, and would follow the same course.

In some cases, however, the thickening of the artery may interfere with, without completely interrupting, the circulation in the part to which it is distributed, and the degree of the interference may vary from time to time. If, then, in a person whose age and general physical condition, as shown by the state of the tangible arteries, arcus senilis, complexion, and so forth, render the existence of atheromatous arteries in the brain probable, cerebral symptoms of an ill-defined character arise, it is very probable that they are the result of irregularities in the circulation dependent on atheroma.

This state of things is to be distinguished from the more clearly marked conditions which have already been described, partly by the incompleteness of the attack, and partly by its changes in severity and character from time to time—a paralysis undergoing alternations of

¹ *Jahrbuch. f. Kinderheilkunde*, 1877.

improvement and the reverse from day to day, delirium appearing and disappearing in correspondence with the general health, the vigor of the heart, and the state of the digestive organs.

The diagnosis between these incomplete anæmias and an almost precisely similar result of syphilitic endarteritis is to be made chiefly by the history and age. In middle-aged persons general paralysis might present a not very different set of phenomena. A tolerably distinct, but not severe, hemiplegia in an old person, subsiding in a few hours under the influence of a cathartic, and perhaps returning more than once, may often be due to a local and temporary anæmia from atheroma, as well as to slight hemorrhage or a not completely occluding thrombus.

On the other hand, extensive atheroma may exist without serious impairment of the cerebral functions, provided it be evenly distributed and do not interfere with the passage of blood in any one vessel.

The prophylaxis of atheroma has already been considered. We do not know of any drug that can change the nature or extent of the processes going on in the arterial walls, but if any influence can be exerted it is through dietetic and hygienic means.

The consequences of rigidity of the arterial walls, as productive of resistance to the passage of blood, can be warded off to some extent by promoting the vigor of the heart. Treatment should therefore be directed to the improvement of the nutrition of the body in general and the heart in particular. Heart tonics and laxatives are the classes of medicaments most likely to be useful. Perhaps it is to its effect in increasing the force of the heart contractions, like digitalis, that coffee owes its reputation as a preservative from apoplexy.

ATROPHY AND HYPERTROPHY OF THE BRAIN.

By H. D. SCHMIDT, M. D.

ATROPHY OF THE BRAIN.

INTRODUCTION AND DEFINITION.—Atrophy of the brain may originate during intra-uterine life or by defective development during the early periods of childhood, or it may occur during adult life, when the organ is fully developed. The atrophy is characterized by a diminution of the normal bulk of the brain-substance, in consequence of which the latter does not entirely fill the cavity of the cranium, but leaves a greater or less space to be occupied by a serous fluid. Generally, the atrophy affects, in a symmetrical or asymmetrical manner, larger or smaller portions of the brain; an atrophy symmetrically affecting all parts of the brain has never been observed, even in microcephalia. Nevertheless, when the atrophy affects both hemispheres of the cerebrum, it is generally called total, whilst it is designated partial when it is limited to only one hemisphere or to other individual parts of the brain, such as the cerebellum, the large cerebral ganglia, etc.

For the sake of convenience we shall treat the atrophy of the brain occurring during childhood, when the organ is still developing, separately from that of the fully-developed brain of the adult.

1. Atrophy of the Brain during Childhood.

When congenital or originating during infancy the atrophy is either primarily due to certain pathological processes taking place in the substance of the brain, or secondary, being due to lesions of the skull, such as premature ossification of the sutures. Total atrophy of the brain at this period of life leads to an early death, while children affected with partial atrophy may continue to live, though almost always in a state of idiocy. The forms mostly observed in children are unilateral or bilateral atrophy of the cerebrum, partial or almost entire absence of the cerebellum, imperfect development of the large cerebral ganglia, and slight partial atrophy of the medulla oblongata. The large commissures as well as the crura cerebri are very seldom found atrophied.

The most frequent and, from a practical point of view, the most important of these forms is the unilateral atrophy of the cerebrum, for the reason that in a mild form it is to a certain degree consistent with the

mental and physical development of the child. It is mostly found on the left side. In some cases the atrophy extends evenly throughout the hemisphere, while in others it affects more or less one or the other lobe. The loss in the bulk of the hemisphere may amount to only a slight diminution, or to as much as to one-half of the normal size. Its thickness above the ventricle may be reduced to a few millimeters; in some cases even the membranes of the brain may lie in contact with the ependyma. The ventricle of the atrophied hemisphere is almost always enlarged. The convolutions of the cerebrum are very narrow, sometimes quite indistinct. One or both of the corpora striata also are generally found atrophied. In many cases even the atrophy extends to one of the crura cerebri and to the pyramid of the same side, and to the anterior and lateral columns of the spinal cord on the opposite side. Frequently, one or the other lateral half of the cerebellum also is found affected. The condition of the substance of the cerebrum is nearly the same as in the senile atrophy of the brain to be described hereafter. The skull is mostly thickened on the side of the atrophy, and frequently asymmetrical.

SYMPTOMS.—In most cases the mental capacity is below the normal standard, and frequently borders on or represents a state of idiocy. The temperament of the patient is generally irritable and very excitable. The most prominent symptom is an incomplete paralysis on the side opposite to the atrophied hemisphere, which is the more pronounced the more the corpus striatum, thalamus opticus, and crus cerebri are involved. Frequently, there are contractures of the flexor and pronator muscles of both extremities, particularly of the upper; the muscles of the trunk remain free; sometimes one or the other half of the face is also paralyzed. Epileptic convulsions also are frequently present. Blindness and deafness, with a defective sense of smell and a blunted sensibility of the paralyzed limbs, as well as neuralgia of the latter, and headache, have also been observed.

CAUSES.—Besides the causes already mentioned, atrophy of the brain occurring in children after birth may be induced by injuries of the head, inflammation of the enveloping membranes, of the ependyma, or of the substance of the brain itself.

TREATMENT.—Atrophy of the brain in children is perhaps, in the majority of cases, incurable; it is therefore only in the milder cases that the patient may be benefited by treatment. Electricity and gymnastic exercises have been recommended. At any rate, it must be pursued in a very systematic manner, and based upon the principles established and practised by the late E. Seguin of New York in his Physiological School for Weak-minded Children, consisting in improving the mind, first by training the child to the use of his limbs by means of light mechanical work, etc.

2. Atrophy of the Fully-developed Brain.

In the brain of the adult the atrophy may be partial or total, symmetrical or asymmetrical, in the same sense as before used in connection with the atrophy of the brain of children. It may, further, be stationary,

when the atrophying process remains limited to the part where it originated; or, progressive, when it extends to other parts of the brain. Generally, partial, asymmetrical, and stationary atrophy is due to certain accidental pathological processes, producing a destruction or loss of portions of the substance of the brain, such as apoplexy, softening, etc., by which the nutrition of the neighboring parts becomes disturbed. Total, symmetrical, and progressive atrophy, on the other hand, actually depends upon certain constitutional disturbances of the nutritive process in general, such as chronic alcoholic intoxication, etc.

CAUSES.—As already mentioned, the causes of atrophy of the brain in the adult may be direct or indirect. The former are generally represented by certain pathological processes which directly affect the substance of the brain, as, for instance, apoplectic hemorrhagic effusions into the brain-substance, thrombosis or embolism of the cerebral arteries, encephalitis, chronic serous effusions into the ventricles, inflammation and œdema of the pia mater, etc. To the latter or indirect causes, which affect the organ by disturbing or lowering the nutrition of its substance, belong the retrogressive processes of old age or of insanity; the introduction into the system of certain noxious substances, such as lead or alcohol; furthermore, certain wasting diseases, such as phthisis, Bright's disease, etc.

PATHOLOGICAL ANATOMY.—The cerebrum particularly is found diminished in volume. While the convolutions are thinner than normal, their intervening sulci are broader. The white substance presents a dirty-white color, and is abnormally dense and tough, especially near the ventricles. The latter are enlarged and filled with serum; their ependyma is thickened and frequently covered with granulations. The cortical layer appears of a dirty, rusty-brown or yellow color, is pale, soft, or hard, and frequently is found to adhere to the pia mater. In very pronounced cases the white substance is almost as tough as leather, and contracts upon section, especially in the convolutions; its cut surface is rendered concave. Sometimes the surface of the convolutions, after the removal of the pia mater, appears finely shrivelled. The dura mater is often found thickened and adhering to the skull. The space created in the cavity of the cranium by the atrophy of the brain is filled by serous effusions into the tissue of the pia mater, the subarachnoidal space, arachnoid sac, and ventricles.

The histological changes associated with atrophy of the brain differ in the different forms. In cases of partial atrophy caused by hemorrhages, etc. the destructive process generally embraces all the tissues at first, while the secondary degenerations particularly affect the nervous elements. In total atrophy the pathological process appears to commence in the connective tissue, and to involve the nervous elements subsequently; though in a number of cases, especially of senile atrophy, the nervous elements appear to be primarily affected. The blood-vessels also undergo certain changes, giving rise to the contraction of the brain-substance.

SYMPTOMS.—In partial atrophy of the brain the primary symptoms resemble those which characterize the particular destructive process to which the atrophy is due. The most prominent are the symptoms of motor disturbance, which are always semilateral and correspond to the extent and seat of the lesion; frequently they remain stationary. The

sensibility of the paralyzed parts is but slightly diminished, and the mind generally undisturbed. But when the effects of the original lesion extend, in the form of a secondary degeneration of the nervous elements, to neighboring parts, or even to the other hemisphere, the cerebral functions may become secondarily disturbed.

In senile atrophy of the brain, which represents the most simple form of total atrophy of this organ, the first symptoms frequently appear toward the end of some intercurrent disease. They consist in a very slow and gradually increasing derangement of the cerebral functions, associated with a general loss of innervation, manifesting itself by talkative wanderings of the mind, restless sleep, hallucinations, foolish activity, attacks of tremor senilis, etc. The intellectual functions diminish and the memory is lost. The physical forces also gradually sink, the tremor senilis increases, and the patient, no more able to walk, becomes confined to bed. Finally, a relaxation of the sphincters takes place, and death is produced by the disturbance of the automatic functions of deglutition and respiration.

Total atrophy of the brain, when due to an extensive meningitis or to a general disturbance of the nutrition, as is met with in drunkards, may finally lead to a condition known as general paralysis of the insane. This disease, however, will be found treated elsewhere in this work.

TREATMENT.—There is no special treatment for atrophy of the brain; all that can be done is to palliate and combat the symptoms as they arise.

HYPERTROPHY OF THE BRAIN.

INTRODUCTION.—Notwithstanding the numerous measurements and weighings of human brains made in the course of time by different investigators, no absolute standard measure or weight has as yet been established by which we can accurately determine a pathological increase or decrease in the size and weight of this organ. The want of such a standard is principally due to the difference generally existing in the dimensions and weights of even a certain number of brains taken from individuals belonging to the same race or nation. The same difficulties are met with in the attempt at establishing a rule by which to measure the mental capacity of a certain brain, for the question has as yet not been solved whether this capacity depends upon the quantity or quality of the brain-substance. In speaking of hypertrophy of the brain, therefore, we must keep in mind that a large brain must not be considered hypertrophied unless there exists a disproportion between its size and that of the cavity from which it was removed; in other words, when its growth or hypertrophy meets a resistance at the inner walls of the cranial cavity. According to Virchow, a further distinction must be made between the increase (hyperplasia) of the nervous elements themselves and that of the supporting connective tissue, the neuroglia. To the latter condition particularly corresponds the peculiar doughy consistence of the white substance of hypertrophied brains.

ETIOLOGY.—Hypertrophy of the brain is sometimes congenital, and then associated with dwarfishness and a defective development of the cranium. Generally, however, it is an extra-uterine affection, originating mostly during infancy and childhood, though it is also met with at the age of puberty, and even in adult life. The male sex is more predisposed to the affection than the female. When hypertrophy of the brain occurs during infancy, it is almost always associated with an excessive development of the lymphatic glands, with a defective involution of the thymus gland, and with rickets, but generally without cachexia. No special exciting cause can be assigned to the affection during youth or adult age, though it has been stated that during these periods of life the disease may supervene upon tubercle or carcinoma of the brain. Repeated active or passive congestion (Rokitanski, Andral), as well as the introduction of lead into the system, has also been supposed to incite the disease.

PATHOLOGICAL ANATOMY.—Directly after the removal of the vault of the cranium, and on cutting through the dura mater, the brain, as if liberated from pressure, is observed to swell out to such a degree as to render the replacement of the removed skull-cap impossible. The enveloping membranes are found closely adapted to one another and to the brain; they are very thin, bloodless, and dry, and their vessels are empty and pressed flat. The hemispheres of the cerebrum are large, and their convolutions, mutually pressing against one another, are flattened at their surfaces, so that the intervening sulci are hardly recognizable. After the removal of the brain from the skull the abnormal dimensions of the cerebrum present a remarkable contrast to the normal size of the cerebellum, pons, and medulla oblongata, which also appear flat and broad from pressure. When a horizontal section is made through the hemispheres of the cerebrum and a little above the corpus callosum, the centrum ovale appears unusually large. The cavities of the ventricles are very narrow, their walls touching one another. There is no serum in the pia mater or in the ventricles. The substance of the brain is pale, bloodless, and dry. The white substance, upon which the hypertrophy particularly depends, is of a doughy consistence, comparable to the boiled white of an egg or cheese, whilst the gray substance is so pale as to be hardly distinguishable from the former.

The condition of the skull is, according to Rokitanski,¹ as follows: In cases in which the hypertrophy of the brain has advanced to a high degree, and in which the sutures of the skull are united, the bones of the cranium are found thinner and their inner table roughened by absorption. This is especially the case in the bones which form the vault of the cranium. The holes or other deficiencies found at the base of the cranium in the plates of the frontal, ethmoid, and sphenoid bones are not entirely due to the absorbing process, but rather to the thinness of these bones. In infants the cavity of the cranium enlarges in proportion to the hypertrophy of its contents; the head then resembles in form so much that of hydrocephalus that it may lead to errors in diagnosis. In some cases in which the disease rapidly develops to a high degree there is observed on the infant's skull a loosening and separation of the sutures of the cranial vault, with red coloration and suffusion of their cartilages.

¹ *Lehrbuch der Pathologischen Anatomie*, 3d ed., 1855, vol. ii. p. 431.

SYMPTOMS.—There is a gradually increasing muscular weakness, manifesting itself especially in the lower extremities, and giving rise to an unsteady, stumbling gait and frequent falling, caused perhaps by the excessive weight of the head, and also an inability of securely grasping objects. Besides these disturbances of motion, epileptic spasms appear, at first light in degree and at long intervals, but becoming later on in the course of the disease more frequent and severe. Continuous or intermittent attacks of headache almost always accompany the disease, and, furthermore, vertigo, tinnitus aurium, photophobia, and dimness of sight with dilatation of the pupil; general sensation also becomes blunted, but without ever amounting to anæsthesia. In a number of cases there is no disturbance of the psychical functions, though in others symptoms of mental excitement amounting even to delirium have been observed. Most frequently the intelligence sinks from the beginning of the disease, to end in complete idiocy. The pulse also has been observed to fall considerably during the last stage.

The **COURSE** of the disease is, according to Andral and Hasse,¹ almost always chronic, and if an acute development of the affection has been spoken of, it may be supposed that the latter has commenced a considerable time previous to the manifestation of the symptoms during the last stage. Andral divides the disease into two stages, of which the first is chronic and frequently latent, whilst the other is more acute and leads to a rapid fatal termination. In most cases death is caused by such intercurrent affections as give rise to irritation and hyperæmia of the brain, and thus increase the already abnormal pressure upon this organ.

DIAGNOSIS, PROGNOSIS, AND TREATMENT.—It has already been mentioned that errors in diagnosis may very easily be committed on account of the great resemblance in the form of the head in cases of hypertrophy of the brain and of hydrocephalus, though it has been stated that in the former affection convulsions, in the form of epileptic spasms, predominate, to be followed during the last stage by symptoms of depression; whilst in hydrocephalus the symptoms of depression manifest themselves from the beginning of the disease, and, moreover, the rachitic deformities are more prominently shown in the form of a chicken-breast. A positive diagnosis can only be made by the autopsy.

There are no remarks to be made on the prognosis and treatment of hypertrophy of the brain.

¹ "Krankheiten des Nervensystems," 2d ed., 1869, in *Handbuch der Speciellen Pathologie und Therapie*, edited by R. Virchow, vol. iv. 1st div., p. 578.

SYPHILITIC AFFECTIONS OF THE NERVE-CENTRES.

By H. C. WOOD, M.D., LL.D.

Introduction.

SYPHILITIC affections of the nerve-centres are best studied by separating those of the spinal cord from those of the cerebrum, and in the present article this natural division of the subject is adopted. Further, cerebral syphilis in its most characteristic or gummatous form usually attacks the brain-membranes, or perhaps in some cases the perivascular sheaths of the vessels, and only secondarily affects the tissue of the brain itself. The question of the occurrence of specific disease of the brain-cortex is so important that it shall have a separate discussion. It is perfectly well proven that with or without other brain lesion the vessels of the brain may undergo an atheromatous degeneration as the direct result of a syphilitic dyscrasia; but such disease links itself on the one hand with the subject of syphilitic disease of the general vascular system, and on the other hand with cerebral apoplexies, softenings, and other degenerations. Moreover, the space here allotted to brain syphilis is very insufficient. I, therefore, shall not enter upon the further discussion of syphilitic degeneration of the brain-vessels. The etiology of brain and spinal syphilis is best discussed under one heading.

GENERAL ETIOLOGY.—We do not know why in any individual case syphilis selects one portion of the nervous centres rather than another for attack; indeed, it is only rarely that any exciting cause can be discovered.

It is not unnatural to expect that any agency which is capable of exciting an inflammation of a nerve-centre may, when present in a syphilitic person, provoke a specific disease of such centre. Thus, thermic fever is a very common cause of chronic meningitis, and in the *Journ. de Méd. et Chir.* (Paris, 1879, p. 191) a case is reported in which cerebral syphilis followed a sunstroke; I have myself seen one similar instance, and in Roberts's case of precocious cerebral syphilis (see p. 804) the first convulsion came whilst the man was fishing on a very hot day, and may have been precipitated by the exposure.

Blows and other traumatisms would be expected to figure largely as exciting causes of nervous syphilis, but they, in fact, are only rarely present. I have seen one or two cases of specific brain disease attributed to violence by the patient, and several cases of possibly specific spinal dis-

ease—one in which a poliomyelitis followed a fall on the ice; one in which, after a fall from a cart and marked spinal concussion, a local myelitis developed;¹ and one of a general myelitis following an injury by a horse. The only records of such cases are those of Broadbent² and those collected by Heubner.³

Various authorities attach much influence to over-study and other forms of cerebral strain in exciting brain syphilis. Engelstedt is stated to have reported cases having such etiological relations, and Fournier⁴ affirms that he has especially seen the disease in professional men and other persons habitually exercising their brains to excess. Neither in private nor public practice have I met with an instance where over-brainwork could be considered a distinct etiological factor, whilst I have seen some hundreds of cases from amongst the laboring classes, in whom the intellectual faculties are chiefly dormant.

The drift of the evidence in medical literature is so pronounced, and so in accord with my own experience, that I believe it may be positively affirmed that in the vast majority of cases of nervous syphilis no exciting cause can be found.

Inherited syphilis seems to be less prone than the acquired diathesis to attack the nervous system, but is certainly capable of so acting. As early as 1779, Joseph Glenck⁵ reported a case of a girl, six years old, cured by a mercurial course of an epilepsy of three years' standing and of other manifestations of hereditary syphilis. Graefe found gummatous tumors in the cerebrum of a child nearly two years old.⁶ O. Huebner⁷ details the occurrence of pachymeningitis hæmorrhagica in a syphilitic infant under a year old. Hans Chiari⁸ reports a case in which very pronounced syphilitic degeneration of the brain-vessels was found in a child fourteen months old. Both Barlow⁹ and T. S. Dowse¹⁰ report cases of nerve syphilis in male infants of fifteen months. For other similar cases the reader is referred to an article by J. Parrott,¹¹ and to a paper by M. E. Troisier.¹²

Recorded cases prove decisively that even after puberty specific nervous affections may primarily attack the unfortunate offspring. Thus, Nettleship reports¹³ the development of a cerebral gumma in a girl of ten years, and J. A. Ormerod¹⁴ of a tumor of the median nerve (probably gummatous) in a woman of twenty-three, both the subjects of inherited syphilis. Thomas S. Dowse¹⁵ details a case of cerebral gumma at the age of ten years, and Samuel Wilks¹⁶ one of epilepsy, from inherited taint, in a boy of fourteen. J. Hughlings-Jackson reports¹⁷ paraplegia with epilepsy in a boy of eight, hemiplegia in a girl of eighteen, and hemiplegia in a woman of twenty-two;¹⁸ the nervous affection in each case being associated with or dependent upon inherited syphilis. E. Mendel reports¹⁹ a case of a child

who had inherited syphilis, and developed in her fifteenth year a maniacal attack with hallucinations. I have seen cerebral syphilis occur at twenty-one years of age as the first evident outbreak of the inherited disorder.

When a nervous affection develops first at a comparatively late period, and no very apparent evidences of the inherited taint are present, there is great danger of the case being misunderstood; indeed, in some instances an immediate diagnosis may be scarcely possible. It is probable that in most of the reported recoveries from alleged tubercular meningitis the disease has been syphilitic.

Some time since I saw, in an orphan of fourteen, a chronic basal meningitis, and in the absence of any history and of any evidences of syphilis gave the fatal prognosis of tubercular disease; but, to my astonishment, under the long-continued and free use of iodide of potassium complete recovery occurred. Another child, reported by a very good practitioner as cured of tubercular meningitis, and afterward for a long time under my own care, I believe suffered from hereditary syphilis. Cases of this character have also been reported by F. Dreyfous.¹

It is of course very important to diagnose between a tubercular meningitis and one due to hereditary syphilis. Without a history certainty is not possible, but a general indefiniteness of symptoms and slowness of progression should arouse suspicion, especially if the absence of the pulse-retardation indicated that the vault rather than the base of the cranium was involved.

The relation of inherited syphilis to various nervous affections not distinctly specific cannot yet be determined. Arrested development, and the consequent epilepsy, idiocy,² early brain sclerosis, are probably sometimes due to the inheritance; and the cases collected by E. Mendel³ show that chronic hydrocephalus is frequently of specific origin.⁴

Another very important question connected with the etiology of these disorders is as to the time of their development. Nervous diseases following acquired syphilitic infection certainly belong to the advanced stages of the disorder. Huebner reports⁵ a case in which thirty years elapsed between the contraction of the chancre and the nervous explosion. I have seen a similar period of thirty years. Fournier reports intervals of twenty-five years, and thinks from the third to the tenth year is the period of maximum frequency of nervous accidents.

The fact that nervous syphilis may occur many years after the cessation of all apparent evidences of the diathesis is of great practical importance, especially as the nervous system is more prone to be attacked when the secondaries have been very light than when the earlier manifestations have been severe. I have repeatedly seen nervous syphilis in persons whose secondaries have been so slight as to have been entirely overlooked or forgotten, and who honestly asserted that they never had had syphilis, although they acknowledged to gonorrhœa or to repeated exposure, and confessed that their asserted exemption was due to good fortune rather than to chastity.

⁵ *Archiv f. Psychiatrie*, Bd. i. 309.

The following citations prove that this experience is not peculiar. Dowse¹ says: "Often have I had patients totally ignorant of having at any time acquired or experienced the signs or symptoms of syphilis in its primary and secondary stages, yet the sequelæ have been made manifest in many ways, particularly in many of the obscure diseases of the nervous system." Buzzard² reports a case of nervous syphilis where the patient was unconscious of the previous existence of a chancre or of any secondaries. Rinecker also calls attention³ to the frequency of nervous syphilis in persons who afford no distinct history of secondary symptoms.

Although syphilis is prone to attack the nervous system many years after infection, it would be a fatal mistake to suppose that nervous disease may not rapidly follow the chancre. What is the minimum possible intermediate period we do not know, but it is certainly very brief, as is shown by the following cases of this so-called precocious nervous syphilis. Alfrik Ljunggrén of Stockholm reports⁴ the case of H. R——, who had a rapidly-healed chancre in March, followed in May of the same year by a severe headache, mental confusion, and giddiness. Early in July H. R—— had an epileptic attack, but was finally cured by active antisypilitic treatment. Although the history is not explicit, the nervous symptoms appear to have preceded the development of distinct secondaries other than rheumatic pains.

Davaine is said⁵ to have seen paralysis of the portio dura "a month after the first symptoms of constitutional syphilis." E. Leyden⁶ found advanced specific degeneration of the cerebral arteries in a man who had contracted syphilis one year previously. R. W. Taylor details a case in which epilepsy occurred five months after the infection.⁷ In the case of M. X——, reported by Ad. Schwarz,⁸ headache came on the fortieth day after the appearance of the primary sore, and a hemiplegia upon the forty-sixth day. S. L——⁹ had a paralytic stroke without prodromes six months after the chancre. A. P. L——¹⁰ had an apoplectic attack seven months after the chancre; A. S——, one five months after her chancre. In a case which recently occurred in the practice of A. Sydney Roberts of this city the chancre appeared after a period of incubation of twenty-six days, and two months and eight days subsequent to this came the first fit; eight days after the first the second convulsion occurred, with a distinct aura, which preceded by some minutes the unconsciousness. An interesting observation in this connection is that of Ern. Gaucher¹¹ of a spinal syphilis occurring six months after the appearance of a chancre.

This citation of cases might be much extended, but is sufficient to show that nervous syphilis occurs not very rarely within six months after infection, and may be present in two months.

Gummatous Brain Syphilis.

CLINICAL HISTORY.—Brain syphilis of the type now under consideration may declare itself with great suddenness. An apoplectic attack, a convulsive paroxysm, a violent mania, or a paralytic stroke may be the first detected evidence of the disease. In most of these cases the coming storm ought to have been foreseen, and to a greater or less degree averted. The onset of cerebral syphilis is, however, generally more gradual, the symptoms coming on slowly and successively. Proper treatment, instituted at an early stage, is usually successful, so that a careful study of these prodromes is most important. They are generally such as denote cerebral disturbance, and, although they should excite suspicion, are not diagnostic, except as occurring in connection with a specific history or under suspicious circumstances.

Headache, slight failure of memory, unwonted slowness of speech, general lassitude, and especially lack of willingness to mental exertion, sleeplessness or excessive somnolence, attacks of momentary giddiness, vertiginous feelings when straining at stool, yelling or in any way disturbing the cerebral circulation, alteration of disposition,—any of these, and, a fortiori, several of them, occurring in a syphilitic subject, should be the immediate signal of alarm, and lead to the examination of the optic discs, for in some cases the eye-ground will be found altered even during the prodromic stage. Of course if choked disc be found the diagnosis becomes practically fixed, but the absence of choked disc is no proof that the patient is free from cerebral syphilis. In regard to the individual prodromic symptoms, my own experience does not lend especial importance to any one of them, although, perhaps, headache is the most common. There is one symptom which may occur during the prodromic stage of cerebral syphilis, but is more frequent at a later stage—a symptom which is not absolutely characteristic of the disease, but which, when it occurs in a person who is not hysterical, should give rise to the strongest suspicion. I refer to the occurrence of repeated, partial, passing palsies. A momentary weakness of one arm, a slight drawing of the face disappearing in a few hours, a temporary dragging of the toe, a partial aphasia which appears and disappears, a squint which to-morrow leaves no trace, may be due to a non-specific brain tumor, to miliary cerebral aneurisms, or to some other non-specific affection; but in the great majority of cases where such phenomena occur repeatedly the patient is suffering from syphilis or hysteria.

The first type or variety of the fully-formed syphilitic meningeal disease to which attention is here directed is that of an acute meningitis. I am much inclined to doubt whether an acute syphilitic meningitis can ever develop as a primary lesion—whether it must not always be preceded by a chronic meningitis or by the formation of a gummatous tumor; but it is very certain that acute meningitis may develop when there have been no apparent symptoms, and may therefore seem to be abrupt in its onset. Some years ago I saw, in consultation, a man who in the midst of apparent health was attacked by violent meningeal convulsions, with distinct evidences of acute meningitis. He was apparently saved from death by very heroic venesection, but after his return to consciousness developed very rapidly a partial specific hemiplegia, showing that a latent gumma had

probably preceded the acute attack. On the other hand, an acute attack is liable at any time to supervene upon a chronic syphilitic meningitis. At the University Hospital dispensary I once diagnosed chronic cerebral syphilis in a patient who the next day was seized with violent delirium, with convulsions and typical evidences of acute meningitis, and died four or five days afterward. At the autopsy an acute meningitis was found to have been engrafted on a chronic specific lesion of a similar character. In the case reported by Gamel,¹ in which intense headache, fever, and delirium came on abruptly in an old syphilitic subject and ended in general palsy and death, the symptoms were found to depend upon an acute meningitis secondary to a large gumma.

In this connection may well be cited the observation of Molinier² in which violent delirium, convulsions, and coma occurred suddenly. A very curious case is reported by D. A. Zambaco³ in which attacks simulating acute meningitis occurring in a man with a cerebral gummatous tumor appear to have been malarial. In such a case the diagnosis of a malarial paroxysm could only be made out by the presence of the cold stage, the transient nature of the attack, its going off with a sweat, its periodical recurrence, and the therapeutic effect on it of quinine.

In the cases of chronic brain syphilis which have come under my observation, most usually after a greater or less continuance of prodromes such as have been mentioned, epileptic attacks have occurred with a hemiplegia, or a monoplegia, which is almost invariably incomplete and usually progressive; very frequently diplopia is manifested before the epilepsy, and on careful examination is found to be due to weakness of some of the ocular muscles. Not rarely oculo-motor palsy is an early and pronounced symptom, and a marked paralytic squint is very common. Along with the development of these symptoms there is almost always distinct failure of the general health and progressive intellectual deterioration, as shown by loss of memory, failure of the power to fix the attention, mental bewilderment, and perhaps aphasia. If the case convalesces under treatment, the amelioration is gradual, the patient travelling slowly up the road he has come down. If the case end fatally, it is usually by a gradual sinking into complete paralysis, or the patient is carried off by an acute inflammatory exacerbation, or, as in two of my cases, amelioration may be rapidly occurring and a very violent epileptic fit produce a sudden fatal asphyxia. Death from brain-softening around the tumor is not infrequent, but a fatal apoplectic hemorrhage is rare.

The clinical varieties of cerebral meningeal syphilis are so polymorphic and kaleidoscopic that it is almost impossible to reduce them to order for descriptive purposes. Fournier separates them into the cephalic, congestive, epileptic, aphasic, mental, and paralytic, but scarcely facilitates description by so doing. Heubner makes the following types:

"1. Psychical disturbances, with epilepsy, incomplete paralysis (seldom of the cranial nerves), and a final comatose condition, usually of short duration.

"2. Genuine apoplectic attacks with succeeding hemiplegia, in connection with peculiar somnolent conditions, occurring in often-repeated

¹ *Tumeurs gommeuses du Cerveau*, Inaug. Diss., Montpellier, 1875.

² *Revue méd. de Toulouse*, xiv. 1880, 341.

³ *Des Affections nerveuses-syphilitiques*, Paris, 1862, p. 485.

episodes; frequently phenomena of unilateral irritation, and generally at the same time paralyzes of the cerebral nerves.

"3. Course of the cerebral disease similar to paralytica dementia."

In regard to these types, the latter seems to me clear and well defined, but contains those cases which I shall discuss under the head of Cortical Disease.

Meningeal syphilis as seen in this country does not conform rigidly with the other asserted types, although there is this much of agreement, that when the epilepsy is pronounced the basal cranial nerves are not usually paralyzed, the reason of this being that epilepsy is especially produced when the gummatus change is in the ventricles or on the upper cortex. In basal affections the epileptoid spells, if they occur at all, are usually of the form of petit mal; but this rule is general, not absolute. The apoplectic somnolent form of cerebral syphilis, for some reason, is rare in this city, and it seems necessary to add to those of Heubner's a fourth type to which a large proportion of our cases conform. This type I would characterize as follows:

4. Psychical disturbance without complete epileptic convulsions, associated with palsy of the basal nerves and often with partial hemiplegia.

The most satisfactory way of approaching this subject is, however, to study the important symptoms in severalty, rather than to attempt to group them into recognizable varieties of the disease; and this method I shall here adopt.

Headache is the most constant and usually the earliest symptom of meningeal syphilis; but it may be absent, especially when the lesion is located in the reflexions of the meninges which dip into the ventricles, or when the basal gumma is small and not surrounded with much inflammation. The length of time it may continue without the development of other distinct symptoms is remarkable. In one case¹ at the University Dispensary the patient affirmed that he had had it for four years before other causes of complaint appeared. It sometimes disappears when other manifestations develop. It varies almost indefinitely in its type, but is, except in very rare cases, at least so far paroxysmal as to be subject to pronounced exacerbations. In most instances it is entirely paroxysmal; and a curious circumstance is, that very often these paroxysms may occur only at long intervals: such distant paroxysms are usually very severe, and are often accompanied by dizziness, sick stomach, partial unconsciousness, or even by more marked congestive symptoms. The pain may seem to fill the whole cranium, may be located in a cerebral region, or fixed in a very limited spot. Heubner asserts that when this headache can be localized it is generally made distinctly worse by pressure at certain points, but my own experience is hardly in accord with this. Any such soreness plainly cannot directly depend upon the cerebral lesion, but must be a reflex phenomenon or due to a neuritis. According to my own experience, localized soreness indicates an affection of the bone or of its periosteum. In many cases, especially when the headache is persistent, there are distinct nocturnal exacerbations.

It will be seen that there is nothing absolutely characteristic in the headache of cerebral syphilis; but excessive persistency, apparent causelessness, and a tendency to nocturnal exacerbation should in any cephal-

¹ *Book Y*, p. 88, 1879.

algia excite suspicion of a specific origin—a suspicion which is always to be increased by the occurrence of slight spells of giddiness or by delirious mental wandering accompanying the paroxysms of pain. When an acute inflammatory attack supervenes upon a specific meningeal disease it is usually ushered in by a headache of intolerable severity.

When the headache in any case is habitually very constant and severe, the disease is probably in the dura mater or periosteum; and this probability is much increased if the pain be local and augmented by firm, hard pressure upon the skull over the seat of the pain.

Disorders of Sleep.—There are two antagonistic disorders of sleep, either of which may occur in cerebral syphilis, but which have only been present in a small proportion of the cases that I have seen. Insomnia is more apt to be troublesome in the prodromic than in the later stages, and is only of significance when combined with other more characteristic symptoms. A peculiar somnolence is of much more determinate import. It is not pathognomonic of cerebral syphilis, yet of all the single phenomena of this disease it is the most characteristic. Its absence is of no import in the theory of an individual case.

As I have seen it, it occurs in two forms: In the one variety the patient sits all day long or lies in bed in a state of semi-stupor, indifferent to everything, but capable of being aroused, answering questions slowly, imperfectly, and without complaint, but in an instant dropping off again into his quietude. In the other variety the sufferer may still be able to work, but often falls asleep while at his tasks, and especially toward evening has an irresistible desire to slumber, which leads him to pass, it may be, half of his time in sleep. This state of partial sleep may precede that of the more continuous stupor, or may pass off when an attack of hemiplegia seems to divert the symptoms. The mental phenomena in the more severe cases of somnolency are peculiar. The patient can be aroused—indeed in many instances he exists in a state of torpor rather than of sleep; when stirred up he thinks with extreme slowness, and may appear to have a form of aphasia; yet at intervals he may be endowed with a peculiar automatic activity, especially at night. Getting out of bed; wandering aimlessly and seemingly without knowledge of where he is, and unable to find his own bed; passing his excretions in a corner of the room or in other similar place, not because he is unable to control his bladder and bowels, but because he believes that he is in a proper place for such act,—he seems a restless nocturnal automaton rather than a man. In some cases the somnolent patient lies in a perpetual stupor.

An important fact in connection with the somnolence is that it may develop suddenly without marked premonition. Thus in a case reported by J. A. Ormerod¹ a man who had been in good health, save only for headache, awoke one morning in a semi-delirious condition, and for three days slept steadily, only arousing for meals; after this there was impairment of memory and mental faculties, but no more marked symptoms.

Apathy and indifference are the characteristics of the somnolent state, yet the patient will sometimes show excessive irritability when aroused, and will at other periods complain bitterly of pain in his head, or will groan as though suffering severely in the midst of his stupor—at a time,

¹ *Brain*, vol. v. 260.

too, when he is not able to recognize the seat of the pain. I have seen a man with a vacant, apathetic face, almost complete aphasia, persistent heaviness and stupor, arouse himself when the stir in the ward told him that the attending physician was present, and come forward in a dazed, highly pathetic manner, by signs and broken utterances begging for something to relieve his head. Heubner speaks of cases in which the irritability was such that the patient fought vigorously when aroused; this I have not seen.

This somnolent condition may last many weeks. T. Buzzard¹ details the case of a man who after a specific hemiplegia lay silent and somnolent for a month, and yet finally recovered so completely as to win a rowing-match on the Thames. I have seen a fair degree of recovery after a somnolence of four months' duration.

In its excessive development syphilitic stupor puts on the symptoms of advanced brain-softening, to which it is indeed often due. Of the two cases with fatal result of which I have notes, one at the autopsy was found to have symmetrical purulent breaking down of the anterior cerebral lobes; the other, softening of the right frontal and temporal lobes, due to the pressure of a gummatous tumor, and ending in a fatal apoplexy.

This close connection with cerebral softening explains the clinical fact that apoplectic hemorrhage is very apt to end the life in these cases of somnolent syphilis. But a prolonged deep stupor in persons suffering from cerebral syphilis does not prove the existence of extensive brain-softening, and is not incompatible with subsequent complete recovery. As an element of prognosis it is of serious but not of fatal import.

Paralysis.—When it is remembered that a syphilitic exudation may appear at almost any position in the brain, that spots of encephalic softening are a not rare result of the infection, that syphilitic disease is a common cause of cerebral hemorrhage, it is plain that a specific palsy may be of any conceivable variety, and affect either the sensory, motor, or intellectual sphere. The mode of onset is as various as the character of the palsy. The attack may be instantaneous, sudden, or gradual. The gradual development of the syphilitic gumma would lead us, a priori, to expect an equally gradual development of the palsy; but experience shows that in a large proportion of the cases the paralysis appears suddenly, with or without the occurrence of an apoplectic or epileptic fit. Under these circumstances it will be usually noted that the resulting palsy is incomplete; in rare instances it may be at its worst when the patient awakes from the apoplectic seizure, but usually it progressively increases for a few hours, and then becomes stationary. These sudden partial palsies probably result from an intense congestion around the seat of disease or from stoppage of the circulation in the same locality; whatever their mechanism may be, it is important to distinguish them from palsies which are due to hemorrhage. I believe this can usually be done by noting the degree of paralysis.

A suddenly-developed, complete hemiplegia or other paralysis may be considered as in all probability either hemorrhagic or produced by a thrombus so large that the results will be disorganization of the brain-substance, and a future no more hopeful than that of a clot. On the

¹ *Clinical Lectures on Dis. Nerv. Syst.*, London, 1882.

other hand, an incomplete palsy may be rationally believed to be due to pressure or other removable cause; and this belief is much strengthened by a gradual development. The bearing of these facts upon prognosis it is scarcely necessary to point out.

Although the gummata may develop at almost any point, they especially affect the base of the brain, and are prone to involve the nerves which issue from it. Morbid exudations, not tubercular or syphilitic, are rare in this region. Hence a rapidly but not abruptly appearing strabismus, ptosis, dilated pupil, or any paralytic eye symptom in the adult is usually of syphilitic nature. Syphilitic facial palsy is not so frequent, whilst paralysis of the nerve from rheumatic and other inflammation within its bony canal is very common. Paralysis of the facial nerve may therefore be specific, but existing alone is of no diagnostic value. Since syphilitic palsies about the head are in most instances due to pressure upon the nerve-trunks, the electrical reactions of degeneration are present in the affected muscles.

There is one peculiarity about specific palsies which has already been alluded to as frequently present—namely, a temporary, transient, fugitive, varying character and seat. Thus an arm may be weak to-day, strong to-morrow, and the next day feeble again, or the recovered arm may retain its power and a leg fail in its stead. These transient palsies are much more apt to involve large than small brain territories. The explanation of their largeness, fugitiveness, and incompleteness is that they are not directly due to clots or other structural changes, but to congestions of the brain-tissues in the neighborhood of gummatus exudations. Squint due to direct pressure on a nerve will remain when the accompanying monoplegia due to congestion disappears.

Motor palsies are more frequent than sensory affections in syphilis, but hemianæsthesia, localized anæsthetic tracts, indeed any form of sensory paralysis, may occur. Numbness, formications, all varieties of paræsthesia, are frequently felt in the face, body, or extremities. Violent peripheral neuralgic pains are rare, and generally when present denote neuritis. Huguenin, however, reports¹ a severe trigeminal anæsthesia dolorosa, which was found, after death from intercurrent disease, to have depended upon a small gumma pressing upon the Gasserian ganglion. A somewhat similar case has also been reported by Allen McLane Hamilton.²

The special senses are liable to suffer from the invasion of their territories by cerebral syphilis, and the resulting palsies follow courses and have clinical histories parallel to those of the motor sphere. The onset may be sudden or gradual, the result temporary or permanent. Charles Mauriac³ reports a case in which the patient was frequently seized with sudden attacks of severe frontal pain and complete blindness lasting from a quarter to half an hour; at other times the same patient had spells of aphasia lasting only for one or two minutes. I have seen two cases of nearly complete deafness developing in a few hours in cerebral syphilis, and disappearing abruptly after some days. Like other syphilitic palsies, therefore, paralyses of special senses may come on suddenly or gradually, and may occur paroxysmally.

Among the palsies of cerebral syphilis must be ranked aphasia. An

¹ *Schwiez. Corr. Blät.*, 1875.

² *Alienist and Neurologist*, iv. 58.

³ *Loc. cit.*, p. 31.

examination of recorded cases shows that syphilitic aphasia is subject to vagaries and laws similar to those connected with other specific cerebral palsies. It is usually a symptom of advanced disease, but may certainly develop as one of the first evidences of cerebral syphilis. Coming on after an apoplectic or epileptic fit, it may be complete or incomplete: owing to the smallness of the centre involved and the ease with which its function is held in abeyance, a total loss of word-thought is not so decisive as to the existence of cerebral hemorrhage as is a total motor palsy. Like hemiplegia or monoplegia, specific aphasia is sometimes transitory and paroxysmal. Buzzard¹ records several such cases. Mauriac² details a very curious case in which a patient, after long suffering from headache, was seized by sudden loss of power in the right hand and fingers, lasting about ten minutes only, but recurring many times a day. After this had continued some time the paroxysms became more completely paralytic, and were accompanied by loss of the power of finding words, the height of the crises in the palsy and aphasia being simultaneously reached. For a whole month these attacks occurred five or six times a day, without other symptoms except headache, and then the patient became persistently paralytic and aphasic, but finally recovered. To describe the different forms of specific aphasia and their mechanism of production would be to enter upon a discussion of aphasia itself—a discussion out of place here. Suffice it to say that every conceivable form of the disorder may be induced by syphilis.

Owing to the centres of speech being situated in the cortical portion of the brain, aphasia in cerebral syphilis is very frequently associated with epilepsy. Of course right-sided palsy and aphasia are united in syphilitic as in other disorders. If, however, the statistics given by Tanowsky³ be reliable, syphilitic aphasia is associated with left-sided hemiplegia in a most extraordinarily large proportion. Thus in 53 cases collected by Tanowsky, 18 times was there right-sided hemiplegia, and 14 times left-sided hemiplegia, the other cases being not at all hemiplegic. Judging from the autopsy on a case reported in Mauriac's brochure, this concurrence of left-sided paralysis and aphasia depends partly upon the great frequency of multiple brain lesions in syphilis, and partly upon the habitual involvement of large territories of the gray matter secondarily to diseased membrane. An important practical deduction is that the conjoint existence of left hemiplegia and aphasia is almost diagnostic of cerebral syphilis.

Probably amongst the palsies may be considered the disturbances of the renal functions, which are only rarely met with in cerebral syphilis, and which are probably usually dependent upon the specific exudation pressing upon the vaso-motor centres in the medulla. Fournier speaks of having notes of six cases in which polyuria with its accompaniment, polydipsia, was present, and details a case in which the specific growth was found in the floor of the fourth ventricle. Cases have been reported of true saccharine diabetes due to cerebral syphilis,⁴ and I can add to these an observation of my own. The symptoms, which occurred in a

¹ *Loc. cit.*, p. 81.

² *Aphasie et Hémip légia droite Syphilit.*, Paris, 1877.

³ *L'Aphasie syphilitique.*

⁴ Consult Servantié, *Des Rapports du Diabète et de la Syphilis*, Paris, Thèse, 1876; also, case reported by L. Putzel, *New York Med. Record*, xxv. 450.

man of middle age, with a distinct specific history, were headache, nearly complete hemiplegia, and mental failure, associated with the passage of comparatively small quantities of a urine so highly saccharine as to be really a syrup. Under the influence of the iodide of potassium the sugar in a few weeks disappeared from the urine.

Epilepsy.—Epileptic attacks are a very common symptom of meningeal syphilis, and are of great diagnostic value. The occurrence in an adult of an epileptic attack or of an apoplectic fit, or of a hemiplegia after a history of intense and protracted headache, should always excite grave suspicion.

Before I had read Fournier's work on *Nervous Syphilis* I taught that an epilepsy appearing after thirty years of age was very rarely, if ever, essential epilepsy, and unless alcoholism, uræmic poison, or other adequate cause could be found was in nine cases out of ten specific; and I therefore quote with satisfaction Fournier's words: "*L'épilepsie vraie, ne fait jamais son premier début à l'âge adulte, à l'âge mûr. Si un homme adulte, au dessus de 30, 35, à 40 ans, vient, à être pris pour la première fois d'une crise épileptique, et cela dans la cours d'une bonne santé apparente, il y a, je vous le répète, huit ou neuf chances sur dix pour que cette épilepsie soit d'origine syphilitique.*"

Syphilitic epilepsy may occur either in the form of petit mal or of haut mal, and in either case may take on the exact characters and sequence of phenomena which belong to the so-called idiopathic or essential epilepsy. The momentary loss of consciousness of petit mal will usually, however, be found to be associated with attacks in which, although voluntary power is suspended, memory recalls what has happened during the paroxysm—attacks, therefore, which simulate those of hysteria, and which may lead to an error of diagnosis.

Even in the fully-developed type of the convulsions the aura is only rarely present. Its absence is not, however, of diagnostic value, because it is frequently not present in essential epilepsy, and it may be pronounced in the specific disease. It is said that when in an individual case the aura has once appeared the same type or form of approach of the convulsion is thereafter rigidly adhered to. The aura is sometimes bizarre: a severe pain in the foot, a localized cramp, a peculiar sensation, indescribable and unreal in its feeling, may be the first warning of the attack. An aura may affect a special sense. Thus, I have at present a patient whose attacks begin with blindness.

In many, perhaps most, cases of specific convulsions, instead of a paroxysm of essential epilepsy being closely simulated, the movements are in the onset, or more rarely throughout the paroxysm, unilateral; indeed, they may be confined to one extremity. This restriction of movement has been held to be almost characteristic of syphilitic epilepsy, but it is not so. Whatever diagnostic significance such restriction of the convulsion has is simply to indicate that the fit is due to a cortical organic lesion of some kind. Tumors, sclerosis, and other organic lesions of the brain-cortex are as prone to cause unilateral or monoplegic epilepsy when they are not specific as when they are due to syphilis.

Sometimes an epilepsy dependent upon a specific lesion implicating the brain-cortex may be replaced by a spasm which is more or less local and is not attended with any loss of consciousness. Thus, in a case now con-

valescent in the University Hospital, a man aged about thirty-five offered a history of repeated epileptic convulsions, but at the time of his entrance into the hospital, instead of epileptic attacks, there was a painless tic. The spasms, which were clonic and occurred very many times a day, sometimes every five minutes, were very violent, and mostly confined to the left facial nerve distribution. The trigeminus was never affected, but in the severer paroxysms the left hypoglossal and spinal accessory nerves were profoundly implicated in all of their branches. Once, fatal asphyxia from recurrent laryngeal spasm of the glottis was apparently averted only by the free inhalation of the nitrite of amyl. The sole other symptom was headache, but the specific history was clear and the effect of antisyphilitic remedies rapid and pronounced.

It is very plain that such attacks as those just detailed are closely allied to epilepsy; indeed, there are cases of cerebral syphilis in which widespread general spasms occur similar to those of a Jacksonian epilepsy, except that consciousness is not lost, because the nervous discharge does not overwhelm the centres which are connected with consciousness.¹ On the other hand, these epileptoid spasmodic cases link themselves to those in which the local brain affection manifests itself in contractions or persistent irregular clonic spasms. Contractures may exist and may simulate those of descending degeneration,² but in my own experience are very rare.³

The clonic spasms of cerebral syphilis may assume a distinctly choreic type, or may in their severity simulate those of hysteria, throwing the body about violently.⁴ It is, to my mind, misleading, and therefore improper, to call such cases syphilitic chorea, as there is no reason for believing that they have a direct relation with ordinary chorea. They are the expression of an organic irritation of the brain-cortex, and are sometimes followed by paralysis of the affected member; in other words, the disease, progressing inward from the brain-membrane, first irritates, and then so invades a cortical centre as to destroy its functional power.⁵

Psychical Symptoms.—As already stated, apathy, somnolence, loss of memory, and general mental failure are the most frequent and characteristic mental symptoms of meningeal syphilis; but, as will be shown in the next chapter, syphilis is able to produce almost any form of insanity, and therefore mania, melancholia, erotic mania, delirium of grandeur, etc. etc. may develop along with the ordinary manifestation of cerebral syphilis, or may come on during an attack which has hitherto produced only the usual symptoms. Without attempting any exhaustive citation of cases, the following may be alluded to.

A. Erlenmeyer reports⁶ a case in which an attack of violent headache and vomiting was followed by paralysis of the right arm and paresis of the left leg, with some mental depression; a little later the patient suddenly became very cheerful, and shortly afterward manifested very distinctly delirium of grandeur with failure of memory. Batty Tuke reports⁷ a case in which, with aphasia, muscular wasting, strabismus,

and various palsies, there were delusions and hallucinations. In the same journal¹ S. D. Williams reports a case in which there were paroxysmal violent attacks of frontal headache. The woman was very dirty in her habits, only ate when fed, and existed in a state of hypochondriacal melancholy. Leiderdorf details a case with headache, partial hemiplegia, great psychical disturbance, irritability, change of character, marked delirium of grandeur, epileptic attacks, and finally dementia, eventually cured by iodide of potassium.² Several cases illustrating different forms of insanity are reported by N. Manssurow.³

That the attacks of syphilitic insanity, like the palsies of syphilis, may at times be temporary and fugitive, is shown by a curious case reported by H. Hayes Newington,⁴ in which, along with headache, failure of memory, and ptosis in a syphilitic person, there was a brief paroxysm of noisy insanity.

DIAGNOSIS.—In a diagnosis of cerebral syphilis a correct history of the antecedents of the patients is of vital importance. Since very few of the first manifestations of the disorder are absolutely characteristic, whilst almost any conceivable cerebral symptoms may arise from syphilitic disease, treatment should be at once instituted on the appearance of any disturbance of the cerebral functions in an infected person.

Very frequently the history of the case is defective, and not rarely actually misleading. Patients often appear to have no suspicion of the nature of their complaint, and will deny the possibility of syphilis, although they confess to habitual unchastity. My own inquiries have been so often misleading in their results that I attach but little weight to the statements of the patient, and in private practice avoid asking questions which might recall unpleasant memories, depending upon the symptoms themselves for the diagnosis.

The general grounds of diagnosis have been sufficiently mapped out in the last section, but some reiteration may be allowable. After the exclusion of other non-specific disease, headache occurring with any form of ocular palsy or with a history of attack of partial monoplegia or hemiplegia, vertigo, petit mal, epileptoid convulsions, or disturbances of consciousness, or attacks of unilateral or localized spasms, should lead to the practical therapeutic test. Ocular palsies, epileptic forms of attacks occurring after thirty years of age, morbid somnolence, even when existing alone, are sufficient to put the practitioner upon his guard. It is sometimes of vital importance that the nature of the cephalalgia shall be recognized before the coming on of more serious symptoms; any apparent causelessness, severity, and persistence should arouse suspicion, to be much increased by a tendency to nocturnal exacerbations or by the occurrence of mental disturbance or of giddiness at the crises of the paroxysms. Not rarely there are very early in these cases curious, almost indefinable, disturbances of cerebral functions, which may be easily overlooked, such as temporary and partial failures of memory, word-stumbling, fleeting feelings of numbness or weakness, alterations of disposition. In the absence of hysteria an indefinite and apparently disconnected series of nerve accidents is of very urgent import. To use the words of Hughlings-Jackson, "A random association or a random succession of

¹ April, 1869.

³ *Die Tertiäre Syphilis*, Wien, 1877.

² *Medicin Jahrbucher*, xx. 1864, p. 114.

⁴ *Journ. Ment. Sci.*, London, xix. 555.

nervous symptoms is very strong warrant for a diagnosis of a syphilitic disease of the nervous system." Cerebral syphilis occurring in an hysterical subject may be readily overlooked until fatal mischief is done. When any paralysis occurs a study of the reflexes may sometimes lead to a correct diagnosis. Thus in a hemiplegia the reflex on the affected side in cerebral syphilis is very frequently exaggerated, whilst in hysteria the reflexes are usually alike on both sides. When both motion and sensation are disturbed in an organic hemiplegia, the anaesthesia and motor paralysis occur on the same side of the body, whilst in hysteria they are usually on opposite sides.

In all cases of doubtful diagnosis the so-called therapeutic test should be employed, and if sixty grains of iodide of potassium per day fail to produce iodism, for all practical purposes the person may be considered to be a syphilitic. No less an authority than Seguin has denied the validity of this, but I believe, myself, that some of his reported cases were suffering from unsuspected syphilis. I do not deny that there are rare individuals who, although untainted, can resist the action of iodide, but in ten years' practice in large hospitals, embracing probably some thousands of cases, I have not met with more than one or two instances which I believed to be of such character. Of course in making these statements I leave out of sight persons who have by long custom become accustomed to the use of the iodide, for although in most cases such use begets increase of susceptibility, the contrary sometimes occurs. Of course the physician who should publicly assert that a patient who did not respond to the iodide had syphilis would be a great fool, but in my opinion the physician who did not act upon such a basis would be even more culpable.

PROGNOSIS.—Cerebral meningeal syphilis varies so greatly and so unexpectedly in its course that it is very difficult to establish rules for predicting the future in any given case. The general laws of prognosis in brain disease hold to some extent, but may always be favorably modified, and patients apparently at the point of death will frequently recover under treatment. The prognosis is not, however, as absolutely favorable as is sometimes believed, and especially should patients be warned of the probable recurrence of the affection even when the symptoms have entirely disappeared. The only safety after the restoration of health consists in an immediate re-treatment upon the recurrence of the slightest symptom. The occurrence of a complete, sudden hemiplegia or monoplegia is sufficient to render probable the existence of a clot, which must be subject to the same laws as though not secondary to a specific lesion. If a rapid decided rise of temperature occur in an apoplectic or epileptic attack, the prognosis becomes very grave. An epileptic paroxysm very rarely ends fatally, although it has done so in two of my cases.

The prognosis in gummatous cerebral syphilis should always be guardedly favorable. In the great majority of cases a more or less incomplete recovery occurs under appropriate treatment, and I have seen repeatedly patients who were unconscious, with urinary and fecal incontinence, and apparently dying, recover. Nevertheless, so long as there is any particle of gummatous inflammation in the membrane the patient is liable to sudden congestions of the brain, which may prove rapidly fatal, or he may die in a brief epileptic fit. On the one hand there is an

element of uncertainty in the most favorable case, and on the other so long as there is life a positively hopeless prognosis is not justifiable.

PATHOLOGY.—Gummatous inflammation of the brain probably always has its starting-point in the brain-membranes, although it may be situated within the brain: thus, I have seen the gummatous tumors spring from the velum interpositum in the lateral ventricle. The disease most usually attacks the base of the brain, and is especially found in the neighborhood of the pons Varolii and the optic tract. It may, however, locate itself upon the vault of the cranium, and in my experience has seemed to prefer the anterior or motor regions. The mass may be well defined and roundish, but more usually it is spread out, irregular in shape, and more or less confluent with the substance of the brain beneath it. It varies in size from a line to several inches in length, and when small is prone to be multiple. The only lesion which it resembles in gross appearance is tubercle, from which it sometimes cannot be certainly distinguished without microscopic examination.

The large gummata have not rarely two distinct zones, the inner one of which is drier, somewhat yellowish in color, opaque, and resembles the region of caseous degeneration in the tubercle. The outer zone is more pinkish and more vascular, and is semi-translucent.

On microscopic examination the most characteristic structures are small cells, such as are found in gummatous tumors in other portions of the body. These cells are most abundant in the inner zone, which, indeed, may be entirely composed of them. In the centre of the tumor they are more or less granular and atrophied; in some cases the caseous degeneration has progressed so far that the centre of the gumma consists of minute acicular crystals of fat. In the external or peripheral zone of the tumor the mass may pass imperceptibly into the normal nerve tissue, and under these circumstances it is that it contains the spider-shaped cells or stellate bodies described by Jastrowitch, and especially commented upon by Charcot and Gombault and by Coyne. These are large cells containing an exaggerated nucleus and a granular protoplasm, which continues into multiple, branching, rigid, refracting prolongations, which prolongations are scarcely stained by carmine. Alongside of these cells other largish cells are often found without prolongations, but furnished with oval nuclei and granular protoplasm. Amongst these cells will be seen the true gummatous cells, as well as the more or less altered neuroglia and nerve-elements. In the perivascular lymphatic sheaths in the outer part of the gumma is usually a great abundance of small cells. The spider-shaped cells are probably hypertrophied normal cells of the neuroglia, and have been considered by Charcot and Gombault as characteristic of syphilitic gummata of the brain. In a solitary gumma, however, of considerable size from the neighborhood of the cerebellum, studied by Coyne and Peltier, there were no stellated cells. Coyne considers that their presence is due to their previous existence in the normal state of the regions affected by the gumma. Exactly what becomes of syphilitic gumma of the brain in cases of recovery it is difficult to determine. It is certain that they become softened and disappear more or less completely, and it is probable that the cicatrices or the small peripheral cysts which are not rarely found in the surfaces of the brain are sometimes remnants of gummatous tumors. In a number of cases collected by Gros and Lance-

reaux there were small areas of softened tissue or small calcareous and caseous masses or cerebral lacunæ corresponding to the cicatrices of softening or imperfect cysts, coincident with evidences of syphilis elsewhere. V. Cornil also states that he has found small areas of softening with well-established syphilitic lesions of the dura mater and cranium, but believes that the lacunæ or cysts depend rather upon chronic syphilitic lesions of cerebral arteries than upon gummatous inflammation.

When a gummatous tumor comes in contact with an artery, the latter is usually compressed and its walls undergo degeneration. The specific arteritis may pass beyond the limit of the syphilome and extend along the arterial wall. Not rarely there is under these circumstances a thrombus, and if the artery be a large one secondary softening of its distributive brain-area occurs.

TREATMENT.—The treatment of cerebral syphilis is best studied under two heads: First, the treatment of the accidents which occur in the course of the disease; second, the general treatment of the disease itself.

It must be remembered that in the great majority of cases in which death occurs in properly-treated cerebral syphilis the fatal result is produced by an exacerbation—or, as I have termed it, an accident—of the disease. Under these circumstances the treatment should be that which is adapted to the relief of the same acute affection when dependent upon other than specific cause. In a large proportion of cases the acute outbreak takes the form either of a meningitis or else of a brain congestion. In either instance when the symptoms are severe free bleeding should be at once resorted to. The amount of blood taken is of course to be proportionate to the severity of the symptoms and the strength of the patient. I have seen life saved by the abstraction of about a quart of blood, whilst in other cases a few ounces suffice. Care must be, of course, taken not to mistake a simple epileptic fit for a severe cerebral attack; but when this fit has been preceded by severe headache and is accompanied by stupor, with marked disturbance of the respiration, measures for immediate relief are usually required; and if the convulsions be perpetually repeated or if there be violent delirious excitement, the symptoms may be considered as very urgent. In taking blood the orifice should be large, so as to favor a rapid flow, and the bleeding be continued until a distinct impression is made upon the pulse. In some cases which I have seen in which the action of the heart continued to be violent after as much blood as was deemed prudent had been taken, good results were obtained by the hypodermic injection of three drops of the tincture of aconite-root every half hour until the reduction of the pulse and the free sweating indicated that the system was coming under the influence of the cardiac sedative.

Of course, I do not mean to encourage the improper or too free use of the lancet in these cases, but in the few fatal cases which I have seen I have almost invariably regretted that blood had not been taken at once very freely at the beginning of the acute attack. In most of these cases the symptoms had progressed too far for good to be achieved before I reached the patient. After venesection, or in feeble cases as a substitute for it, the usual measures of relief in cerebral congestion should be instituted. I shall not occupy space with a discussion of these meas-

ures, as they are in no way different from those to be employed in cases not syphilitic.

The most important part of the treatment of cerebral syphilis itself is antisypilitic, and the practitioner is at once forced to select between the iodide of potassium and the mercurial preparations. In such choice it must be remembered that even a very small amount of syphilitic deposit in the brain may at any time cause a sudden congestion or other acute attack, and is therefore a very dangerous lesion. I have seen a cerebral syphilis which was manifested only by an epileptic attack occurring once in many months, and in which after death the affected membrane was found to be not larger than a quarter of a dollar, and the deposit not more than an eighth of an inch in thickness, suddenly produce a rapidly fatal congestion; and I have known a case fast progressing toward recovery suddenly ended by the too long continuance of the arrest of respiration during an epileptic fit. I have, myself, no doubt of the superiority of the mercurials over the iodide of potassium as a means of producing absorption of gummatous exudates; and as these exudates in the brain are so very dangerous, a mercurial course should in the majority of cases of cerebral syphilis be instituted so soon as the patient comes under the practitioner's care. When, however, there is a history of a recent prolonged free use of the mercurial, or when there is marked specific cachexia, the iodide should be chosen. Cachexia is, however, a distinctly rare condition in cerebral syphilis, the disease usually developing in those who have long had apparent immunity from the constitutional disorder. In my opinion the best preparation of the mercurial for internal use is calomel. It should be given in small doses, one-quarter of one grain every two hours, guarded with opium and astringents, so as to prevent as far as possible disturbance of the bowels, and should be continued until soreness of the teeth, sponginess of the gums, or other evidences of commencing ptyalism are induced. After this the dose of the mercurial should be so reduced as simply to maintain the slight impression which has been created, and the patient should be kept under the mercurial influence for some weeks.

A very effective method of using the mercury is by inunction, and where the surroundings of the patient are suitable the mercurial ointment may be substituted for the calomel. It should be applied regularly, according to the method laid down in my treatise on therapeutics. I have sometimes gained advantage by practising the mercurial unction and at the same time giving large doses of iodide of potassium internally.

After a mercurial course the iodide of potassium should always be exhibited freely, the object being not only to overcome the natural disease, but also to bring about the complete elimination of the mercury from the system. There is no use in giving the iodide in small doses; at least a drachm and a half should be administered in the twenty-four hours, and my own custom has been to increase this to three drachms unless evidences of iodism are produced. The compound syrup of sarsaparilla covers the disagreeable taste of the iodide of potassium better than any other substance of which I have knowledge. Moreover, I am well convinced that there is some truth in the old belief that the so-called "Woods" are of value in the treatment of chronic syphilis.

I have seen cases in which both the iodide of potassium and the mercurials had failed to bring about the desired relief, but in which the same alteratives, when given along with the "Woods," rapidly produced favorable results. The old-fashioned Zittmann's decoction, made according to the formula of the United States Dispensatory, may be occasionally used with very excellent effect. But I have gradually come into the habit of substituting a mixture of the compound fluid extract and the compound syrup of sarsaparilla in equal proportions. The syrup itself is too feeble to have any influence upon the system, but is here employed on account of its flavor. A favorite method of administration is to furnish the patient with two bottles—one containing a watery solution of the iodide of potassium of such strength that two drops represent one grain of the drug, and the other the sarsaparilla mixture above mentioned. From one to two drachms of the solution of the iodide may be administered in a tablespoonful of the sarsaparilla well diluted after meals. When the patient has been previously mercurialized, or there is any doubt as to the propriety of using mercurials, corrosive sublimate in small doses may be added to the solution of the iodide, so that one-tenth to one-fifteenth of a grain shall be given in each dose. I have never seen especial advantage obtained by the use of the iodides of mercury. They are no doubt effective, but are not superior to the simpler forms of the drug.

Syphilitic Disease of the Brain-Cortex.

The psychical symptoms which are produced by syphilis are often very pronounced in cases in which the paralysis, headache, epilepsy, and other palpable manifestations show the presence of gross brain lesions. In the study of syphilitic disease of the brain-membranes sufficient has been said in regard to these psychical disturbances, but the problem which now offers itself for solution is as to the existence or non-existence of syphilitic insanity—*i. e.* of an insanity produced by specific contagion without the obvious presence of gummatous disease of the brain-membranes. Very few alienists recognize the existence of a distinct affection entitled to be called syphilitic insanity, and there are some who deny that insanity is ever directly caused by syphilis. It is certain that insanity often occurs in the syphilitic, but syphilis is abundantly joined with alcoholism, poverty, mental distress, physical ruin, and various depressing emotions and conditions which are well known to be active exciting causes of mental disorder. It may well be that syphilis is in such way an indirect cause of an insanity which under the circumstances could not be properly styled syphilitic.

If there be disease of the brain-cortex produced directly by syphilis, of course such disease must give rise to mental disorders; and if the lesion be so situated as to affect the psychic and avoid the motor regions of the brain, it will produce mental disorder without paralysis—*i. e.* an insanity; again, if such brain disease be widespread, involving the whole cortex, it will cause a progressive mental disorder, accompanied by gradual loss of power in all parts of the body, and ending in dementia with general paralysis; or, in other words, it will produce an affection

more or less closely resembling the so-called general paralysis of the insane, or dementia paralytica.

As a man having syphilis may have a disease which is not directly due to the syphilis, when a syphilitic person has any disorder there is only one positive way of determining during life how far said disorder is specific—namely, by studying its amenability to antisymphilitic treatment. In approaching the question whether a lesion found after death is specific or not, of course such a therapeutic test as that just given is inapplicable. We can only study as to the coexistence of the lesion in consideration with other lesions known to be specific. Such coexistence of course does not absolutely prove the specific nature of a nutritive change, but renders such nature exceedingly probable.

What has just been said foreshadows the method in which the subject in hand is to be here examined, and the present article naturally divides itself into two sections—the first considering the coexistence of anatomical alterations occurring in the cerebral substance with syphilitic affections of the brain-membranes or blood-vessels, the second being a clinical study of syphilitic insanity.

In looking over the literature of the subject I have found the following cases in which a cerebral sclerotic affection coincided with a gummatous disease of the membrane. Gros and Lancereaux¹ report a case having a clear syphilitic history in which the dura mater was adherent to the skull. The pia mater was not adherent. Beneath, upon the vault of the brain, was a gelatinous exudation. The upper cerebral substance was indurated, and pronounced by Robin after microscopic examination to be sclerosed. At the base of the brain there were atheromatous arteries and spots of marked softening.

Jos. J. Brown² reports a case in which the symptoms were melancholia, excessive irritability, violent outbursts of temper, very positive delusions, disordered gait, ending in dementia. At the autopsy, which was very exhaustive, extensive syphilitic disease of the vessels of the brain and spinal cord was found. The pia mater was not adherent to the brain. The convolutions, particularly of the frontal and parietal lobes, were atrophied, with very wide sulci filled with bloody serum. The neuroglia of these convolutions was much increased, and “appeared to be more molecular than normal, the cells were degenerated, and in many places had disappeared, their places being only occupied by some granules.” These changes were most marked in the frontal convolutions.

H. Schule reports³ a very carefully and meritoriously studied case. The symptoms during life exactly simulated those of dementia paralytica. The affection commenced with an entire change in the disposition of the patient; from being taciturn, quiet, and very parsimonious, he became very excited, restless, and desiring continuously to buy in the shops. Then failure of memory, marked sense of well-being, carelessness and indifference for the future, developed consentaneously with failure of the power of walking, trembling of the hands, inequality of the pupils, and hesitating speech. There was next a period of melancholy, which was in time followed by continuous failure of mental and motor powers, and

¹ *Affec. Nerv. Syphilis*, 1861, p. 245.

² *Journ. Ment. Sci.*, July, 1875, p. 271.

³ *Allgem. Zeitschrift f. Psychiatrie*, xxviii. 171, 172.

very pronounced delirium of grandeur, ending in complete dementia. Death finally occurred from universal palsy, with progressive increase of the motor symptoms. At the autopsy characteristic syphilitic lesions were found in the skull, dura mater, larynx, liver, intestines, and testicles. The brain presented the macroscopic and microscopic characters of sclerosis and atrophy; the neuroglia was much increased, full of numerous nuclei, the ganglion-cells destroyed. The vessels were very much diseased, some reduced to cords; their walls were greatly thickened, and full of long spindle-shaped cells, sometimes also containing fatty granules.

C. E. Stedman and Robt. T. Edes report¹ a case in which the symptoms were failure of health, ptosis, trigeminal palsy with pain (anæsthesia dolorosa), finally mental failure with gradual loss of power of motion and sensation. At the autopsy the following conditions were noted: apex of the temporal lobe adherent to dura mater and softened; exuded lymph in neighborhood of optic chiasm; sclerosis of right Gasserian ganglion, as shown in a marked increase of the neuroglia; degeneration of the basal arteries of the brain.

These cases are sufficient to demonstrate that sclerosis of the brain-substance not only may coexist with a brain lesion which is certainly specific in its character, but may also present the appearance of having developed *pari passu* with that lesion and from the same cause.

It has already been stated in this article that cerebral meningeal syphilis may coexist with various forms of insanity, and cases have been cited in proof thereof. It is of course very probable that in some of such cases there has been that double lesion of membrane and gray brain matter which has just been demonstrated by report of autopsies; but if we find that there is a syphilitic insanity, which exists without evidences of meningeal syphilis, and is capable of being cured by antispecific treatment, such insanity must be considered as representing the disease of the gray matter of the brain. Medical literature is so gigantic that it is impossible to exhaust it, but the following list of cases is amply sufficient to prove the point at issue—namely, that there is a syphilitic insanity which exists without obvious meningeal disease, and is capable of being cured by antisymphilitic treatment:

| No. | Reporter and Journal. | Symptoms. | Results.—Remarks. |
|-----|---|---|---------------------------------------|
| 1 | Louis Streisand <i>Die Lues als Ursache der Dementia</i> , Inaug. Diss., Berlin, 1878. | Epilepsy, delirium of exaltation, alteration of speech, headache, failure of memory. | Rapid cure with mercury. |

| 10 | <i>Ibid.</i> | Religious melancholia, with two attempts at suicide, ending in mania. | Iodide of potassium, cure. |
| 11 | <i>Ibid.</i> | At times very violent, yelling, shrieking, destroying everything she could get hands on, at times erotomania; no distinct history of infection, but her habits known to be bad, and had bone ozena and other physical syphilitic signs. | Iodide of potassium, cure. |
| 12 | <i>Ibid.</i> | Epileptic attack followed by a long soporose condition, ending in mental confusion, he not knowing his nearest friends, etc.; almost dementia. | Cured by mercurial inunction. |
| 13 | <i>Ibid.</i> | Great fear of gend'armes, etc., mania, with hallucinations, loud crying, yelling, etc., then convulsion, followed by great difficulty of speech. | Cured by mercurial inunctions with iodide internally; subsequently return of convulsions, followed by hemiplegia and death. |
| 14 | <i>Ibid.</i> | Great unnatural vivacity and loquacity, wanted to buy everything, bragged of enormous gains at play, etc.; some trouble of speech. | Iodide of potassium, cure. Attended to business, and seems as well as before. Relapsed. (See Symptoms.) |
| | <i>Ibid.</i> Relapse of Case 14. | Fifteen months after discharge from asylum relapse; symptoms developing very rapidly, delirium of grandeur of the most aggravated type, with marked progressive dementia, failure of power of speech, and finally of locomotion. | Failure of various anti-specific treatment. |
| 15 | A. Erlenmeyer <i>Die Luetischen</i> , etc. | Failure of mental powers, inequality of pupils, trembling of lip when speaking, uncertainty of gait, almost entire loss of memory, once temporary ptosis and strabismus. | Iodide of potassium in ascending doses failed. Recovery under mercurial inunctions. |
| 16 | <i>Ibid.</i> | Failure of mental powers, pronounced delirium of grandeur, hallucinations of hearing, failure of memory, strabismus and ptosis coming on late. | Iodide of potassium, corrosive-sublimate injections. Cure. |
| 17 | <i>Ibid.</i> | Failure of memory and mental powers, slight ideas of grandeur, disturbance of sensibility and motility, aphasia coming on late. | Cure with use of iodide and mercurial inunctions. |
| 18 | <i>Ibid.</i> | Melancholy, great excitability, ideas of grandeur; after a long time sudden ptosis and strabismus. | Iodide of potassium failed; mercurial course improved; joint use cured patient. |
| 19 | <i>Ibid.</i> | Various cerebral nerve palsies, great relief by use of mercurial inunctions, then development of great excitement, delirium of grandeur, failure of memory and mental powers, and finally death from apoplexy; no autopsy. | |
| 20 | J. B. Chapin <i>Amer. Journ. Insanity</i> , vol. xv, p. 249. | Melancholia with attempted suicide, epilepsy, headache, somnolent spells. | Iodide of potassium, cure. |
| 21 | <i>Ibid.</i> | Acute mania, noisy, very destructive; syphilitic disease of tibia. | Iodide of potassium, cure. |
| 22 | Snell | Maniacal excitement. | Cured by specific treatment. |
| 23 | Wm. Smith <i>Brit. Med. Journ.</i> , July, 1868, p. 30. | Apathetic melancholy, indelicate, speaking only in monosyllables, and much of the time not at all, sullen and menacing. | Rapidly cured by conjoint use of iodide and mercurials. The symptoms first developed 3 months after chancre. |

A study of the brief analyses of the symptoms just given shows that syphilitic disease of the brain may cause any form of mania, but that the symptoms, however various they may be at first, end almost always in dementia unless relieved.

Of all the forms of insanity, general paralysis is most closely and frequently simulated by specific brain disease. The exact relation of the diathesis to true, incurable, general paralysis it is very difficult to deter-

mine. It seems well established that amongst persons suffering from this disorder the proportion of syphilitics is not only much larger than normal, but also much larger than in other forms of insanity. Thus, E. Mendel¹ found that in 146 cases of general paralysis, 109, or 75 per cent., had a distinct history of syphilis, whilst in 101 cases of various other forms of primary insanity only 18 per cent. had specific antecedents. H. Obersteiner has 1000 cases of mental disease,² 175 cases of dementia paralytica; of these, 21.6 per cent. had syphilis; moreover, of all the syphilitic patients 51.4 per cent. had dementia paralytica.

Various opinions might be cited as to the nature of this relation between the two disorders, but for want of space the curious reader is referred to the work just quoted and to the thesis of C. Chauvet³ for an epitome of the most important recorded opinions.

Those who suffer from syphilis are exposed in much greater proportion than are other persons to the ill effects of intemperance, sexual excesses, poverty, mental agony, and other well-established causes of general paralysis. It may be that in this is sufficient explanation of the frequency of general paralysis in syphilitics, but I incline to the belief that syphilis has some direct effect in producing the disease. However this may be, I think we must recognize as established the opinion of Voisin,⁴ that there is a syphilitic periencephalitis which presents symptoms closely resembling those of general paralysis. Such cases are examples of the pseudo-paralyse générale of Fournier.⁵

The question as to the diagnosis of these cases from the true incurable paresis is of course very important, and has been considered at great length by Voisin,⁶ Fournier,⁷ and Mickle.⁸

The points which have been relied upon as diagnostic of syphilitic pseudo-general paralysis are—

The occurrence of headache, worse at night and present amongst the prodromes; an early persistent insomnia or somnolence; early epileptiform attacks; the exaltation being less marked, less persistent, and perhaps less associated with general maniacal restlessness and excitement; the articulation being paralytic rather than paretic; the absence of tremulousness, especially of the upper lip (Fournier); the effect of anti-specific remedies.

When the conditions in any case correspond with the characters just paragraphed, or when any of the distinguishing characteristics of brain syphilis, as previously given, are present, the probability is that the disorder is specific and remediable. But the absence of these marks of specific disease is not proof that the patient is not suffering from syphilis. Headache may be absent in cerebral syphilis, as also may insomnia and somnolence. Epileptiform attacks are not always present in the pseudo-paralysis, and may be present in the genuine affection; a review of the cases previously tabulated shows that in several of them the megalomania was most pronounced; and a case with very pronounced delirium of grandeur, in which the autopsy revealed unquestionably specific brain lesions, may be found in Chauvet's *Thesis*, p. 31.

⁸ *Brit. and For. Med.-Chir. Review*, 1877.

I have myself seen symptoms of general paralysis occurring in persons with a 'specific history in which of these so-called diagnostic differences the therapeutic test was the only one that revealed the true nature of the disorder. In these cases a primary, immediate diagnosis was simply impossible.

Case 14 of the table is exceedingly interesting, because it seems to represent as successively occurring in one individual both pseudo and true general paralysis. The symptoms of general paralysis in a syphilitic subject disappeared under the use of mercury, to return some months afterward with increased violence and with a new obstinacy that resisted with complete success antisyphilitic treatment. Such a case is some evidence that syphilis has the power to produce true general paralysis.

In conclusion, I may state that it must be considered as at present proven that syphilis may produce a disorder whose symptoms and lesions do not differ from those of general paralysis; that true general paralysis is very frequent in the syphilitic; that the only constant difference between the two diseases is as to curability; that the curable sclerosis may change into or be followed by the incurable form of the disease. Whether under these circumstances it is philosophic to consider the so-called pseudo-general paralysis and general paralysis as essentially distinct affections, each physician can well judge for himself.

Spinal Syphilis.

The subject of spinal syphilis is at present a difficult and unsatisfactory one. The recorded cases with well-observed autopsies are comparatively few, and when recovery occurs much uncertainty must rest upon the nature of the lesion. More than this, there is scarcely any chronic degeneration of the spinal cord which has not been attributed to syphilis, and my own experience as well as the records of medical literature lead to the very positive conclusion that all the various spinal scleroses are much more frequent in infected than in non-infected persons. Whether this is due to a direct or indirect influence of the disease is uncertain, but I shall not here discuss the relation of these chronic inflammations of the cord to syphilis.

It seems necessary to briefly consider at this place acute and subacute myelitis in their relations to syphilis. That these affections are not rare in syphilitics is certain. In the *Revue de Médecine* (Jan., 1884) Dejerine records the case of a person suffering from chronic syphilis in whom there were fulgurant pains with increasing weakness of the legs, and subsequently, after very severe exposure to the weather, a sudden development of complete paraplegia followed by trophic troubles, and death in twenty-eight days. At the autopsy there was found a central myelitis with pronounced lesion of the ganglionic cells, inflammatory changes of the pia mater, capillaries, and neuroglia, extreme alteration of the nerve-roots, and secondary degeneration of the columns of Goll and the lateral columns. In a second case recorded by Dejerine there appears to have been no exposure or apparent immediate exciting cause. The symptoms and lesions were similar to those just spoken of, but death occurred in eight days.

Whether such attacks as these occurring in syphilitic subjects are produced directly by the syphilis or not is at present doubtful. The same is

true of subacute myelitis, of which I have reported two rather peculiar fatal cases in syphilitic subjects. The general symptoms of this affection are progressive loss of power with grossly exaggerated reflexes, severe twitchings and jerkings of the legs, rigidity, usually more or less marked pain, and other sensory disturbances in the legs, and finally partial anæsthesia and complete paraplegia, paralysis of bladder, bed-sores, and death from exhaustion. At the autopsy the most important change in the cord has been the presence of great numbers of round neuroglia-cells in both gray and white matter. One of my cases died of a rapidly developed central myelitis supervening upon the subacute disease, and affording lesions similar to those described by Dejerine in addition to the changes of the subacute affection.

In another class of spinal cases occurring in syphilitics the symptoms resemble those of the so-called acute ascending paralysis (Landry's paralysis). The fourth variety of syphilitic diseases of the spinal cord of Huebner¹ includes these cases. According to Huebner, they are without anatomical lesions, but in the majority of the recorded cases no proper microscopic study of the cord has been made. Huebner states, however, that Kussmaul failed in one case after such study to detect lesion. As some of these cases may really have been instances of peripheral neuritis, it is essential that in the future the peripheral nerves as well as the spinal cord be carefully studied. I have seen one case which might be placed in this category. The first symptom was some numbness in the legs, with a small deep sharp-cut ulcer on the plantar surface of the great toe; directly after this loss of motion and sensation in the legs and thighs, rapidly becoming almost complete and spreading quickly to the trunk and arms, so that in one week the patient was a flaccid, helpless mass, and the breathing so interfered with that he was believed to be dying. After almost losing the power of swallowing this patient began to get better, and finally so regained power of his hands and feet that he was able to partially dress himself and walk a distance of ten or twelve feet, when he was suddenly seized with a pleural effusion and died. During the first week of his disease his temperature was 100° F. At the autopsy the spinal membranes were found to be normal. But in the cord there were very distinct lesions found; the neuroglia seemed everywhere more granular than normal; the ganglionic cells were not distinctly diseased; the white matter in various places was much changed, the tissue appearing abnormally dense and opaque where most affected; the nerve-tubules appeared to gradually lose their myeline, and in places were reduced to simple axis-cylinders. Finally, the axis-cylinders became smaller and smaller until in the most altered portions of the cord they disappeared. As the autopsy was obtained with great difficulty, it was not possible to get the peripheral nerves for study.

In regard to these very acute cases, it seems to me uncertain whether the disease should be attributed to the syphilis. In my own case twenty years had elapsed since the chancre, alcohol was habitually used in great excess, and the attack was apparently precipitated by great exposure. On the other hand, the man bore well enormous doses of iodide of potassium, and slowly progressed under them.

Finally, there is a class of disease of the spinal cord in which the

¹ *Ziemssen's Encyclopædia*, vol. xii.

lesion is undoubtedly the direct outcome of a syphilitic diathesis. In these cases the exudation commences primarily in the membranes of the cord, and may extend into the cord itself. In this class I would include the first two varieties of syphilitic spinal disease of Huebner. The number of recorded autopsies is not great; the only cases with which I am acquainted are those referred to in the note at the bottom of this page.¹

The lesions in these cases are entirely similar to those of brain syphilis. The disease very rarely or never begins in the interior of the cord. I know of no recorded case: Wagner's case, in which a yellow nodule was found within the cervical marrow, was probably not one of syphilis. If a gummatous inflammation does occur inside of the cord, it probably starts from the ependyma. The gummatous exudate may occur in the form of small multiple formations or of an extensive meningitis, with an infiltration of the membranes and their spaces with gummatous material. The membranes are usually agglutinated with one another and with the surface and with the cord. The exudation is usually made up of roundish cells, and in several cases spindle-shaped cells have been noticed, as have also the peculiar Deitres corpuscles already described as they occur in brain syphilis. The changes in the cord itself vary somewhat. In Winge's case the white matter seems to have undergone a rapid myelitis from pressure. It was of a grayish color, with numerous fine granular masses, corpora amylacea, pigment-masses, and fatty globules, the nerve-fibres being broken up. In other cases the change has been a sclerosis. The vessels of the cord have been noticed by various observers in the different stages of the degeneration seen in syphilis of the brain. They are often greatly dilated, their walls thickened, and, together with the lymph-spaces, infiltrated with small cells. Minute hemorrhages have been found.

The so-called syphilitic callus, as described by Heubner, is probably the remnant of a true gummatous inflammation. It consists of a circumscribed induration one to several lines in thickness, originating apparently from the dura mater, and causing sometimes adherence with the vertebræ, in others with the membranes of the spinal cord. In a case described by Virchow of this character the lesion was cervical, and the symptoms were stiffness in the nape of the neck, pains in the neck and arms, and finally paralysis in both arms. A second case is elaborately described by Heubner in his article in *Ziemssen's Encyclopædia*.

SYMPTOMS.—As the lesion of gummatous spinal syphilis affects primarily membranes of the cord, in the beginning of the attack the symptoms chiefly arise from the implication of the nerve-roots. Of course these symptoms vary with the seat of the lesion, for it must be remembered that the meningeal irritation is at first usually localized in a small region. As in a majority of cases this lesion affects a posterior portion of the cord, and as the posterior nerve-roots seem especially sensitive to irritations of this character, pain is usually a very marked and

¹ Winge (*Dublin Med. Press*, 2d Series, vol. ix., 1863); Moxon (*Dublin Quarterly Journ.*, li., 1870); Charcot and Gombault (*Archiv. d. Physiologie*, tome v., 143, 1873); Schultze (*Archiv. Psychiat.*, xii. 567); Thos. Buzzard (*Diseases of Nervous System*, 1882, p. 407); Julliard (*Étude Crit. sur les Localis. Spinal de la Syphilis*, 1879); Westphal (*Arch. Psychi.*, vol. xi.); Greif (*Arch. Psychi.*, xii. 579); Homolle (*Progrès méd.*, 1876).

precocious symptom of spinal syphilis. The seat of the pain varies with the seat of the lesion. At first the pain is slight, but in most cases it soon becomes severe. It is sometimes situated at a fixed spot on the spinal column, where, according to Heubner, it may be increased on pressure. I have seen two or three such cases, but have and still do believe that under these circumstances the patient was suffering not simply from a spinal syphilis, but also from an implication of the vertebral periosteum or of the vertebræ themselves. In one of my cases this diagnosis was confirmed at the autopsy. When the lesion is purely meningeal there is probably no marked local tenderness. The severe pains usually felt in the extremities or in the trunk are often fulgurant; sometimes they are described as resembling the thrust of a knife, and not rarely they closely resemble the pains of locomotor ataxia. In some instances the pains are comparatively slight and are aching in character. Paræsthesiæ are not rare phenomena: such are formications, tingling in the extremities, numbness and feeling as though the limb were asleep, intense sense of coldness on the surface, sensation of water running over the limb. Early in the disorder there is sometimes very marked hyperæsthesia, but later, even though the pain persists, blunting of sensibility is marked, and there may be a complete anæsthesia. This anæsthesia is sometimes localized in certain parts of the limb. Thus, in a case reported by Alfred Mathieu,¹ although there was complete anæsthesia of the outer side of the left leg and foot, the inner side retained its normal sensibility. In some cases there is the abdominal cincture of ordinary myelitis. The records show that even in these early stages there may be diplopia, amblyopia, or other disorder of vision, and the pupil may be distinctly affected. In these cases it is probably the upper portion of the cord which is affected.

Disturbances of motility in the majority of cases do not develop until some time after sensation has been affected, but may come on very early. Usually, the first symptoms are those of irritation, such as rigidity of the neck, back, and limbs or even of isolated groups of muscles. Tremors have been described as frequently present. These may be convulsive, and are often plainly reflex in their origin; indeed, I am inclined to believe that they are always reflex tremblings, and never true tremors. Heubner describes a case in which a paralyzed limb was thrown into violent tremblings whenever passive motion was attempted. The patella-reflex is usually grossly exaggerated, although it may be lost in the later stages of the disorder. Not rarely there is the condition which has received the misnomer of spinal epilepsy. This exaggeration of the reflexes may be limited to one leg, when it is almost pathognomonic. In some cases severe cramps are excited by movement. Usually there is no tenderness. These symptoms of the meningitic stage may continue for weeks or months without there being pronounced paralysis, although locomotion is not rarely interfered with by the stiffness of the legs. Finally, if the case progresses the patient notices a weakness in one or both legs, or (if the disease be situated high up in the spinal cord) in one arm, which rapidly increases until there is almost complete loss of power. This rapid increase of palsy following long-continued disturbance of sensation is almost pathognomonic. In most cases one side of the body is more

¹ *Ann. de Dermatol. et Syph.*, vol. iii., 1882.

affected than the other. The sphincters are prone to be implicated, and in advanced stages of the disease there is usually complete loss of control over the bladder and rectum. The patient may live for months without very distinct change of this condition, or bed-sores and other trophic disturbances may rapidly develop and death ensue in a short time. I have seen under these circumstances marked elevation of temperature, rapid feeble pulse, mental weakness, and the general symptoms of septicæmia last for many weeks. Ammoniacal cystitis is of course prone to be developed during this stage. When motility fails, sensibility is usually blunted, although the pains may even increase. Heubner affirms that an incompleteness of the anæsthesia is characteristic of the disorder.

The typical course of spinal syphilis, such as has been described, may be variously departed from. Sometimes the power of co-ordination is early affected, and the symptoms may resemble those of locomotor ataxia. I doubt, however, whether under any circumstances there is a loss of the patella-reflex in the early stages of the gummatous disease of the spinal cord. In other cases the paralytic symptoms may be very prominent from the beginning: thus, in the case of R. P——, aged 27, which I believed to be gummatous disease of the spinal cord, the first disorder was a feeling of malaise lasting for about a week, followed by the sudden, rapidly-developed paralysis of the bladder, loss of power in the legs, and to a less extent in the arms, the only pain being a dull, steady ache in the arms. The bowels were obstinately costive. Double vision was soon very pronounced. When I first saw the patient, about three weeks after this, there was decided impairment of sensibility in the legs, but not in the arms; marked muscular weakness of both legs and arms; no loss of co-ordinating power; dropping of the right eyelid, with double vision; and only some slight aching pains in the arms. By the use of large doses of iodide of potassium and other appropriate measures a good recovery was secured.

A case illustrating the occasional difficulty of diagnosing spinal syphilis is reported by C. Eisenlohr.¹ The first symptom was obstinate constipation, with very great discomfort after defecation; then appeared incontinence of urine with weakness of the legs: finally, a sudden complete palsy of the right leg occurred, with marked anæsthesia in both legs, partial loss of power in left leg, violent boring abdominal pains, and distress in the bladder. In the last stages there were severe neuralgic pains in both legs, with complete loss of sensation, bed-sores, atrophy of the leg-muscles, with reactions of degeneration, and death from exhaustion. At the autopsy an advanced meningitis was found which had apparently commenced in the regions of the cauda equina, and given rise to complete degeneration of the nerves. The only alteration of the cord was an ascending degeneration of the posterior columns.

Again, owing to the diseased condition of the vessels, a spinal syphilis may be suddenly interrupted by an apoplectic accident.

In a patient of my own, who was believed to be suffering from gummatous spinal meningitis, there was an abrupt development of violent tearing pains, loss of power and sensibility, and all the other symptoms which are characteristic of meningeal spinal hemorrhage. A. Weber

¹ *Neurolog. Centralb.*, 1884, p. 73.

reports a case in which, after doubtful premonitory symptoms, such as vertigo, loss of power on the right side, pressure on the top of the head, and tinnitus aurium, there was a sudden development of convulsions, and death. At the autopsy a syphilome of the right vertebral artery was found with a recent thrombosis of the basilar artery.¹

TUMORS OF THE BRAIN AND ITS ENVELOPES.

By CHARLES K. MILLS, A. M., M. D., AND JAMES HENDRIE LLOYD A. M., M. D.

DEFINITION.—Under the head of Tumors of the Brain and its Envelopes will be considered all forms of growths occurring within the skull, whether these involve the cranium itself, the membranes of the brain, the brain-substance, or several of these parts conjointly. A large majority of these growths spring from the brain-membranes.¹

With the exception of such merely substitutional terms as cerebral or intracranial growths, neoplasms, or adventitious products, we have no general synonyms for brain tumors.

The literature of the subject of brain tumors is second only to that of such subjects as syphilis and hysteria. Vol. ii. of the *Index Catalogue of the Library of the Surgeon-General's Office, U. S. A.*, contains no less than 632 references to this subject: number of books, 43; articles, 589. The books and papers occur in different languages, as follows: British, 142; French, 174; German, 133; American, 91; Italian, 30; Latin, 15; Swedish, 14; miscellaneous, 33.

ETIOLOGY.—Under predisposing or constitutional causes are first to be classed such special inheritances as tuberculosis or carcinoma and tendencies to vascular degeneration. The occurrence of syphilis of course predisposes its victims to cerebral or membranous growths, as it does to other so-called tertiary forms of this disorder.

Hereditary predisposition only enters in so far as the individual inherits a general tendency to the development of such affections as cancer and tubercle. Hereditary tendency to a brain tumor per se does not exist, but the individual who is of the tuberculous or cancerous diathesis under special causes may develop an intracranial growth. As to the comparative frequency with which diathetic tumors originate, a reference to the tabular statement which will be given under Path-

¹ To this article will be appended a table of one hundred cases of brain tumor. Our researches included the investigation of many more cases, four to five hundred in all. Such a table, indeed, could be indefinitely extended. Our object, however, has been not so much to present a large number of cases, and these in great detail, but rather in the most condensed manner to give a definite number, carefully selected, from which to draw conclusions. The cases have not been chosen with the view of upholding any peculiar or preconceived views as to pathology, diagnosis, localization, etc., but because of the carefulness with which they have been recorded. They have been selected also, as will be seen, with the view of determining by clinico-pathological data the possibility of localizing such growths during life. Many of our general conclusions as to pathology, symptomatology, and diagnosis have been drawn from this table.

ology will be sufficient. Gliomata are very common, but with them vie in frequency sarcomatous, tubercular, and gummatous growths. Any table, unless it includes a very large number of cases—at least a thousand or more—would be misleading as to the proportionate frequency of these different forms of intracranial constitutional diseases; but it is safe to say that syphilitic, tuberculous, and carcinomatous or sarcomatous tumors are of comparatively frequent occurrence.

Tumors of the brain occur oftener among men than women. This fact is dependent largely upon the difference between the habits and occupations of the two sexes. Men, in the first place, are much more addicted to alcoholic, venereal, and other abuses which give rise to special degenerations or constitutional infection; and secondly, they are more exposed to traumatisms. In 100 cases the tumors occurred among males in 58 cases, among females in 40 cases, and sex was not recorded in 2 cases.

Statistics show that intracranial growths are more likely to occur between puberty and middle age. Although gliomata may be found at any age, brain tumors in children are more likely to be of this character. This is what might be expected from the nature of these growths. Histologically, gliomata are most closely allied to the embryonal stage of the connective tissue, and, according to Cohnheim, tumors generally are the result of a surplusage of embryonal tissue—tissue which has remained over after the requirements of normal development have been met. Of 16 gliomata, 3 occurred in patients under ten years, 2 between the ages of ten and twenty, and 4 between twenty and thirty.

One hundred cases gave the following results as to age:

| | |
|-------------------------------|------------------|
| Under 10 years | 10 cases. |
| From 10 to 20 years | 12 " |
| " 20 to 30 " | 18 " |
| " 30 to 40 " | 24 " |
| " 40 to 50 " | 12 " |
| " 50 to 60 " | 13 " |
| " 60 to 70 " | 3 " |
| Over 70 years | 1 " |
| Not recorded | 7 " |
| | <hr/> 100 cases. |

It is now generally admitted that injuries play a most important part as exciting causes of brain tumors. Frequently in our experience an apparently direct relation has existed between a head injury and the origin of the neoplasm. In 6 out of 12 cases reported by one of us,¹ a history of traumatism was present, although in 5 of these a history of syphilis was also present. The great frequency with which injuries of all kinds occur must of course not be overlooked in this connection. It is said by those who oppose the idea of the direct causal relations of injury that almost every one could trace such disease to falls or blows which few escape. In some of the cases of brain tumor, however, the history of injury bears a direct relation in time to the initial symptoms of the tumor. Certain tumors, as the fibromata, osteomata, angiomas, would appear to be of more frequent occurrence as the direct result of traumatism. The part played by injuries in the production of carcinomata and sarcomata, whether in the brain or elsewhere, has not infre-

¹ *Archives of Medicine*, vol. viii. No. 1, August, 1882.

quently been the subject of dispute. We have no doubt that, a constitutional predisposition existing, an injury frequently leads directly to the development of some form of malignant growth. In not a few of the syphilitic cases the history would appear to show that an injury to the skull had localized the constitutional poison.

Echinococci and cysticerci are found within the cranium, and sometimes give rise to tumors, but the statement of Obernier can hardly be regarded as true, that they play an important part in the production of cerebral tumors. Our table shows only two cases of this kind.

SYMPTOMATOLOGY.—The symptoms of intracranial tumors from the standpoint of the course or progress of the affection can be divided into an early or beginning, a middle or developed, and a late or terminal stage.

Headache, vertigo, and vomiting are early symptoms, varying in severity from slight to very serious manifestations, and slight and changing mental phenomena are present. Eye symptoms, such as slight diminution or blurring of vision, may or may not show themselves; the ophthalmoscope may reveal the earliest appearances of choked disc or neuroretinitis.

In the second or middle stage, the period of the fully-developed disease, we have an intensification and greatly increased constancy of all the general symptoms, with some additional manifestations. Mental disorder increases; headache becomes more violent, and sometimes more localized; amblyopia tends to advance to complete blindness, with marked swelling of the papilla, or special disorders of vision, such as hemianopsia, occur; palsies, ataxia, convulsions, contractures, rigidity of limbs, altered reflexes, local spasms, anæsthesia, hyperæsthesia, paræsthesiæ, neuralgias, appear according to the extent and location of the growth. Certain special phenomena, according largely to the seat of the tumor, may also appear, such as disorders of hearing, taste, or smell, polyuria, diabetes, albuminuria, polyphagia, or dysphagia.

In the third or terminal stage paralysis, anæsthesia, convulsions, etc. become more profound; mentality sometimes decreases to nearly complete imbecility, although in many cases a fair amount of mental power is preserved almost to dissolution. Involvement of the bowels and bladder becomes a distressing symptom, involuntary evacuations adding to the torments of the patient. Bed-sores, acquired or trophic, appear; the patient's limbs are painfully contracted; great emaciation is usually present. With agonized head, often blind or deaf, with torturing pains in anæsthetic, paralyzed, and wasted limbs, covered with painful sores, filthy involuntarily, imbecile or demented, death comes as a thrice-happy relief.

Cases have been reported in which intracranial tumors of considerable size were discovered on autopsy, and had evidently been present for years without their presence having been discovered or even suspected; but these are extremely rare. In general terms, however, it may be said that every case of brain tumor must give rise to symptoms. These symptoms may be few or many, slight or severe, brief or protracted, constant or paroxysmal, according to circumstances. Our experience and study of the literature of the subject lead us to the conclusion that the pathological character of the growth would have some influence as to the severity and prominence of symptoms. Gliomata—which are

sometimes hard to distinguish from the brain-substance, particularly the soft gliomata, producing comparatively little pressure—when located in certain so-called latent areas of the brain might escape detection during life; so might also very small tumors of any kind situated deeply in the substance of the brain.

The position taken by Obernier, that individuality has much to do with the activity of symptoms of brain tumor, has some strength. He refers particularly to the psychical response to the irritation caused by brain tumors, which differs very much in different individuals. The fact, which has been pointed out in the article on Hysteria, that hysterical symptoms are often present in cases of brain tumor as well as in other forms of organic disease, is also sometimes the cause of mistake by the diagnostician. The cases of Hughes Bennett and Eskridge will be referred to in this connection under Diagnosis.

When the subject of local diagnosis is considered farther on, those regions which are most active and those which hold an intermediate position in the production of particular and distinctive symptoms will be more particularly discussed.

The possibility of the existence of multiple tumors should never be overlooked. These are of comparatively frequent occurrence, and sometimes give rise to a puzzling symptomatology. In our search through the literature of the subject for cases we met with many examples of multiple tumors. In preparing our table multiple tumors were usually omitted. They give sometimes symptoms and signs so conflicting as to make a local diagnosis impossible, and even to confuse the expert as to general diagnosis. In other cases, however, one growth of larger size or in an active region takes command of the situation, and leads clearly to its diagnosis in spite of other less significant tumors. This was shown, for example, in one of our cases (Case 14). From the symptoms not only was the presence of the larger tumor diagnosticated, but its exact location was indicated during life. Post-mortem examination, however, showed a smaller tumor at the inferior angle of the right lobe of the cerebellum, and also some basal meningitis with effusion which had not been suspected. The first tumor was one of the ascending frontal convolution, extending into the fissure of Rolando. Its presence and location had been diagnosticated by the right brachial monoplegia and paresis of the leg, which later increased to paralysis of the limb, with right facial paresis, ptosis, partial anæsthesia of right side of face, and slight clonic spasms of the right arm. At the present time, when the question of operating for the removal of brain tumors is so prominently before the profession, and is now generally regarded as justifiable for growths in this one location, the cortical motor area, the possibility of the coexistence of another tumor should be carefully weighed. In this case, owing to the clear diagnostic indications, the question of operation was considered at the time of consultation, but fortunately—in large part because the patient was almost in extremis—it was decided not to operate. The operation would have been futile, the autopsy showing that the probable immediate cause of death was the basilar effusion which accompanied the cerebellar growth.

In another case reported by one of us¹ three gummata were found in

¹ *Arch. Med.*, viii. No. 1, August, 1882.

three different locations: one in the prefrontal region, another in the retro-central fissure, and a third in the supramarginal convolution. The general symptoms of brain tumor were present in this case, but no localization was possible.

The following are other illustrations of multiple tumors and of tumors with other lesions out of a large number which we have collected:

M. 44.—Several severe falls on the head. Recent chancre with secondary symptoms. Six months before death headache which grew worse; most severe in right supraorbital region, and also obstinate vomiting, vertigo, hiccough, insomnia. Some loss of power on both sides. Slow in answering and indisposed to talk. Choked discs. Involuntary evacuations. Some improvement under treatment, and then relapse. Complete blindness. Polyuria. Specific gravity of urine as low as 1003 and 1005. Appetite at times ravenous. During last few weeks of illness head inclined to the right side, probably from spasm. Intense thirst throughout the illness.

(1) Large sarcoma in the white substance of the right parietal and frontal lobes, involving ascending parietal convolutions. (2) Softening and abscess of the right temporo-sphenoidal lobe and posterior base of the right anterior lobe. Softened mass size of a hickory-nut in the upper portion of the right ascending frontal convolution. (3) Small cystic tumors of the choroid plexuses.¹

M. 5.—Convulsions, beginning either in right foot or in right face; not unconscious during fits. Right-sided hemiplegia. Double optic neuritis, followed by atrophy. Gradual increase in size of head, with gaping sutures. Later, rigidity of right arm and leg. Shortly before death the following symptoms suddenly set in: headache, convulsions of right side with unconsciousness and retraction of head, rigidity of right arm, and tremor of right leg. Later, both arms flexed, with constant tremors of left arm, spreading over whole body. Right sterno-cleido-mastoid was stiff; almost opisthotonos.

(1) Enormous tubercular tumor of left cerebral hemisphere, extending from depth of Sylvian fissure and eroding skull. Corpus striatum soft and diffuent. Weight, over eleven ounces. (2) Tumor, double size of pea, in lower part of middle lobe of cerebellum.² This case was especially interesting for the onset of the cerebellar symptoms late in the case, caused probably by a late appearance of the cerebellar tumor.

M. 2.—Screaming fits. Vomiting. Paralysis of left side of face, including corrugator and orbicularis palpebrarum. Winking in both eyes suspended. Paralysis of external rectus muscle. Agitation and contractures of right arm and leg. Later, unsteady movement of head and right arm and jerking of right leg.

(1) Small glioma in left hemisphere of cerebellum, and (2) a similar tumor projecting from left lateral half of floor of fourth ventricle at common nucleus of the abducens and facial nerves.³

F. 45.—Epileptiform attacks for fourteen years. Vertigo, occipital headache, disordered vision, intolerance of light, sleeplessness, excitability, constipation, with paræsthesia of left side. Retraction of head,

¹ J. T. Eskridge, *Trans. of Philada. Path. Society*, for 1878-79, vol. ix. p. 119.

³ W. H. Broadbent, *Proc. Clin. Soc. Lond.*, v. 66-68.

vomiting. Very late, convulsive movements of right eye and right side of mouth; then general clonic spasms, coma, and death. No paralysis. For twenty-six years there had been an induration of one breast, which toward end of life had a somewhat scirrhus appearance.

(1) Glioma in right hemisphere of cerebellum $1\frac{3}{4}$ inches in diameter. (2) Glioma in centre of middle lobe of left hemisphere of the cerebrum $\frac{3}{4}$ inch in diameter. Surrounding nervous tissue softened and broken down.¹

M. 65.—Sudden attack of spasm of left arm, with paresis and coldness and numbness. Headache and staggering. Wandering in mind. Not unconscious. Twitching in eye. Two days later violent convulsion in entire left half of body, with vomiting; not unconscious. After convulsion left hemiplegia, with left deviation of tongue. Head and eyes turned to right; vertigo. Partial anæsthesia of left face, body, and limbs. Paræsthesia; painful nervous shocks through affected limbs. Sounds in back of head. Later, mind cleared up and many symptoms ameliorated. Very late, convulsion and coma. Cheyne-Stokes respiration, involuntary evacuations. Duration, seven weeks.

(1) Tumor in ascending parietal convolution at junction of upper and middle thirds. (2) Large tumor occupied entire occipital lobe, but did not present on surface, reaching to convexity of descending cornu of lateral ventricle.²

Headache is the most frequent and positive symptom of brain tumor. It is rarely absent; in most cases it has peculiar characteristics. Its usual type might be described as continuous pain, sometimes of persistent severity, but generally with exacerbations or paroxysms of great violence. No suffering can surpass that which some of the victims of intracranial neoplasms are compelled for months or years to endure. It is only equalled by the torture produced by malignant growths in the vertebral axis, the throat, or the bones of the pelvis. The pain is not, however, always of this character. In a comparatively few cases it is described by the patient as dull or moderate, or he simply complains of distressing sensations of weight, pressure, or constriction. Usually in these cases, however, the pain increases and becomes less and less endurable. In 100 cases the headache is described as agonizing, violent, severe, or torturing 20 times; as moderate or dull, 26 times. It is simply mentioned 20 times, but here presumably it was of the ordinary severe type. Thus in 66 cases, or 66 per cent., headache of some type was recorded. No mention was made of headache at all in 29 cases, in some of which, however, it was doubtless present. In only 5 cases was it stated not to have been present: 3 out of these 5 were said to be gliomata, and of the other 2, one was probably gliomatous, and the other a cyst in the brain-substance. Tumors of this kind, which exert comparatively little pressure and which are not connected with the membranes, are probably those which are least likely to cause pain. In several instances the patients complained spontaneously of the pain being greatest in the region of the head nearest the seat of growth. With reference to cerebellar tumors, it is somewhat generally supposed that occipital pain is usually present. It

¹ William L. Bradley, *Tr. Conn. Med. Soc.*, 1880, p. 39.

² W. H. Broadbent, *Tr. Clin. Soc. Lond.*, v. 233-236.

sometimes is and sometimes is not. In 15 cases of tumor of the cerebellum and of the fourth ventricle the pain was described as occipital twice, as fronto-occipital three times, and as cervico-occipital once. Callender has noticed that cortical lesions are more frequently accompanied by localized pains than lesions of deeper parts.¹ Some of our cases would seem to bear out this view, although the data are not numerous or complete.

In a few cases percussion of the head elicited or intensified pain in the region corresponding to the location of the tumors. We believe that percussion of the skull may afford valuable aid in localizing encephalic tumors, particularly when they are meningeal or cortical. Ferrier² holds that percussion often elicits pain over the cranial region beneath which a lesion is localized, and Alex. Robertson of Glasgow³ has also directed attention to the value of percussion of the skull in the localization of disease on the surface of the brain.

Vomiting is of frequent occurrence, although it does not usually come on as early or remain as persistently as headache. It is more likely to be paroxysmal, with longer or shorter intervals of relief. It frequently occurs at the time of the exacerbations of the headache, and between the paroxysms of vomiting, nausea, slight or great, is often present. It probably occurs in about 50 per cent. of all cases of brain tumor. It is recorded as having been present in 34 out of 100 cases. It was comparatively infrequent in antero-frontal growths, occurring only twice out of 10 cases.

A case reported by one of us (Case 70) was a remarkable example of persistent cerebral vomiting. For four weeks before her death the patient vomited almost incessantly. The tumor in this case involved the middle cerebellar peduncle and the adjacent region of the right cerebellar hemisphere, and had grazed and superficially softened the floor of the fourth ventricle.

We incline to agree with Ferrier⁴ that the majority of cases of cerebral vomiting can be ascribed to irradiation of irritation by the nerves of the cerebral membranes or to the physical effects of acute pain. The nuclei of the trigeminus and of the vagus are in close anatomical relationship in the medulla oblongata. Irritative impressions conveyed from the cerebral membranes, and particularly from the dura mater, to the trigeminal nuclei in the medulla are transferred to the vagus and give rise to vomiting. In tumors of the cerebellum the vomiting may be brought about through the affection of the centres of equilibration and the concurrent vertiginous sensations (Ferrier), or it may be due to direct irritation by contiguity of the floor of the fourth ventricle. In general, the tumors situated farthest forward in the brain appeared to be the least likely to give rise to vomiting.

Vertigo was noted in 31 out of 100 cases. Under this general designation dizziness, giddiness, reeling, insecurity in the erect posture, etc. have been included. The vertigo can be explained in several ways

¹ *St. Bartholomew's Hospital Reports*, 1869, and Ferrier's *Localization of Cerebral Disease*, p. 99.

² *Brain*, January, 1879.

³ *Abstr. Internat. Med. Congress*, 1881, p. 85, and *Journal of Nervous and Mental Disease*, April, 1882.

⁴ *Brain*, July, 1879.

besides by the view which refers it to an affection of centres of equilibration in the cerebellum. Like headache and vomiting, it seems sometimes to be the outcome of pure irritation of the cerebral membranes. Alterations in the intracranial circulation produced by the growth of the tumor is another probable cause. Experiments have demonstrated the existence of a communication between the arachnoid cavity and the labyrinth, and consequently the increased intracranial tension present may result in pressure on the labyrinthine fibres of the auditory nerve, and thus occasion vertigo.

The importance of ophthalmoscopic examinations in suspected cases of brain tumor can scarcely be overestimated. They will often serve to clinch the diagnosis in favor of tumor. Of the 100 tabulated cases, choked discs were recorded in 8; optic neuritis or neuro-retinitis in 18. These results serve to show the importance of the examination of the eyes. It will be seen that with Allbutt, Norris, and others we make a distinction between choked disc, papillitis, congestion papilla, or ischæmia of the discs, and descending or interstitial neuritis. The differences between these two varieties of inflammation of the interocular ends of the optic nerve are well presented by Norris in a previous volume of this work,¹ which will make it unnecessary for us to describe the conditions present in these cases. An examination of the tabulated cases will show that true choked discs were present in tumors situated in all portions of the encephalon. They were not infrequently present in tumors of the convexity. Descending neuritis would seem most likely to occur when the tumors are so situated that inflammation set up by them can readily extend by anatomical continuity along the membranes to the optic nerves. The lymph-space theory best accounts for the occurrence of choked discs in cases of tumor situated remotely from the base. In choked disc the appearance is one of intense swelling and engorgement of the optic papilla. In descending neuritis, as described by Graefe and Norris, there is rather a dull-red suffusion of the disc. Some of the cases reported as neuritis may have been choked discs, and the reverse, as physicians often do not make any distinction.

Several practical matters should be borne in mind in connection with this subject of the condition of the eye-ground. In the first place, sight is not always impaired in cases of even somewhat advanced choking of the disc, so that when other symptoms and indications lead to the suspicion of a brain tumor, unexpected confirmation may be obtained by ophthalmoscopic examination. Some remarkable cases of this kind have been reported, and doubtless have been observed by all ophthalmologists and neurologists of large practice. In some cases of growths of large dimensions also careful ophthalmoscopic examination has shown neither choked disc nor neuro-retinitis to be present. In two of Seguin's cases, for instance (Cases 28 and 29), these appearances were absent. In one he reports no neuro-retinitis, but only some fulness of the veins. In the other, a large sarcoma of the centrum ovale, ophthalmoscopic changes were absent. The absence of disturbance of vision, therefore, should not lead the physician to overlook making a thorough ophthalmoscopic examination; nor should the absence of ophthalmoscopic appearances lead him to make up his mind that serious intracranial disease was not present.

¹ Vol. IV, p. 771 *et seq.*

The presence of double choked discs is in the highest degree significant of a brain tumor.

Observations on the temperature of the head have been made in a few cases of tumor of the brain. Full accounts of such observations in two cases (1 and 3 of Table) have been published by one of us.¹ It is not within the scope of the present paper to review the general subject of cranial or cerebral thermometry. We will simply, in passing, recall the labors of E. Seguin,² Broca,³ Gray,⁴ Lombard,⁵ Maragliano and Seppilli,⁶ and Amidon.⁷

L. C. Gray⁸ has recorded some observations in cerebral thermometry in one case of tumor of the brain. The tumor, a soft jelly-like mass the size of a hazelnut, was found between the horizontal branch of the Sylvian fissure and the first temporal fissure, while the whole of the right occipital lobe was converted into a colloid, extremely vascular mass, which gave way under examination, this degeneration also extending anteriorly to the tumor as far as the fissure of Sylvius. Microscopical examination showed it to be a typical glioma.

The temperatures at different stations were as follows :

| | Left. | Right. |
|---------------------|--------|--------|
| Frontal | 96.75° | 98.33 |
| Parietal | 95° | 99.75 |
| Occipital | 96.75 | 100.50 |

The average of the left side was 96.16°; of the right, 99.52°; of the whole head, 97.84°.

In a case of frontal tumor (Case 1 of Table) the average temperatures of the different stations taken were as follows :

| | |
|----------------------------------|-------|
| Middle frontal station | 96.5° |
| “ occipital “ | 95.5° |
| Right frontal “ | 95° |
| Left “ “ | 94.7° |
| Right parietal “ | 94.7° |
| Left “ “ | 94.4° |

In another case, reported in full by one of us⁹ (Case 94), a gumma involved the basal termination of the corpus callosum, the peduncles of the corpus callosum, the lamina cinerea, and anterior perforated spaces; and the average temperatures at the different stations were as follows:

| | |
|---|-------|
| Right frontal station | 97.1° |
| Left “ “ | 97.4° |
| Right parietal “ | 97.6° |
| Left “ “ | 94° |
| Right occipital “ | 97° |
| Left “ “ | 94.5° |
| Right anterior vertical station | 97° |
| Left “ “ “ | 94° |
| Right posterior “ “ | 96.6° |
| Left “ “ “ | 94.3° |

⁶ Quoted in *Archives of Medicine*, 1879.

⁷ *Archives of Medicine*, April, 1880.

⁸ *N. Y. Medical Journal*, August, 1878.

⁹ *New York Medical Record*, Aug. 9, 1879.

In a gumma in the cortical motor zone of the right side the head-temperatures, taken once, were found to be for the right parietal region, 97.2° ; for the left, 96° . In another tumor of the right motor zone the right frontal region gave a temperature of 98° ; the left, of 96° . In a tumor of the left occipito-parietal region the temperatures were for the right parietal region, 98° ; for the left, 97.8° . Although the temperature of the head was only taken once in each of these three cases, the observations were carefully made with tested thermometers.

J. T. Eskridge, in a case of a tumor of the cerebellum with monocular hemianopia (Case 76), made the following temperature observations:

| | |
|------------------------------------|---------------------------------------|
| Axillary | R. 98.6° ; L. 98.6° |
| Head: | |
| Anterior frontal station | R. 98.4° ; L. 98.4° |
| Posterior " " | R. 98.5° ; L. 98.6° |
| Superior " " | R. 98.4° ; L. 98.4° |
| Parietal " " | R. 99.2° ; L. 98.6° |
| Rolandic " " | R. 98.8° ; L. 99.1° |
| Occipital " " | R. 99.4° ; L. 99.1° |
| Posterior central " | 99° . |
| Anterior " " | 99° . |

The normal average temperatures, as determined by Gray, were as follows:

| | |
|---|-----------------|
| Left frontal station | 94.36° |
| Right " " | 93.71° |
| Left parietal " | 94.44° |
| Right " " | 93.59° |
| Left occipital " | 92.66° |
| Right " " | 91.94° |
| Left side of the head | 93.83° |
| Right " " | 92.92° |
| The whole head, exclusive of the vertex | 93.51° |
| Motor region of the vertex | 91.67° |
| The whole head, inclusive of the vertex | 92.66° |

We conclude that in brain tumors the average temperature of the whole head is elevated several degrees above the normal, and that the elevation of temperature is usually greatest at the station nearest the seat of the growth.

Mental disturbance of some description was present in about one-third of all the cases studied. Doubtless they were not recorded in a large number of cases. Obernier says: "If the psychical qualities of a patient suffering from cerebral tumor be analyzed, and a careful comparison made of the former with the existing mental condition, certain symptoms of mental disturbance will be discovered in most cases where the tumor is a growing one." The disturbances may be in any sphere of the mind—in intellection, volition, emotion, or perception. Mental slowness and uncertainty, inability to fix the attention, impossibility of continuous mental action, apathy, or stupidity, with hesitation or slowness of speech, were strikingly exhibited in cases of tumor of the antero-frontal region. In Case 1 the patient's mental condition was studied with great care, and in the detailed report of the case¹ the following facts were noted: The psychical manifestations were among the most important features of the case. Although comparatively uneducated, he had been when

¹ *Philadelphia Medical Times*, Jan. 18, 1879.

in health intelligent and energetic. He had never during his illness had the gay humor or delirium of grandeur seen in the general paralysis of the insane. His condition, on the whole, was one of intellectual slowness and uncertainty. He seemed to have great difficulty in receiving mental impressions and in directing the movements of his body. His faculty of attention was, in great measure, destroyed. It could only be fixed, and then but partially, by distinctly and vehemently repeating a question or command. He could hear, but it was necessary to make a tremendous external impression on his sense of hearing in order to call out a mental response. He sometimes appeared to me like a man dazed by a great catastrophe which he could not understand. He was not aphasic, although he manifested certain striking peculiarities of speech, or, rather, of the manner of speaking. What he said, either spontaneously or in answer to questions, was spoken clearly and distinctly and in a firm, loud voice. His sentences were short, but complete; neither words nor syllables were omitted; and he made no mistakes in articulation, enunciation, or pronunciation. In answering he did not seem to be able to retain for any length of time a hold upon the same idea or to follow a particular train of thought. He did not wander from one subject to another, but he would suddenly stop speaking, as if unable to go farther. Often on being questioned he would try to reply, and after a sentence or two would sob and burst into tears like a violently hysterical woman. He would at times have what might be termed volcanic outbursts of speech. When all was perfectly quiet in the ward he would suddenly explode with a sentence or two, and then again subside into stillness. Exclamations of this kind might be repeated at intervals of a few minutes for hours together, or they might recur only at intervals of hours. Sometimes what he said would be connected with some past events of which he seemed to have a vague recollection; often it would be a demand for something to eat or drink; and often, again, it would be a paroxysm of profanity.

Impairment of will is not uncommon in antero-frontal and other cerebral tumors, and failure of memory, depression of spirits, and even acute mania, occur. Many of the patients are emotional, excitable, and irritable; they often sob and cry, apparently from the great pain. In some cases, however, emotional conditions are present which seem to be dependent on some special localization of the tumor. Hallucinations were noted in two of our tabulated cases. In one case, a tumor of the motor zone, the patient had delusions that some one was about to take him away. There were also illusions of fear or persecution. In another the patient had visual hallucinations.

Speech-defects of various kinds occur in connection with intracranial growths. Ladame, quoted by Rosenthal, has cited forty-five cases of disturbances of speech in which the tumor occupied the most varied regions of the brain. Peculiar disorders of speech from special localizations will be treated of under Local Diagnosis.

Local spasms, which go under various names, as cramps, twitchings, epileptoid attacks, athetosis or athetoid movements, are common symptoms, particularly of growths which involve the cortical motor area. They are of great diagnostic value. They are commonly, although not invariably, accompanied by paresis, which is usually most marked in the

part most affected by the spasm. These local spasms, beginning in one extremity, in a finger or toe it may be, often spread toward the centre, until they involve to a greater or less extent the whole limb, the side of the face, or one-half of the body. Sometimes instead of this they recur with the same definite movements over a long period. They are the expression of irritation of cerebral centres or tracts connected with the muscles or groups of muscles affected by the abnormal movement. They should always lead the physician to carefully consider the great probability of a lesion in some way involving the motor area.

Tumors of the cerebellum, pons, and medulla oblongata sometimes give rise to general convulsions which closely simulate attacks of grave epilepsy. These convulsions or general spasms are among the most important symptoms of intracranial neoplasms. More than paralysis, they may be regarded as general symptoms, as they are more likely to occur from tumors situated in different and distant regions of the brain than paralysis. They are by no means confined to cases in which the lesion is situated in the so-called motor area of the brain or in the cerebellum or pons-medulla region. Both physiological and pathological experiments have shown that convulsions violent in character, but having certain special characteristics, may originate from severe irritation of the dura mater. According to Duret,¹ irritation of the sensory nerves of the dura mater cause reflex spasms or contractures of the muscles of organic life. These spasms or contractures may occur in the face, eyeballs, neck, trunk, or limbs, and sometimes on one side and sometimes on the other. They tend to diffuse and invade neighboring groups of muscles. "They have never the localization, the measured and purposed character, of the contractions which belong to the lesions of the cortex. They frequently become transformed into permanent contractures." The application of these facts and conclusions to brain tumors is evident. As neoplasms are so frequently connected, either directly with the dura mater or with the fused membranes, it is evident that the convulsive attacks from which the patient suffers may occur from tumors located anywhere within the cavity of the skull.

General convulsions, as well as local or unilateral spasms, are present in many tumors of the motor cortex; but if their method of origin and their progress are closely watched they will usually be seen to begin with local twitchings.

A glance at the table will show examples of convulsion in almost every region of the brain.

Contractures—conditions of tonic spasm which continue more or less persistently—may be either early or late symptoms. They may occur in one or several limbs, in the face, or rarely in the neck. They are probably due in some cases to persistent irritation of the dura mater, in others to comparatively slight but continuous irritation of motor centres, and in still others to advanced degeneration of the motor tracts.

Choreas and choreic movements are not frequent, unless some of the forms of local spasm are regarded as local choreas. In one of Petrina's cases, a glioma involving the substance of both frontal lobes, choreic movements of the right arm were present, and in this same case tremor

¹ *Sur les Traumatismes cérébraux*, par H. Duret, chapter iii., summarized in *Brain*, vol. i., 1878, p. 47.

in both arms was also a symptom. Tremor simulating that of paralysis agitans or multiple cerebral sclerosis is occasionally observed, and sometimes a tremor which is nervous or hysteroidal in character is one of the results of the great suffering of the patient.

Paralysis or paresis is of course one of the most frequent evidences of the existence of an intracranial tumor. The palsies of cerebral tumors are chiefly unilateral, but the loss of power may be in one or both limbs, in one side of the face, or in the entire one-half of the body, according to location and extent. Tumors of the cortical motor zone usually begin their paralytic manifestations with paresis of one member or one side of the face, which goes on, as the growth increases in size, to more or less complete hemiplegia.

The paralysis which results from brain tumor is due either to pressure or to absolute destruction of tissue. In the latter case the destruction is brought about not only by the simple displacement of brain-substance, but also through the obliteration of blood-vessels and the consequent softening.

Peculiar forms of paralysis occur as the result of neoplasm growing in special locations, as will be more clearly shown under Local Diagnosis. Thus we have the alternating paralyses from tumors of the crus cerebri or of the lower part of the pons, and paraplegia, or perhaps what might be better called double hemiplegia, from multiple tumors which affect both sides of the brain. In rare cases paralysis of all four extremities has resulted from a growth in the middle line of the base of the brain. Some form of paralysis is recorded to have been present in 20 cases out of 100.

Apoplecticform attacks sometimes take place suddenly during the progress of cases of brain tumor. A patient who has been suffering for months with the general symptoms of tumor, and who may or may not have had some paresis of the limbs or face, has an attack of unconsciousness, from which he arouses after a time, and is then found to be almost completely hemiplegic. After such attacks, in some cases, the symptoms of brain-irritation, particularly the headache and vomiting, subside or greatly improve. Such attacks may be explained in several ways—from the occurrence of congestion with œdema, of intercurrent hemorrhage, or of softening from obliteration of blood-vessels by the advancing growth; and the temporary subsidence or more permanent disappearance of the headache and other symptoms is probably, in some cases at least, owing to the diminution of tension because of the breakdown of tissue in the neighborhood of the growth. Sometimes the seizures which occur during the progress of the case are both epileptiform and apoplecticform in character.

Sometimes in cases of intracranial tumor there are present in the cranial nerve-trunks and the muscles supplied by them the changes known as the reactions of degeneration. These changes are characteristic of the peripheral palsies, and indeed sharply distinguish them from paralyses of central origin. The exception to this rule in cases of intracranial growths is, of course, only apparent and not real, because these palsies, when caused by the pressure of a tumor on a nerve-trunk, even within the cavity of the skull, and not upon their proper centres or intracerebral tracts, are as much peripheral as though the injury was caused by compression of these nerve-

trunks outside of the skull. These reactions of degeneration are briefly as follows: The nerve-trunk gradually, sometimes rapidly, loses its response to both the galvanic and faradic currents. The muscle loses its response to faradism coincidently with the nerve-trunk, but to galvanism it is apt to exhibit first increased excitability, then gradually lessening excitability: and with this lessening response it puts on the so-called qualitative changes. These consist of the serial alterations—*i. e.* the negative pole, instead of exciting the more active reaction at closure, gives a less response than the positive pole at closure, and also calls forth a response at opening which may be greater than the opening contraction of the positive pole, which may be abolished. In health the positive pole causes often an active response, and the negative pole none, or almost none, at opening. Finally, occur modal alterations in the affected muscles, which consist of a slow, lazy contraction instead of a quick, lively one as in health, and a tendency in the muscle to remain contracted (tetany) while the current is passing. The many modifications—or, better, the partial exhibitions of these changes and the conditions underlying them—are to be sought in detail in special treatises. It is sufficient to say that they have been reported in a number of cases of brain tumor, and that the nerves in whose distributions they would be especially seen are the motor oculi, or third, the abducens, or sixth, and the facial, or seventh. It is doubtful if a very exact electrical examination could be made of many muscles supplied by these nerves, except in the case of the facial, and possibly the elevator of the upper eyelid. It is in the case of the seventh nerve that the recorded observations have been made. It will be noticed, by reference to the table, that the third, sixth, and seventh nerves are frequently involved in tumors of the crus and pons-medulla region, and that the paralysis is usually on the side of the lesion. These are the cases which would exhibit the reactions of degeneration. It has been said that in ordinary hemiplegia, and also in paralyses from tumors of the brain high in the motor region, the affected side exhibits simply a qualitative increase to electrical excitation; and this may be explained by the increased excitability to all stimuli of the lower or spinal-cord centres when cut off from the brain. The statement, however, which has been made, that in tumors of the cerebellum the sound side exhibits a quantitative decrease, sounds like a paradox, and requires further tests before being accepted as a fact in electro-diagnosis.

Ataxia has been observed in cases of brain tumor situated in various locations. The symptom described as ataxia, staggering, or staggering backward, is more particularly observed in cases of tumor of the cerebellum, pons, and corpora quadrigemina.

Changes in the state of the reflexes are somewhat frequent. Usually the skin and tendon reflexes will be increased on the side opposite the lesion, although some striking exceptions, probably due to the positions of the growth, occur.

Atrophy of the limbs is sometimes present, but usually in brain tumor, as the lesions are above the nutritive connection of the nerve, true atrophies do not occur.

True neuralgias are frequent, particularly in the distribution of the trigeminal. Trigeminal neuritis also undoubtedly occurs in lesions

involving this nerve at its origin, in its course, or in the Gasserian ganglion.

Anæsthesia, either in the form of local or hemianæsthesia, was observed in about 20 per cent. of the cases. It is rarely present as an isolated symptom, but frequently accompanies unilateral paresis. In a partial or variable form it most frequently is seen in connection with tumors of the Rolandic region. It is a marked symptom in postero-parietal growths and those involving the posterior part of the internal capsule. It may take the form of loss of sensation to pain, touch, pressure, temperature, etc.

Hyperæsthesia occurs so commonly as to be almost regarded as a general symptom of brain tumor. Sometimes it is confined to the head; sometimes it is generally diffused; more frequently it is present in the limb or limbs affected with the paralysis. With hyperæsthesia the patients often complain of spontaneous pain in the limbs.

Diplopia or double vision is a somewhat frequent symptom, occurring most commonly, of course, when the ocular nerves are involved directly or indirectly by the tumor; hence tumors of the floor of the skull, of the crus cerebri, of the pons, or of the cerebellum are most likely to give rise to this symptom. A close study of the character of diplopia and of other symptoms which go with it will usually enable a local diagnosis to be made. Diplopia, however, does sometimes occur in tumors situated remotely from the base, either because of pressure, because of general nervous weakness, or possibly because of involvement of cortical oculo-motor centres.

Ptoxis is another symptom, generally unilateral, and most frequently present in connection with strabismus, diplopia, and dilatation of the pupil from involvement of the third nerve. Dilatation of the pupil and contraction of the pupil may be present as general symptoms of tumors. The latter is most probably due to meningeal irritation.

Hemianopsia is another ocular symptom sometimes present in cases of brain tumor, as it may also be in other forms of encephalic lesion. It was present in 5 of 100 cases. Norris¹ gives a full description, brought well up to the present time, of this symptom, and a discussion of the lesions upon which it depends. Seguin² also discusses this subject. Starr³ has collected a large number of cases of lesion causing this symptom, some of which have been reproduced in our table. We will not go into any details as to the character of this symptom, referring the reader to the sources indicated. In the first case given in our table (Case 10) the hemianopsia was produced by a tumor in front of, and impinging upon, the optic chiasm; in the other four cases (Cases 40, 41, 42, and 43) the tumor was situated in the occipital lobe, and was surrounded by an area of destroyed tissue. Hemianopsia is not, strictly speaking, a symptom of brain tumor, but is likely to be present in cases occurring in certain regions of the brain. Starr's conclusions with reference to lateral homonymous hemianopsia when it is not produced by a lesion of one optic tract are that it may result from a lesion situated either (1) in the pulvinar of one optic thalamus; (2) in the posterior part of one interior capsule or its radiation backward toward the occipital lobe; (3) in the medullary portion of the occipital lobe; or

¹ Vol. IV.

² Pp. 84, 85 of present Volume.

³ *Amer. Journ. Med. Sci.*, N. S., vol. lxxxvii., January, 1884, p. 65.

(4) in the cortex of one occipital lobe. The conclusions of Seguin are only different in so far as they more closely limit the position of the lesion.

Phosphenes, or subjective sensations of light, occur in various forms—simply flashes or sheets of light, scintillations, balls of fire, etc. They are not very common as isolated phenomena, and probably are dependent in most cases upon irritation of the nerve and retina in some of the stages of neuro-retinitis. Even visual hallucinations are occasionally present, as in one of Bennett's cases of tumor of the Rolandic region.

Conjugate deviation of the eyes, with rotation of the head, a symptom of the early stages of apoplectic attacks, is also sometimes observed in brain tumor. The patient is found with both eyes turned to one side and slightly upward, as if looking over one or the other shoulder, the head and neck being usually rotated in the same direction. Sometimes the deviation is slight, sometimes it is marked. Frequently the muscles of the neck on one side are rigid. The eyes are commonly motionless, but occasionally exhibit oscillations. This sign, well known to neurologists, usually disappears in cases of apoplexy in a few hours or days, although it occasionally persists for a long time. It will be more fully considered under Local Diagnosis.

Diminution or loss of hearing, tinnitus, and hyperæsthesia of hearing are all occasionally observed. The most decided disturbances of this sense are those which are found in connection with tumors of the base or of the cerebellum in such a position as to involve the auditory nerve or auditory tracts. Tinnitus, acoustic hyperæsthesia, with complete or partial deafness, accompanying facial paralysis, with or without paresis of the limbs of the opposite side, indicate clearly a tumor of the base so situated as to involve the superficial origin or intracranial course of the auditory and facial nerves.

The sense of smell is affected, of course, when the olfactory bulbs are involved in the growth, either directly or by pressure, as in certain tumors of the antero-frontal region (Cases 4 and 8). Disturbances in the power of consciously perceiving odors, or abnormal perceptions of odors or hallucinations of smell, are sometimes present in cerebral tumors involving certain convolutions. The lower postero-parietal region or the temporo-sphenoidal region of the base would seem, from the few reported cases, to be implicated when this sense is centrally affected. Smell was lost or impaired in two cases of tumors of the postero-parietal region, in one limited to the supramarginal convolutions. In a case reported by Allan McLane Hamilton (Case 47), an induration of the lower part of the right temporo-sphenoidal lobe involving the uncinate gyrus, the patient, preceding light epileptic attacks, always had an olfactory aura of a peculiar character—a disagreeable odor, sometimes of smoke and sometimes of a fetid character. In this case the olfactory nerves were examined and found to be healthy.

Taste may be involved in several ways. In the first place, subjective sensations of taste, particularly the so-called metallic taste, may be present when the growths involve the cranial nerves in such a way as to cause irritation to be conveyed to the nucleus of the hypoglossal. When it is remembered that a mild galvanic current applied to the nape of the neck or face will often cause this metallic taste, it can be seen

that the irritation of a tumor situated at almost any point of the base might lead to abnormal taste-phenomena. Neoplasms involving the trunk of the portio dura may of course cause diminution or loss of taste on the anterior extremity of the tongue by the involvement of the chorda tympani nerve. In the very few cases in which the hypoglossal trunk may be involved disturbances of taste posteriorly may occur. In two cases (Cases 33 and 36) some possible indications as to the cortical areas of taste are given. One was a tumor so situated as to cause pressure on the orbital, and possibly anterior, portion of the temporo-sphenoidal lobe; the other was a lesion closely localized to the supramarginal lobule.

Trophic disturbances of decided character are sometimes present in cases of brain tumor. Their presence, character, and extent depend upon the position of the tumor and the cranial nerves involved. Trophic disorders of the eye have been noted in cases of tumor of the antero-frontal region, and also of various positions at the base, especially those so situated as to involve the trigeminal nerve. In a fibroma of the superior antero-frontal region (Case 1) conjunctivitis and corneitis of the left eye, with anæsthesia of the conjunctiva, were present, and were very marked symptoms. This patient, who was under the care of one of us at the Philadelphia Hospital, was examined by O. E. Shakespeare, ophthalmologist to the hospital. At his first examination the bulbar conjunctivæ were slightly injected and the cornea clear. The sensibility of the cornea was possibly a little lowered. Ten days later, at a second examination, the central corneal epithelium of the left eye was found to be hazy and the whole bulbar conjunctivæ much congested. "This condition soon developed into a severe superficial corneitis, which was mainly limited to a central area of an extent about equal to three-fourths of the diameter of the cornea, which threatened to slough, a narrow peripheral ring of the cornea being comparative unaffected. At the same time the engorgement of the bulbar conjunctiva increased. The sclera, the iris, and the deeper parts were apparently not involved in the inflammatory process."

Disturbances of respiration were observed in a number of cases in various stages. Cheyne-Stokes breathing was usually a late symptom. In a case of tubercular meningitis with a tubercular granulation springing from the left side of the fourth ventricle (Case 82) it was present. Extraordinary slowing of respiration occurred in a tumor of the right middle cerebellar peduncle and cerebellar hemisphere which caused irritation and softening of the floor of the fourth ventricle. The respirations ran as low as four and five per minute two weeks before death.

Persistent epistaxis and a tendency to hemorrhage from the mucous membranes were interesting vaso-motor phenomena in a case situated in the upper left quarter of the pons (Case 84). Profuse perspiration, more marked on one side, was observed in a case of tumor in front of the optic chiasm. Polyphagia was observed in two cases, one a growth of the cerebellum and the other on the floor of the skull. Polyuria was a very marked symptom in Case 95, a tumor at the base of the brain at a spot corresponding to the sella turcica, and diabetes was present in a case of frontal tumor. Albuminuria was recorded twice—once in the same case in which diabetes was present, and again in a case of

multiple tumor of the supramarginal convolution of one side and the angular gyrus of the other. Somnolence was occasionally observed.

Constipation or torpor of the bowels occurs somewhat frequently in the early stages of the brain tumor, giving place in the terminal periods to involuntary evacuations. The conditions of the bladder are practically the same. It is either not involved or suffers from torpor or paresis of the muscular walls early in the disorder, and later, and especially very late, incontinence from paralysis of the sphincter results.

DURATION, COURSE, AND TERMINATION.—The duration of cases of intracranial tumor is very uncertain. In many of the reported cases no definite information is given as to the exact length of time from the initial symptoms until the fatal termination. The few cases in which the time was recorded showed a duration of from three months to as many years.

In a few cases, even in some which are not syphilitic in character, a remission of all the symptoms and what appears to be an approximate cure sometimes take place, the general symptoms, such as headache, vertigo, vomiting, spasms, etc., disappearing for a time. Even the condition of the eyes and the paralysis in rare instances make marked improvement. In these cases, in all probability, the progress of the growth of the tumor is arrested either by the remedies employed or spontaneously, and the acute or subacute phenomena of congestion, œdema, etc. around the tumor subside. These patients may remain for a long period or until cut off by some other disease without any change for the worse; but the sword constantly hangs above their heads, and any excitement, traumatism, the abuse of alcohol or other narcotics, an attack of fever, or some other special exciting cause, may again light up the intracranial disorder, to then progress more or less rapidly to a fatal termination.

This fatal termination may occur in various ways. Sometimes a sudden apoplectic attack occurs. This may be an intercurrent hemorrhagic apoplexy, although our personal experience would not lead us to believe this mode of termination is common. In a few cases the enormous irritation of the cerebral growth suddenly or gradually inhibits the heart's action through the impression made on the pneumogastric. Apoplectic attacks which may or may not terminate fatally sometimes are the result of a sudden giving way of necrosed brain-tissue, the necrosis having resulted from the obliteration of numerous blood-vessels by the advancing growth. Blood-poisoning occasionally takes place from abscesses in proximity to the tumor. In some cases the patients slowly but surely emaciate, or are exhausted and worn out by the agonizing pain and incessant vomiting which they are called upon to endure. Occasionally a more or less diffused and violent meningitis hastens the fatal issue.

COMPLICATIONS AND SEQUELÆ.—Tumors of the brain may be complicated with other affections due to the same cause. Thus, for example, in a case of gumma other evidences of syphilis may be present in the form of nodes, eruptions, etc. A sarcoma or carcinoma of the brain may be associated with similar disease in other organs. Such affections as cystitis, pyelitis, keratitis, etc., which have been discussed under Symptomatology, are secondary complications of cases of tumor. As intra-

cranial tumors almost invariably terminate fatally, strictly speaking we have no sequelæ.

PATHOLOGY.—We present in tabular form the various classes of tumors found in the one hundred cases of brain tumor in the table appended to this article :

| | | | | | |
|-------------------------|---|------------------------|----|------------------------|----|
| Carcinoma | 7 | Fibro-glioma | 2 | Myxo-sarcoma | 1 |
| Cholesteotoma | 1 | Fibroma | 4 | Myxo-glioma | 2 |
| Cyst | 2 | Glioma | 16 | Osteoma | 2 |
| Echinococcus | 2 | Glio-sarcoma | 1 | Sarcoma | 15 |
| Enchondroma | 1 | Gumma | 13 | Tubercle | 13 |
| Endothelioma | 1 | Lipoma | 1 | Unclassified | 16 |

The histology of tumors of the brain does not in the main differ from that of the same growths as found in other parts of the body, so that a detailed description of their structures, even though founded upon original research, could not offer many novel facts in a field which has been so thoroughly cultivated. Such a description would probably repeat facts which have already been presented in other parts of this work, and which are better and more appropriately put forth in special treatises devoted to the science of pathology. It is proper, however, for the sake of convenience and thoroughness, to make brief mention of the structure of brain tumors, and especially to dwell upon certain features of these morbid growths which may be considered characteristic of their encephalic location, and hence have not only pathological but also clinical interest. It is hardly worth while to refer to speculations which aim to elucidate the very foundations of the science, except that in a few of these theories we gain an additional insight into both the structure and conduct of some very characteristic brain tumors.

Cohnheim's theory was that tumors are formed from foci of embryonal tissue which had been non-utilized or left over in the intra-uterine development of the body. Many have not accepted this idea, but have rather considered that in tumors we witness a reversion of tissue to lower or embryonic types.¹ Whether we accept either or neither of these propositions, the idea sought to be conveyed is that in all these morbid structures we have a tissue of low or degraded character, springing in most instances from a connective or non-differentiated tissue. This fact is brought out very clearly in many of these intracranial growths. Virchow² has said that tumors originate in the cells of the connective tissue, although his law has been condemned as not of sufficient breadth, since it seems to ignore the epithelial and myomatous tumors. Dermoid cysts, of which an example is given in the table of spinal tumors,³ are said to illustrate the embryonic function revived—*i. e.* the tendency of lower tissues to spontaneously differentiate into higher and more complex ones.

The gliomata are among the most common and characteristic tumors of the cerebro-spinal axis, to which system and its prolongation into the retina they are confined. They invariably spring from the neuroglia or connective tissue of the nerve-centres, and reproduce this tissue in an embryonal state. They greatly resemble the brain-substance to naked-eye inspection, but have, histologically, several varieties of structure.

¹ Article "Pathology" in *Brit. Encyc.*, by C. Creighton.

² Quoted by Cornil and Ranvier.

³ Page 1107.

These variations depend upon the relations of the cell-elements to the fibres or felted matrix of the neoplasm. In the hard variety the well-packed fibrous tissue preponderates over the cell-elements, and we have a tumor resembling not a little the fibromata (Obernier). The second variety, or soft gliomata, show a marked increase of cells of varied shapes and sizes, with a rich vascular supply which allies these growths to the sarcomata. The elements of gliomata sometimes assume a mucoid character, which allies them, again, to the myxomata.

W. Osler has recently described¹ to the Philadelphia Neurological Society the structure of certain of these tumors, from which we abstract the following facts: One point referred to is that gliomata sometimes contain larger cells and coarser fibres than are usually shown. The structures are (1) The "spinnen" or spider-cells (characteristic of glioma), which present variations in size; (2) large spindle-shaped cells with single large nuclei (some of the

FIG. 43.

Flat Glioma-cell with its Fibrillar Connections (Osler).

FIG. 44.

(1) Homogeneous translucent fibre-cell; (2) cells like unipolar ganglion-cells; (3) giant cell (Osler).

largest cells met with in tumors); (3) cells like the ganglion-cells of nerve-centres, with large nuclei and one or more processes: some are balloon-shaped with single processes; they are larger than the spider-cells; (4) translucent band-like fibres, tapering at each end, without nucleus or granular protoplasm, regarded as a vitreous or hyaline transformation of the large spindle-cells. Klebs (quoted by Osler) holds that the ganglion-like cells are derived from the nerve-cells of the gray matter, "and that in the development of this variety all elements of the nerve-tissue participate." Osler examined the advancing region of

¹ "Structure of Certain Gliomas," *Philada. Med. News*, Feb. 20, 1886.

the tumor, and was not able to satisfy himself that the nerve-cells were in process of proliferation. He thinks they are connective-tissue elements. He has seen but two out of five cerebral gliomata which were of small-celled type.

The gliomata are subject to fatty degeneration, which usually occurs in the central (older) portions of the mass. The more vascular forms are also peculiarly liable to hemorrhage, which is probably caused in some instances by this process of retrograde metamorphosis. These hemorrhages resemble apoplexies, not only in their clinical features, but also on gross examination. Great care is therefore often necessary at the autopsy to distinguish such a hemorrhage, occurring as it does in a brain-like neoplasm, from one caused by the rupture of a diseased artery. The hypertrophy of the pineal gland, sometimes noted, is caused by the formation of gliomatous tissue. Under the microscope it is necessary carefully to distinguish some forms of inflammatory new formations from the gliomata. We have recently seen, by the courtesy of E. N. Brush of the Pennsylvania Hospital for the Insane, photographs of microscopic sections from the ependyma of the lateral ventricles in a case of general paresis, which showed the structure of this degenerated tissue to be a compound of fibres and cells of marked resemblance to gliomatous tissue.¹

Sarcomata of the brain are common, as our table shows. In them the cell-elements predominate, both in the large- and small-celled variety. They are malignant and grow rapidly. The form known as alveolar sarcoma, which has a distinct stroma, is to be distinguished from the cancers; which has probably not always been done.

Tubercle, according to Ross, is the most common of all forms of brain tumor. Our table shows 13 cases out of 100, the gliomata and sarcomata being in larger number. Its favorite seat is in the cortex of both the cerebrum and cerebellum: some observations appear to show that it is more common in the cerebellum and mid-brain region than in the fore-brain, and in children than in adults; some of which points distinguish it from the gummata, which are more common in adults and occur anywhere. Tubercle is another form of development from the connective tissues, usually dependent upon a constitutional taint or predisposition: in it the cell-elements have generally undergone a degeneration into an amorphous cheesy mass. It is apt to be multiple and accompanied by a similar deposit in other organs of the body.

True neuromata are probably very rare growths, and it is likely that some tumors which have been described as such are really connective-tissue tumors of a gliomatous nature, in which some of the cell-elements have been mistaken for the ganglion-cells. Obernier² says that these tumors are small and grow from the gray matter on the surface, also on the ventricular surfaces. They are also found in the white matter. He says they are only found in persons having some congenital or acquired aberration; by which is probably meant some other well-marked neurosis or psychosis. The one hundred tabulated cases afforded no examples of neuromata.

Myxomata are not, histologically, to be distinguished from the glioma-

¹ These micro-photographs were prepared in the laboratory of the State Lunatic Asylum, Utica, New York, by Theodore Deecke.

² *Op. cit.*

tous tissues by anything but the peculiar mucoid changes which their structures have undergone. They are more rare in the brain, as our tables show, than in the spinal cord.

Lipomata are very rare in the brain, according to most observers. The table shows but one example. These tumors, as their name signifies, are made of fat-bearing tissues—another of the connective-tissue class.

The angiomas, somewhat rarely found within the skull, are noted for their abnormal development of the vascular tissues: they are composed mainly of blood-vessels and the connective tissue, which supports them in closely-packed masses. They also present cavernous enlargements. They are of especial interest in cerebral pathology, because the lesion known as pachymeningitis hæmorrhagica, often found in dementia paralytica, is considered by some to be angiomatous; although by far the most generally accepted view of this latter condition is that it is due to arterial degeneration, and in part is an inflammatory exudate.

Syphilitic tumors, or gummata, are, like tubercle, a special development with degeneration from the connective tissue, due to a constitutional taint. This new growth is sometimes single, sometimes multiple. The corpuscles of the neuroglia are the apparent points of origin of the tumor, the substance of which is the firm, peculiarly gummy, and non-juicy material from which the name is derived. It would be impossible in our allowed space to trace this neoplasm through the successive stages of its development. It has especial clinical interest, inasmuch as it and its damage are probably amenable to specific treatment when it has not progressed to too great a destruction of brain-tissue.

The true cancers, or epithelial neoplasms, are not a common form of tumor of either the brain or spinal cord. They present, as in other parts of the body, a stroma forming alveolar spaces in which are contained the nests of epithelial cells. These tumors thus present characteristic differences in their histology from the connective-tissue or mesoblastic groups, but clinically no very special interest attaches to them. Their location, the rapidity of their growth, and their fatal import are points which they share with most other new growths of the cranial cavity.

The cholesteotomata, or pearl cancers, consist of hardened epithelial cells which have undergone a sort of fatty degeneration.

The psammomata are loosely described as tumors containing sand-like bodies, which bodies are normal about the pineal gland. These sand-like bodies are found in tumors of some histological diversity, and do not appear to have much identity of their own. They occur in sarcomata and carcinomata, and are probably not to be distinguished from mere calcareous infiltration and degeneration. They are most common in sarcomata, as this is one of the most common of cerebral tumors.

True osteomata—*i. e.* tumors with the structure of true bone—are probably rare in the brain, although more common on the inner table of the cranium; but the deposition of calcareous salts has been recorded in a variety of conditions. F. X. Dercum, in a recent paper read before the Philadelphia Pathological Society,¹ has recorded the autopsy of a paretic dement in which case calcareous deposits were scattered throughout both hemispheres and the cerebellum. He believes that “the areas in

¹ *The Medical News*, April 24, 1886, p. 460.

which the concretions were found were probably foci of encephalitis of greater intensity than elsewhere. In these foci inflammatory changes in the walls of the vessels became pronounced; besides which the vessels increased enormously in size and number; so marked is this increase that these foci could, with perfect propriety, be called *angiomata*." This is followed by proliferation of the neuroglia, compression and destruction of nerve-tissue, and deposit of the calcareous salts especially about and upon the coats of the vessels. This case illustrates in the simplest manner the formation of both vascular and sand tumors.

Pacchionian bodies are very common in the brain, and are really small fibromata. They may form true tumors (Cornil and Ranvier) capable of wearing away the bones of the cranium. In fact, even when small they may have corresponding indentations in the skull. They are not to be mistaken for tubercle. Clouston¹ has described excrescences from the white matter of the brain, growing through the convolutions, projecting through the dura mater, and indenting the inner table of the skull; which new growths he calls *hernia of the brain through the dura*. We have not seen such a condition described elsewhere, and think that we have here probably Pacchionian bodies growing from the pia mater. They were found in a case of tumor of the cerebellum.

A cystic formation, constituting a veritable tumor, not unfrequently occurs in the pituitary body and mounts into the third and lateral ventricles. Echinococci and hydatids also occur, and have the same natural history as these parasitic offspring have when found in other parts of the human body.

Obernier refers to an enchondrosis of the basilar process. Our table presents one case of enchondroma.

Some of the gross appearances found on autopsies of tumors of the brain are worthy of note. Often an area of congestion or inflammation, especially of the membranes, is seen about the new growth, and the brain-substance in its immediate vicinity is much more frequently softened. The cerebro-spinal fluid is increased, and, especially when direct pressure has been exerted upon the veins of Galen, are found distended lateral ventricles. When a tumor does not approach the surface, but has attained some size, the hemisphere in which it is located often has a bulging appearance, crowding over upon its neighbor, and the convolutions are flattened by the pressure. The cranial nerve-trunks are occasionally involved in or stretched by the tumor, and also occasionally the bones of the vault or base of the cranium are extensively eroded. This happens especially in cancer and osteo-sarcoma.

A few remarks should be made about the methods of making post-mortem examinations and the gross appearances and conditions likely to be found in brain-tumor cases. As not a few intracranial tumors are connected with the bone or with the dura mater, the latter being adherent to the skull-cap in some positions because of inflammation arising from the seat of the growth, especial care should be taken in removing the calvarium. Examination of the external surface of the dura mater will sometimes reveal the presence of a growth beneath or incorporated with this membrane. The dura mater should not be roughly dragged from the surface of the brain, but should be carefully removed by a pro-

¹ *Journ. Ment. Sci.*, xviii. p. 153.

cess of partial dissection. During this process a meningeal growth will sometimes be found growing apparently from the fused membrane. In such cases it is usually better to so proceed as not to entirely separate the outer membrane from the growth. Indeed, this cannot be done sometimes without injury directly to the specimen, and especially to its cerebral surroundings. The dura mater having been removed, a marked opacity, sometimes a dirty-brown hue shading off into a lighter color, will indicate to the eye the probable presence of a tumor beneath and growing from the pia mater of the cortex. In such a case, and even when no such appearance is present, but a tumor is suspected, the fingers passed carefully over the cerebral surface will feel a hard, and it may be nodulated, mass at some position. A growth, having been located in this way, should not be roughly handled or at once examined by section. An effort should be made to accurately localize it, not only with reference to lobes, but also with reference to convolutions and fissures, and even special portions of these. This is best done, after a thorough examination has been made of the pia mater, by carefully stripping the pia mater from the brain, beginning at points some distance from the growth and gradually approaching it, and leaving the pia mater for a short distance around the growth connected with it. The location having been fixed and other portions of the brain having been examined, if it is not possible or desirable to retain the entire brain as a specimen, a block should be removed embracing a considerable portion of healthy brain-tissue on all sides of the tumor. In order to study the gross internal appearance of the tumor, it is a good plan to make a clean section through the middle of the tumor. From each side of this cut fragments can be taken for microscopical examination without deranging appreciably the size and appearance of the tumor.

When the tumor is not meningeal or cortical, or not situated at the base or floor of the skull, its presence may be revealed, when it is in centrum ovale and of considerable size, by either hardness or fluctuation of the hemisphere in which it is located, this fluctuation not being due to the tumor itself so much as to the breakdown of tissue around it. Large sections in known positions with reference to convolutions and ganglia should be made when examined for tumors deeply situated. If possible, sections close to and just before and behind the growth should be made, so as to assist in the accurate localization.

Small tumors are not infrequently overlooked by careless observers, and even growths of considerable size have escaped discovery by one examiner to be found by another. Tumors in certain special localities, as between the temporo-occipital lobe and the superior surface of the cerebellum in the great longitudinal fissure, or small growths in the substance of the cerebellum or deep in the Sylvian fissure, are more likely than others to be passed by, although this, of course, is not likely to occur when the examination is made by a competent or careful physician.

DIAGNOSIS.—The diagnosis of the existence of an intracranial tumor, as a rule, is not difficult. It can be made with greater certainty than that of almost any other serious encephalic disease.

It is sometimes important to decide as to the nature of an intracranial neoplasm, particularly whether or not it is syphilitic. Little is to be gained by following the plan adopted by some physicians, of treating all cases as if they were due to syphilis, on the principle that these

are the only forms of tumor which can be reached by treatment. The pitiable condition of such patients is sometimes thus made worse. In every case careful and persistent efforts should be made to obtain an authentic previous history from the patient. Whenever possible the physician should search directly for the physical evidences of the former existence of syphilis—for cicatrices on the genitals and elsewhere, for nodes and depressions, for post-cervical and other swellings, etc. A history of previous disease of the throat and of pains in bones and nerves, of epileptiform attacks, of headache, and eye symptoms which have disappeared under treatment, should be sought out. It is not well to give too much credence to the stories of patients, who are not always willing to admit their past lapses from virtue; but, on the other hand, the plan of suspecting everybody who presents advanced cerebral symptoms is often a grievous wrong. Not infrequently external cranial nodes are present in cases of intracranial syphilis.

Carcinomata and sarcomata, particularly the former, are comparatively rapid in their progress. They sometimes involve the bones of the skull, even to the extent of perforation.

The existence of an inherited tendency and of tuberculosis in other organs, with the special phenomena of general tuberculosis, assists in the diagnosis of tubercular tumors.

The frequent occurrence of gliomata in early life, and the comparatively frequent absence of severe irritative symptoms, with the well-preserved general nutrition of the patient, speak for these growths.

Cerebral abscess is, on the whole, more difficult to diagnosticate from intracranial tumor than any other affection. Abscess, however, more frequently than tumor, can be traced directly to a traumatism. It is often associated with disease of the internal ear. Obernier speaks of the headache of cerebral abscess as slight, but this does not correspond with usual experience. Headache, on the whole, may be oftener absent or less agonizing in abscess than in tumor, but it is frequently present, and sometimes of great severity. Its greater mildness in a few cases is to be explained by the fact that abscess does not produce so much pressure within the intracranial cavity, and does not so frequently cause irritation of the branches of the trigeminus in the dura. Undoubtedly, the symptoms of abscess often remain for a long time comparatively latent, with then a sudden outburst of violent symptoms. The course of brain tumor is more uniformly and steadily progressive, and febrile phenomena, the results of pyæmia, are of more frequent occurrence in abscess than in tumor.

In old cases of tumor it is sometimes necessary to differentiate between it and the results of various forms of apoplexy, such as hemorrhage, thrombosis, and embolism. Cerebral hemorrhage, embolism, or thrombosis leaves a condition of paralysis, sometimes with, but usually without, accompanying spasm or convulsion, which simulates closely the paralysis and other permanent conditions of cases of tumor occurring in the same cerebral locality. In these cases, in the first place, the history of the disease will throw considerable light upon the diagnosis. In both hemorrhage and embolism the history is usually one of a sudden attack without special premonitory symptoms. Hemorrhage gives usually a precedent history of diseased kidneys, hypertrophied heart, or athero-

matous blood-vessels, and occurs generally in advanced life; embolism, a history of rheumatism and valvular disease of the heart, occurring at any period of life, early or late. In brain tumor the previous history is usually one of traumatism, of constitutional infection, or of a special predisposing diathesis. Blows and falls upon the head are common antecedents, or a history of syphilis, tuberculosis, scrofula, or cancer is present. Tumor, like embolism and unlike hemorrhage, may occur at any time of life. While slight or dull headache, with more or less vertigo, may be present in cases of hemorrhage and thrombosis, the severe and often agonizing headache, with vomiting and serious vertiginous attacks, which precedes the paralytic or other phenomena of tumor, is a much more conclusive symptom in the latter cases than in the former. Choked discs and optic neuritis are much more likely to occur in tumor than in the other affections.

Brain tumor must sometimes be diagnosticated from the head symptoms of some form of Bright's disease. A case not long since presented itself to one of us with a history of having suffered at frequent intervals for two years with headache of gradually increasing severity. Dimness of vision and slight temporary oedema of the feet, circumscribed and painful swellings along the lymphatics of the thighs and legs, with some mental irritability, were other marked symptoms. The patient had been attended by several physicians of prominence, one of whom had diagnosticated tumor of the brain. The violent, apparently agonizing headache, with the diminution of vision, and the absence of marked symptoms indicating other organic disease, made the diagnosis of a growth in some non-excitabile region of the cerebrum most probable. Examination of the urine showed no albumen. Careful examination of the eye-ground with the ophthalmoscope, however, revealed the appearances of retinitis albuminurica. Under a treatment directed to the relief of chronic nephritis the patient's headache and other symptoms improved.

It must not be forgotten just here, however, that, on the one hand, ophthalmoscopic appearances very similar to those of albuminuric retinitis are sometimes present in rare cases of brain tumor, and also in other constitutional disorders, such as leukæmia; and, on the other hand, that, as stated by Norris,¹ exceptional forms of albuminuric retinitis have been reported where the only change seen in the fundus oculi was pronounced choking of the disc.

Intracranial tumors must be diagnosticated from meningitis in its various forms. In children tubercular meningitis sometimes closely simulates brain tumor. Tumors of the brain are comparatively rare in children, but, as has already been shown, gliomata and other tumors do sometimes occur in early life. The course of tubercular meningitis, whether in children or in adults, differs from that of brain tumor. It is more irregular in its method of advance, or if it shows the regularity which is sometimes present, and which has led authors to subdivide it into three more or less completely separable stages, the symptoms of these stages do not correspond with any closeness to those of the initial, middle, and terminal periods of brain tumor, as already given. Headache is usually present in both affections, although the absence of headache in some cases of gliomata in children must be here borne in

¹ *Op. cit.*

mind. When headache is present in tubercular meningitis, it is less likely to be localized, and, on the whole, it is not so severe as the terrible torture of the neoplasm. Irregular but very decided febrile phenomena are more likely to be present in meningitis than in tumor. Like brain tumor, tubercular meningitis of the convexity may give psychical disturbances, palsies, local spasms, general convulsions, sensory disturbances, peculiar disorders of the special senses, etc.; but these symptoms in the former usually come on more irregularly and are accompanied less frequently with paroxysmal exacerbations of headache, vomiting, vertigo, etc. Tubercular meningitis of the base can be more readily distinguished from cases of tumor by the fact that one cranial nerve after another is likely to become involved in the diffusing inflammatory process. Tubercular meningitis is of shorter duration than the majority of cases of brain tumor, and in it delirium and mental confusion come on more frequently and earlier. A history and physical evidences of more or less generalized tuberculosis favor the diagnosis of tubercular meningitis. In both affections the ophthalmoscope may reveal choked disc or descending neuritis. It will be seen that the differentiation between the affections is not always very clear, although in some cases the decision may be quickly reached from a study of the points here suggested.

Some of the forms of chronic hydrocephalus are difficult to distinguish from tumors, especially gliomata. In hydrocephalus, when not the result of, or not accompanied by, tubercular meningitis, the disease advances more slowly and with less irritative symptoms than in cases of tumor. Headache, vertigo, vomiting, and the other symptoms of meningeal irritation are not so frequently present, although the ophthalmoscopic appearances are often the same.

Rosenthal speaks of the necessity of diagnosing brain tumor from the chronic cerebral softening of Durand-Fardel, from acquired cerebral atrophy, and the cerebral hypertrophy of children. An elementary knowledge of the general symptomatology of intracranial tumors will, however, be sufficient to prevent mistakes of differentiation in these cases. Neither of these affections presents the violent paroxysmal symptoms, the affections of the special senses, or the severe motor and sensory phenomena of intracranial growths.

Acute mania and parietic dementia are sometimes confounded with intracranial growths. A case of brain tumor is more likely to be regarded as one of acute mania than the reverse. In some comparatively rare instances in the course of their sufferings the cases of tumor become maniacal, but even a superficial study of general symptomatology in such a case will be sufficient to clear up the doubt.

Paretic dementers are occasionally supposed to be cases of brain tumor, because of the epileptiform attacks and isolated pareses which occur as the disorder progresses. It is only necessary to refer to this matter, as the mistake would not be likely to be made by one having any familiarity with dementia paralytica.

L. J. Lautenbach, in a recent communication to the Philadelphia Neurological Society, which embodied a large number of ophthalmoscopic examinations of the insane at the State Insane Hospital, Norristown, Pennsylvania, and the Insane Department of the Philadelphia Hospital, and also the results of the investigations of the fundus of the eye in

cases of insanity by other observers, showed that about 16 per cent. of cases of acute mania presented well-defined papillitis—a condition which he described as one of swelling and suffusion of the disc, corresponding to cases reported as choked disc, descending neuritis, and severe congestion of the optic nerve. No reports of post-mortem examinations were made of these cases, but they did not present the clinical history of meningitis or brain tumor. It therefore follows that the existence of papillitis in a case of acute mania does not necessarily point to a gross lesion, such as tumor or meningitis.

In the early stage of posterior spinal sclerosis some of the symptoms of the initial or middle stage of intracranial growths in certain positions are likely to be present; more particularly, such eye symptoms as diplopia from deficiency or paresis of the ocular muscles and disorders of the bladder may mislead. In posterior spinal sclerosis, however, some at least of the pathognomonic symptoms of locomotor ataxia, such as lancinating pains, absent knee-jerk, or Argyle-Robertson pupil, will almost invariably be present. Those tumors of the cerebellum, pons, tubercular quadrigemina, etc. which give rise to ataxic manifestations are usually readily discriminated from posterior spinal sclerosis by the headache, vomiting, and other general symptoms of brain tumor, which rarely occur in ataxia. It is far more difficult to separate non-irritative lesions of certain cerebellar and adjoining regions from the spinal disorder.

Strange to say, one of the most frequent mistakes of diagnosis is that which arises from confounding brain tumor with grave hysteria. In several of our tabulated cases the patients at different periods of the disease and by various physicians had been set down as suffering from hysteria. One of Hughes-Bennett's cases (Case 30), a wayward, hysterical girl of neurotic family, had had her case diagnosticated as hysteria by one of the highest medical authorities of Europe, and yet after death a tumor the size of a hen's egg was found in the cerebrum. In a case reported by Eskridge (Case 76) hysterical excitement and special hysterical manifestations were of frequent occurrence, and misled her physicians for a time. Eskridge remarks, in the detailed report of this case, that to such a degree was the emotional faculty manifest that had no ocular lesion been present there would have been great danger of mistaking the case for one of pure hysteria; and, indeed, a careful physician of many years' experience, not knowing the condition of the eyes, pronounced the woman's condition to be pregnancy complicated by hysteria. A close study of such objective phenomena as choked discs and paralysis will usually be of the most value.

Even malaria has been confounded in diagnosis with brain tumor. Holt¹ reports a case which presented the history of a fever, at first periodical, with marked splenic enlargement, great muscular soreness, and incomplete paralysis, which was diagnosticated to be chronic malarial poison. The patient for a time improved under quinine, but eventually grew worse, and on an autopsy a glioma-sarcoma was found on the inferior surface of the cerebellum. Several years since a physician about fifty years of age was brought to one of us for consultation, and in his case a similar mistake had been made. The case was a clear one of

¹ *Med. Record*, March 1, 1883.

tumor, probably cerebellar, with headache, neuritis, vertigo, and other general symptoms, which pointed to an organic lesion. This patient, who came from a malarial district in the West, had doctored himself, and had been treated by others with enormous doses of quinine and arsenic.

LOCAL DIAGNOSIS.—Niemeyer would hardly say to-day that the brilliant diagnoses where the precise location of a tumor is fully confirmed by autopsy are not usually due to the acumen of the observer, but are cases of lucky diagnosis. It can be asserted with confidence that the exact situation of a tumor can be indicated during life in at least two or three locations. Great caution should be exercised, as insisted upon by Nothnagel,¹ in the localization of tumors of the brain, because, among other reasons, of the frequent polypus-like extension of such tumors.

The subject of local diagnosis can be approached in several ways, according to the method of subdividing the brain into regions. Thus, Rosenthal discusses, in the first place, tumors of the convexity of the brain, but as this is a very general term, covering portions of several lobes, we can see no advantage in making such a subdivision.

A few general remarks might be made in the first place, however, with regard to the general symptoms presented by surface or cortical growths as compared with those which are produced by deep-seated neoplasms. The direct or indirect involvement of the membranes in nearly all cortical tumors makes the symptoms of irritation referable to these envelopes very numerous and important.

The various centres so called, motor, sensory, and of the special senses, which have their highest differentiation in the cerebral cortex, are each and all represented by well-defined tracts of white matter in the centrum ovale and capsules which connect these centres with the lower brain, the spinal cord, and the periphery of the organism. It therefore follows that symptoms produced by localized lesions of the cortex will be reproduced in other cases by those of the tracts which go to or come from these centres. We may thus have a monoplegia or a hemiplegia, a partial anæsthesia or a hemianæsthesia, a hemianopsia, a word-blindness or word-deafness, a loss of power to perceive odors or to appreciate gustatory sensations, from a peculiarly limited tumor or other lesions of either the gray centres of the cortex or of the white matter of the central area of the brain; but these specialized symptoms are more likely to arise from cortical lesions in the case of intracranial neoplasms, because of the much greater frequency with which these adventitious products arise from membranes and therefore involve the cortex.

Peculiar symptoms arise in the case of lesions of the centrum ovale from the fact that it contains not only projection-fibres which more or less directly connect cerebral centres with the outer world; but also a system of commissural fibres which unite corresponding regions of the two cerebral hemispheres by way of the corpus callosum and commissures, and a system of association-fibres which connect different convolutions together, in special cases even those which are situated remotely from each other, but are associated in function.

It is evident, therefore, as asserted by Starr,² that a peculiar set of additional symptoms will be referable to the destruction or irritation of these commissural and association fibres. For example, failure to per-

¹ *Wien. Med. Bl.*, 1, 1882.

² *Med. Record*, vol. xxix. No. 7, Feb. 13, 1886.

form easily corresponding bilateral motions in face, hands, or feet would indicate some obstruction to conduction in the commissural fibres joining the motor convolutions. "Integrity of both occipital lobes, and simultaneous, connected, and harmonious action in both, are necessary to the perfect perception of the whole of any object when the eyes are fixed upon one point of that object." Starr gives the following examples of the methods of detecting a lesion of such fibres: "In the case of the fibres associating the auditory with the motor speech-area the symptoms to be elicited seem to be very simple. Can the patient talk correctly? Can he repeat at once a word spoken to him? These are the questions which any one will ask who examines a case of aphasia. But this is not all. The patient must be further questioned. Can he read understandingly to himself, and tell what he has read? This will test the occipito-temporal tract. Can he read aloud? This will test the occipito-temporo-frontal tract. Can he write what he sees? This will test his occipito-central tract. Can he write what he hears? This will test the temporo-central tract. Can he write what he says, speaking to himself in a whisper? This will test his fronto-central tract. Can he name an odor or a color? Brill has recorded¹ a case of lesion of the cuneus associated with color-blindness to green, and he states that the patient had difficulty in naming various colors on account of the presence of a slight degree of amnesic aphasia. . . . Can the patient write the name of an odor? Can he tell how a surface feels—smooth, or warm, or heavy? Such questions as these will suggest themselves at once to any one who studies the association of ideas subjectively.

"Take as an example a lesion in the centrum ovale of the occipito-temporal region. Such a lesion will produce hemianopsia, because it involves the visual tract of the projection system. It may also produce a peculiar mental condition known as word-blindness, in which the patient is no longer able to associate a word or letter seen with its corresponding sound or with the motion necessary to write it. Charcot has reported a case of this kind. . . . The man, who was a very intelligent merchant, was suddenly seized with right hemianopsia while playing billiards, and was surprised to find that he saw but one-half of the ball and of the table. Soon after he had occasion to write a letter, and after writing it was surprised to find that he could not read what he had just written. He found, however, that on tracing individual letters with the pen or fingers he became conscious of the letters—a few letters (*r, s, t, x, y, z*), however, being an exception to this rule. When a book was given him to read he would trace out the forms of the letters with some rapidity, and thus manage to make out the words. If his hands were put behind him and he was asked to read, he would still be observed to put his fingers in motion and trace the letters in the air. Speech was in no way interfered with, but reading aloud was only accomplished, like reading to himself, by the aid of muscular sense. Here, then, was an example of a lesion which had separated entirely the tract associating sight with speech—viz. the occipito-temporal tract—but had left intact the tract associating sight with muscular sense—viz. the occipito-central tract."

Our tabulated cases, although collected for the purpose of studying inductively the phenomena of intracranial tumors from all points of view,

¹ *Amer. Journ. of Neurology*, Feb., 1883.

have been arranged to indicate, so far as is possible, the special symptoms which are produced by growths in special localities. Thus we have made thirteen subdivisions:

I. Superior antero-frontal region (5 cases).—The lateral and median aspects of the hemisphere from the anterior tip backward to the posterior thirds of the first three frontal convolutions, the region roughly bounded by the coronal suture.

II. Inferior antero-frontal or orbital region (5 cases).—From the anterior tip of hemisphere at the base backward to the optic chiasm and Sylvian fissures.

III. Rolandic region or motor cortex (15 cases).—From antero-frontal region backward nearly to mid-parietal lobe, including posterior thirds of superior middle and inferior frontal convolutions, ascending frontal and ascending parietal convolutions, and anterior extremities of superior and inferior parietal convolutions—lateral and median aspects.

IV. Centrum ovale, fronto-parietal region (5 cases).

V. Postero-parietal region (5 cases).—From Rolandic region to parieto-occipital fissure, including posterior two-thirds of the superior and inferior parietal convolutions and the præcuneus.

VI. Occipital region (9 cases).—Occipital lobe—cortex and centrum ovale.

VII. Temporo-sphenoidal region (4 cases).—Temporo-sphenoidal lobe.

VIII. Basal ganglia and adjoining regions (19 cases).—Caudate nucleus, lenticular nucleus, optic thalamus, internal capsule, corpora quadrigemina, and ventricles except the fourth.

IX. Cerebellum (9 cases).

X. Floor of fourth ventricle (6 cases).—(Directly or indirectly involved.)

XI. Pons varolii and medulla oblongata (8 cases).

XII. Crura cerebri (3 cases).

XIII. Middle region of base of brain and floor of skull (7 cases).—In the main, from optic chiasm backward to pons, in the middle basilar region, in some instances extending beyond this area in special directions.

Tumors of the antero-frontal regions can be diagnosticated with considerable certainty, partly by a study of the actual symptoms observed and partly by a process of exclusion. Headache of the usual type, vertigo, choked discs, inflammatory and trophic affections of the eyes, widely varying body-temperature, and high head-temperature are among the most positive manifestations. Mental slowness and uncertainty seem to be greater in these cases than in others. Mental disturbance of a peculiar character unquestionably occurs in cases of tumor, as of other lesions, in this region. This disturbance is exhibited chiefly in some peculiarity of character, showing want of control or want of attention. The speech-defects present in a number of cases were rather due to the change in mental condition than to any involvement of speech-centres. Under Symptomatology has been given in some detail a study of the psychological condition in one case of antero-frontal tumor. The absence of true paralysis and of anæsthesia is characteristic. Nystagmus and spasm in the muscles of the neck and forearm were present in one instance, but usually marked spasm is not to be expected. Vomiting is less frequent than in tumors situated farther back. Facial and other forms of paresis occasionally are present, but are not marked, and are probably due to involvement

by pressure or destruction of surrounding tissue of neighboring motor areas. Hemianopsia, such as was observed in Case 10, showed involvement of the orbital region. Tumors of the inferior antero-frontal lobe give the same positive and negative characteristics as those of the superior frontal region, with the involvement in addition of smell and certain special ocular symptoms, such as hemianopsia.

Tumors of the motor zone of the cerebral cortex, the region surrounding and extending for some distance on each side of the fissure of Rolando, can be diagnosticated with great positiveness: 15 of the 100 cases are examples of tumors of this region, and in many of these the diagnosis of the location of the growth was accurately made during life. Localized spasm in peripheral muscles; localized peripheral paralysis; neuro-retinitis or choked discs; headache; pain elicited or increased by percussion of the head near the seat of the tumor; and elevated temperature of the head, particularly in the region corresponding to the position of the growth,—are the prominent indications. The spasmodic symptoms usually precede the paralysis in these cases. The spasm is often local, and generally begins in the same part in different attacks—in the fingers or toes or face of one side.

A study of cases of tumor localized to the cortical motor area will show that in almost any case a local twitching convulsion preceded the development of paresis or paralysis. Hughlings-Jackson¹ reports a case of sarcoma, a hard osseous mass on the right side of the head, of eighteen years' standing, subjacent to which was a tumor the size of a small orange growing from the dura mater. The patient was a woman aged forty-nine, whose symptoms were very severe headache and double optic neuritis, with paresis in left leg, followed by slighter paresis in left arm and left face. A very slow, gradual hemiplegia came on by pressure on the cortex without any fit. Jackson says this is the only case which he has seen in which the hemiplegia has not followed a convulsion where the lesion has been on the surface. In all very slowly oncoming hemiplegias which he has seen, except this one, the tumor was in the motor tract.

As the white matter of the centrum ovale and capsules represents simply tracts connecting cerebral centres with lower levels of the nervous system, with each other, or with the opposite hemisphere, lesions of this portion of the cerebrum will closely resemble those cortical lesions to which the tracts are related. We have already referred to the peculiar symptoms referable to involvement of commissural and association fibres. Tumors of the centrum ovale of the fronto-parietal region, of which five examples are reported in the table, vary in symptomatology according to their exact location. Those situated in the white matter in close proximity to the ascending convolutions give symptoms closely resembling those which result from lesions of the adjoining cortical motor centres. In the cases of Osler, Seguin, and Pick (Cases 26, 27, 28, 29) spastic symptoms in the limbs of one side of the body, with or without loss of consciousness, were marked symptoms. In two of these cases some paresis preceded the occurrence of the spasms. They did not, however, fully bear out the idea of Jackson that the hemiparesis or hemiplegia in tumors of the motor tract comes on slowly before the appearance of spasm.

¹ *Medical Times and Gazette*, London, 1874, vol. i. 152.

Tumors of the postero-parietal region present some characteristic peculiarities. In several cases tumors were located in this region, and in several others the white matter of the parietal lobe was softened as the result of the obliteration of blood-vessels by the tumors. In general terms, we might say that hemianæsthesia, partial or complete, and impairment of sight and hearing on the side opposite to the lesions, seemed to be the most constant peculiarities.

Tumors and other lesions of the occipital lobes have in the last few years received extended attention, and, where possible, exact study, because of the opportunities which they furnish for corroborating the work of the experimental physiologists. It is unfortunate that the records of older cases do not furnish the exact detail which would render these tumors among the most important and interesting to be met with in the brain: some cases have, however, been observed with great care, and a few such are included in the table. To understand the special significance of the symptoms of such tumors, it will be well briefly to state some of the well-established facts about the function of the occipital cortex. The investigations of Gratiolet and Wernicke especially have proved that this surface of the brain is in direct connection with the fibres (1) which are continued upward from the posterior or sensory columns of the cord through the posterior portion of the internal capsule, and (2) with the expansion of the optic nerve, or the tract which passes, according to Wernicke, from the thalamus to the occipital lobe. There is but a partial decussation of the optic nerves at the chiasm, so that each half of the brain receives fibres from both eyes. This arrangement is best stated by Munk (quoted by Starr) as follows: "Each occipital lobe is in functional relation with both eyes in such a manner that corresponding halves of both retinal areas are projected upon the cortex of the lobe of the like-named side; *e. g.* destruction of the left lobe produces loss of function of the left halves of both retinae." This, of course, causes the right halves of both fields of vision to appear black. This condition is known as lateral homonymous hemianopsia, and was exhibited in several of the tabulated cases (Cases 40, 41, 42, and 43). It is probable that the dimness of the right eye recorded in Case 38 was really right lateral hemianopsia, as patients mistake this condition for blindness of that eye alone which is on the side upon which the visual fields are blank. It follows that this condition of the eyes will be caused by a destructive unilateral lesion at any point upon the optic tract behind the chiasm; and its exact nature and location are to be inferred from other corroborating symptoms. Among these corroborating symptoms, as will be inferred from the other functions of the occipital cortex, is especially to be considered partial hemiplegia and partial hemianæsthesia. This was observed in Cases 38, 40. These most characteristic localizing symptoms of occipital tumor have usually others, which, if not of such special importance, yet help to form a special complexus. Among these diffused headache is referred to by some writers as characteristic, but it seems to us that a localized headache, with pain on percussion over the affected region, is the only kind in this as in other regions which could have special diagnostic importance. Affections of hearing are recorded by some. It is not at all uncommon to have an incomplete hemiplegia and local paralysis. In Case 41 complete hemiplegia with facial paralysis is recorded. Local palsies, ocular and facial,

are recorded in Cases 36, 37, 38, and 39. It is doubtless by transmitted pressure, or by extension of the tumor, or the softening caused by it, toward the motor fibres, that these more or less incomplete paralyses are caused. The general symptoms, such as vertigo, vomiting, and convulsions, are frequently present with tumors of the occipital lobes. We are at a loss to know upon what data of theory or experience Rosenthal bases his statement that psychic disorders are more common in occipital tumors than in those of the anterior and middle lobes, unless he refers simply to the hebétude and late coma which seem to come generally in these cases.

Tumors of the temporo-sphenoidal region, so far as we have been able to study them, present few characteristic features. Physiology seems to point to the upper temporal convolutions as the cerebral centres for hearing; thus, according to Starr,¹ "disturbances of hearing, either actual deafness in one ear or hallucinations of sound on one side (voices, music, etc.), may indicate disease in the first temporal convolution of the opposite side. Failure to recognize or remember spoken language is characteristic of disease in the first temporal convolution of the left side in right-handed persons, and of the right side in left-handed persons. Failure to recognize written or printed language has accompanied the disease of the angular gyrus at the junction of the temporal and occipital regions of the left side in three foreign and one American case." In two of our four cases of tumor in the temporo-sphenoidal region disturbances of hearing were noted, but in none was the sense studied with sufficient care to throw any light upon the actual character of the disorder. The case of Allan McLane Hamilton (Case 47), already referred to under Symptomatology, was interesting because of the presence of a peculiar aura connected with the sense of smell. Stupidity, want of energy, drowsiness, and general mental failure were marked in tumors of this region.

Tumors of the motor ganglia of the brain are seldom strictly localized to one or the other of these bodies. Growths occurring in this region usually involve one or more of the ganglia and adjacent tracts, and can only be localized by a process of careful exclusion, assisted perhaps by a few special symptoms. Paralysis or paresis on the side opposite to the lesion usually occurs in cases of tumor of either the caudate nucleus or lenticular nucleus; but whether this symptom is due to the destruction of the ganglia themselves, or to destruction of or pressure upon the adjoining capsule, has not yet been clearly determined. In a case of long-standing osteoma of the left corpus striatum (Case 49) the patient exhibited the appearance of an atrophic hemiplegia: his arm and leg, which had been contracted since childhood, were atrophied and shortened, marked bone-changes having occurred. Another case showed only paresis of the face of the opposite side. Clonic spasms were present in two cases, in one being chiefly confined to the upper extremities of the face. In this case paralysis was absent. Disturbances of intellect and speech have been observed in tumors of this region. According to Rosenthal, aphasic disturbances of speech must be due to lesions of those fibres which enter the lenticular nucleus from the cortex of the island of Reil.

Tumors of the optic thalamus usually cause anæsthesia or other dis-

¹ *American Med. Sci.*, N. S. vol. lxxxviii., July, 1884.

turbances of sensation in the extremities of the opposite side. They sometimes show third-nerve palsies of the same side in association with hemiplegia on the opposite side, these symptoms being probably due to pressure owing to the proximity of the neighboring cerebral crus. Speech and gait in such tumors are also often affected.

Tumors of the corpora quadrigemina give rise to disturbances of sight and special ocular symptoms, such as difficulty in the lateral movement of the eyes. Spasms were usually present. Automatic repetition of words was observed in one case, nystagmus in another, and diminished sexual inclinations in a third. In other cases peculiar ataxic movements or a tendency to move backward were noted; other symptoms, such as spasm, vomiting, headache, were general phenomena of intracranial tumors; still others, such as hemiplegia, hemiparesis, or anæsthesia, were probably simply due to the position of the growth in the neighborhood of motor ganglia and tracts.

Tumors of the cerebellum have some special symptoms, which also derive importance from their characteristic grouping. The symptoms which depend upon the lesion in the organ must be distinguished from those which are caused by pressure upon adjacent parts, although these latter symptoms are very important as corroborative evidence of the location. Among the special symptoms is occipital headache (often not present), especially when the pain is increased by percussion about the occiput or by pressure upon the upper part of the neck. In these cases weakness of the gait (Case 75) and other motor phenomena, which are usually described as inco-ordination, are of comparatively frequent occurrence. They are not so much true inco-ordination as tremor of the limbs, rotation (which is usually only partial), and the so-called movements of *manège*. These movements were present in one-third of the cases collected by Leven and Oliver (quoted by Rosenthal). Staggering gait is also present, and may be dependent upon the vertigo, which is apt to be unusually intense in this kind of intracranial tumor (Cases 69 and 71). The symptoms caused by pressure of cerebellar tumors upon adjacent organs are of importance, because in conjunction with the special symptoms they acquire unusual significance. Sight and hearing are the two special senses apt to be affected, because of pressure upon the geniculate bodies and upon the auditory nerve or its nucleus. Descending optic neuritis, progressing to total blindness, and varied forms of oculo-motor paralysis may be present. Strabismus convergens has been said to be a symptom, caused by the paralysis of the sixth nerve. A hemiplegia and hemianæsthesia result sometimes from pressure upon the tracts in the pons or medulla. Continued pressure upon the medulla may eventually, toward the termination of the case, according to Rosenthal, cause disorders of the pulse and of respiration and deglutition. This author gives absence of psychical symptoms as negative evidence which counts for tumors of the cerebellum, but our table shows several instances (Cases 70, 71, 74, and 76) in which were present hebetude, incoherence, or hysteroidal symptoms. It is probable, however, that such symptoms are not as common and distinct as in tumors of the cerebrum.

Certain symptoms—or, better, groups of symptoms—characterize tumors of the pons varolii, and serve to render the local diagnosis comparatively certain. These depend upon the fact that the pons combines in itself, or

has on its immediate borders, nerve-tracts, both motor and sensory, in great complexity, from or to almost every special or general region of the body. Among these symptoms may especially be mentioned alternating and crossed hemiplegia, paralysis of eye-muscles (strabismus), paresis of tongue, dysphagia, anæsthesia (sometimes of the crossed type), and painful affections of the trigeminus. Vaso-motor disturbances have also been noted. In one case persistent and uncontrollable epistaxis hastened the fatal termination of the case.

Conjugate deviation of the eyes, with rotation of the head, as stated under Symptomatology, is a condition often present in tumors of the pons varolii as well as in the early stages of apoplectic attacks. A paper¹ has been published by one of us on a case of tumor of the pons, and from it we will give some discussion of this subject.

Vulpian was probably the first to study thoroughly conjugate deviation. The sign, when associated with disease of the pons, was supposed by him and by others to be connected in some way with the rotatory manifestations exhibited by animals after certain injuries to the pons. Transverse section across the longitudinal fibres of the anterior portions of the pons produces, according to Schiff, deviation of the anterior limbs (as in section of a cerebral peduncle), with extreme flexion of the body in a horizontal plane toward the opposite side, and very imperfect movements of the posterior limbs on the other side. Rotation in a very small circle develops in consequence of this paralysis.² The movements of partial rotation are caused, according to Schiff, by a partial lesion of the most posterior of the transverse fibres of the pons, which is followed in animals by rotation of the cervical vertebræ (with the lateral part of the head directed downward, the snout directed obliquely upward and to the side).

This deviation, both of head and eyes, occurs, however, not only from lesions of the pons and cerebellar peduncles, but also from disease or injury of various parts of the cerebrum—of the cortex, centrum ovale, ganglia, capsules, and cerebral peduncles. It is always a matter of interest, and sometimes of importance, with reference especially to prognosis, to determine what is the probable seat of lesion as indicated by the deviation and rotation.

Lockhart Clarke, Prevost, Brown-Séquard, and Bastian, among others, have devoted considerable attention to this subject. To Prevost we owe an interesting memoir. Bastian, in his work on *Paralysis from Brain Disease*, summarizes the subject up to the date of publication (1875). Ferrier, Priestly Smith, and Hughlings-Jackson have investigated the relations which cortical lesions bear to the deviation of the eyes and head.

It has been pointed out by several of the observers alluded to that when the lesion is of the cerebrum the deviation is usually toward the side of the brain affected, and therefore away from the side of the body which is paralyzed. In a case of ordinary left hemiplegia it is toward the right; in one of right hemiplegia, toward the left. In several cases of limited disease of the pons, however, it has been observed that the deviation has been away from the side of the lesion. In our case (Case 84) the conjugate deviation was to the right, while the tumor was entirely

¹ *Journal of Nervous and Mental Disease*, July, 1881; Case 84 of Table.

² Rosenthal's *Diseases of the Nervous System*, vol. i. p. 125.

to the left of the median line, thus carrying out what appears to be the usual rule with reference to lesions of the pons.

During the life of the patient it was a question whether the case was not one of oculo-motor monoplegia or monospasm from lesion of cortical centres. It is probable, as Hughlings-Jackson believes, that ocular and indeed all other movements are in some way represented in the cerebral convolutions. In the *British Medical Journal* for June 2, 1877, Jackson discusses the subject of disorders of ocular movements from disease of nerve-centres. The right corpus striatum is damaged, left hemiplegia results, and the eyes and head often turn to the right for some hours or days. The healthy nervous arrangement for this lateral movement has been likened by Foville to the arrangement of reins for driving two horses. What occurs in lateral deviation is analogous to dropping one rein; the other pulls the heads of both horses to one side. The lateral deviation shows, according to Jackson, that after the nerve-fibres of the ocular nerve-trunks have entered the central nervous system they are probably redistributed into several centres. The nerve-fibres of the ocular muscles are rearranged in each cerebral hemisphere in complete ways for particular movements of both eyeballs. There is no such thing as paralysis of the muscles supplied by the third nerve or sixth nerve from disease above the *crus cerebri*, but the movement for turning the two eyes is represented still higher than the corpus striatum.

It would seem a plausible theory that we have in this conjugate deviation of the eyes and head a distinct motor analogue to the hemianopsia which results from certain lesions high in the optic tracts. The fact that we never have a distinct oculo-motor monoplegia from high lesions, but always a lateral deviation of both eyes in the same direction, suggests that only a partial decussation of the fibres of the motor nerves of the eyes occurs, and that each hemisphere does not control the whole motor apparatus of the opposite eye, but half of this apparatus in each eye.

Alternating hemiplegia, or paralysis of one side of the body followed by a paralysis of the other side, is observed in tumors of the pons, and is readily accounted for by the close proximity of the motor tracts, a lesion which affects one tract first being very likely, sooner or later, to involve, partially at least, the other, as in Case 84. Cross-paralysis of the face and body may be seen, and like crossed anæsthesia (seen also in Case 84) depends upon the fact that both motor and sensory fibres to the limbs do not decussate at the same level as these fibres to the face. Trigeminal neuralgia, from involvement of the nerve by pressure or otherwise, is recorded in this characteristic group of symptoms. The association of the general with the local paralytic symptoms in the manner stated, the involvement of sensory functions, and the deviation of the eyes and head serve to distinguish tumors of the pons from cortical or high cerebral local lesions. Cases 81, 84, 89, and 90 illustrate these facts in various ways. Case 82, involving the floor of the fourth ventricle, appears to be an exception, as the deviation is toward the side of the lesion.

The special localizing symptoms which indicate a tumor of the *crus cerebri* are paralysis of the oculo-motor nerve upon the same side as the tumor, and especially the tendency of this paralysis to pass to

the other side later in the case; disturbance of the innervation of the bladder; and involvement of the vaso-motor functions. In considering these symptoms in detail it becomes very evident why we have the alternating paralysis of the two oculo-motor nerves. As this trunk arises from the crus, it is in direct risk of injury by the neoplasm, and the extension of the new growth even slightly must later in the case involve its fellow. Therefore a ptosis, followed by a similar symptom on the other side, or other third-nerve symptoms passing from one side to the other, with other characteristic and corroborating symptoms, furnish strong evidence of this lesion, as in Case 93. Rosenthal refers especially to involvement of the bladder, as difficulty of micturition, but the three cases in the table do not present such a symptom. He says that experiments prove that irritation of the peduncle is followed by contraction of the bladder, and that it has been shown that lesions of the crus abolish the influence of the will upon micturition. As this occurs at all levels of the cord, its occurrence with lesions of the crus is not to be considered a very distinctive symptom. The involvement of the vaso-motor functions is one of much interest. Its occurrence is not recorded in the cases of tumors of the crus included in the table, but in Case 94 of twin tumors in front of the optic chiasm it is recorded that profuse perspiration occurred. We believe that the centres for the vaso-motors are not well determined: they seem to be affected by various lesions, especially about the base of the brain. Among other corroborating symptoms may be mentioned rotatory movements and deviation of the head: these rotatory movements are probably caused by the action of the sound side not antagonized by the muscles of the paralyzed side. Lateral deviation of the head is referred to by some. Partial or complete hemiplegia, with facial paralysis on the side opposite to the lesion, may occur; whereas the oculo-motor palsy is seen on the same side as the lesion. Diminution of sensibility happens on the opposite side, or occasionally pain in the legs, as recorded in Case 92. It is of interest to note, with Rosenthal, that the reactions of degeneration are not likely to appear in the facial muscles in this lesion, as it occurs above the nucleus of that nerve, and thus causes a true centric paralysis. The absence of psychic symptoms is usually to be noted.

Tumors anywhere in the middle portion of the base of the brain and floor of the skull, the region of the origin of the various cranial nerves, can of course be diagnosticated with comparative ease by a study of the various forms of paralysis and spasms in the distribution of these nerves, in connection with other special and general symptoms. Varieties of alternate hemiplegia are to be looked for, and also isolated or associated palsies of the oculo-motor, pathetic, facial, trigeminal, and other cranial nerves. In studying these palsies it must be borne in mind that although the lesions producing them are intracranial, the paralyzes themselves are peripheral.

In most cases apparent exceptions to the ordinary rules as to localization are capable of easy explanation; thus, for instance, in a case of tumor of the occipital lobe (Case 44) numbness and pain were present in the right arm, although the tumor was situated in the right hemisphere. The tumor was of considerable size, and may have affected by pressure the adjoining sensory tracts.

Hughlings-Jackson¹ reports a case of tubercular tumor, half the size of a filbert, in the pons under the floor of the fourth ventricle, in the upper third of the left side. A much smaller nodule was found in the right half of the pons. This patient, a man thirty-three years old, had inconstant headache, a gradual incomplete hemiplegia of the right side, with also paresis of the left masseter and right lower face. Sensation was diminished in the right arm, leg, and trunk. The optic discs were normal; the left pupil was smaller than the right. There was lateral deviation of the eyes to the right. Diplopia was present in some positions, and one image was always above the other. Aphasic symptoms were also present. Especial interest attaches to the fact that the facial paralysis in this case was on the same side as the hemiplegia, opposite that of the lesion; whereas usually in lesions of the pons facial paralysis is on the side opposite the hemiplegia. This is explained by the fact that the tracts of the facial nerve decussate in the pons below its upper third, and therefore in this case the lesion caught the nerve-tracts above their decussation.

PROGNOSIS.—The prognosis in intracranial tumors is of course usually in the highest degree unfavorable. The early recognition of the existence of a tumor syphilitic in origin will enable a comparatively favorable prognosis to be made. It is far from correct, however, to suppose that all or a majority of the cases of known syphilitic origin are likely to have a favorable termination. Amidon² puts this matter very correctly as follows: "Has a destructive lesion occurred? and if so, where is it located, and what is its extent? Indications of a destructive lesion should lead one to a cautious prognosis as regards perfect recovery, while the prognosis for life and a moderate amount of health may be good. A gummy intracranial or spinal growth, giving rise to alarming symptoms, may vanish as by magic upon prompt treatment. The symptoms of these frank, specific growths are, as a general thing, characteristic and widely different from those of the more insidious destructive lesions.

"An intracranial gumma often heralds itself by sharp, localized headache, gradually deepening paralysis, aphasia, epilepsy, and optic neuritis, while destructive lesions are more apt to have diffuse, dull headache, stationary or lessening paralysis or aphasia, rarely epilepsy or optic neuritis. Intraspinal gunmata give rise to a painful paraplegia, while an inflammatory or destructive change gives rise to various and atypical sensory and motor manifestations.

"As to the pathology of these cases, I can say but little, as such discussion opens the whole subject of the pathology of syphilis. This I will say, that, so far as can be told without autopsies, no permanent pathological condition was present in these cases which might not have been brought about by other etiological factors which were often present. The periencephalitis might be caused by alcohol, mental strain, or excesses; the arterial occlusion might be due to previous disease not specific."

TREATMENT.—The surgical treatment of tumors of the brain has recently received a great stimulus from the report of a case which

¹ *Med. Times and Gazette*, London, 1874, p. 6.

² *Medical News*, vol. xlviii. No. 3, Jan. 16, 1886, p. 64.

occurred in the practice of A. Hughes-Bennett of London, and which was operated on by Rickman J. Godlee. The case has been included in the table (Case 24), where the symptoms and details of treatment may be read. This case has served to bring into sharp outline many of the difficulties and dangers of such an operation on the one hand, and the few possible and exceptional advantages of it on the other. It must be apparent, in the present state of knowledge and with the additional light of this interesting case, that success must largely depend upon the following conditions: The tumor must be exceptionally localized—*i. e.* not very large—and non-multiple; it must be cortical, or at least not very deep-seated; it is also quite essential that it be in the motor zone, in order to admit of accurate diagnosis. It would seriously impair the usefulness of the operation and the prognosis if the case were of long standing with much necrosis of brain-tissue, or if the growth were malignant and recurring. The secondary complications, as inflammation and sepsis, are of course possible in all surgical cases, and may be guarded against, as well in cerebral as in other surgery. If such a criticism narrows the field for the operation into almost hopeless limits, it may be reflected that one or two successful cases are better than a hundred experimental failures; that cases do occur in which the tumor is just so localized, single, and superficial; that the urgency of distressing symptoms, as pain and convulsions, urge the operation for palliation as well as cure; and that these cases, without relief, are necessarily fatal, and hence justify large risks.

By exclusion and a careful study of the symptoms we believe it may become possible hereafter in some cases to localize in two other accessible regions brain tumors with sufficient accuracy for purposes of operation: these are the antero-frontal region and the postero-parietal region.

The case of Bennett and Godlee was a most successful test of diagnosis, and as a surgical endeavor might have been more successful, as the operator himself suggests, if more careful antiseptic precautions had been used. In the discussion of this case before the Royal Medical and Chirurgical Society¹ it was stated by Hughlings-Jackson that three indications were of special importance for this diagnosis: (1) local persisting paralysis; (2) epileptiform convulsions, those beginning locally; (3) double optic neuritis, which is diagnostic of tumor as distinguished from a sclerotic patch. It is probable that permanent palsy would be left after a successful operation in which the cortical tissue were destroyed, but as this is compatible with life and comfort, it is not likely that, as an alternative, it would be rejected by the patient. McEwen's case, also given in the table (Case 25), is not as accurately reported² as Bennett's, but was partially successful. At the opening over the Rolandic region false membrane was removed, and an incision made which let out grumous red-colored fluid: this was followed by a decrease in the paralysis and improvement in other brain symptoms. It is difficult to understand why the opening was made in the occipital region. The necessity for antiseptic measures is to be especially considered in cerebral surgery. In a recent operation for a case of traumatic epilepsy, under the care of Mills and White, in the Philadelphia Hospital, in which quite extensive injury was done to the membranes in removing fragments of bone, rigid

¹ *Brit. Med. Journ.*, May 16, 1885, p. 988.

² *Glasg. Med. Journ.*, xxi., 1884, p. 142.

antisepsis was employed; and it is not too much to assume that the risks of the operation were much diminished by it and its success ensured in an old and crowded hospital building.

In the medication of tumors of the brain we can unfortunately do but little more than treat the symptoms and ameliorate the various conditions as they arise. There is no specific for these growths, unless the syphilomata be an exception; and experience shows that specific treatment is usually disappointing even when applied to a syphilitic brain tumor. The dietetic and hygienic rules laid down by some are only such as are invariably recommended as routine practice in all kinds of disease; and it almost seems a mockery to offer them to a patient with an intracranial tumor with the same gravity and detail as we suggest them in a curable fever or a hopeful surgical case. It is possible that local depletion and revulsives, by controlling irritation and hyperæmia, may be beneficial, though we should hesitate to add to the sorrows of the patient the action of tartrized antimony, even, with Obernier, in special cases. Hot or cold effusions and the ether spray are worthy of mention. Local applications of the galvanic current might be tried for its catalytic action, but the observations are too few and the theory too inapplicable to allow us to attach much importance to the suggestion. The use of electricity to the limbs for paralytic symptoms certainly does not promise much in the case of an obstinate neoplasm in the brain.

Morphia and bromide of potassium are the two drugs which offer the most promise in these fatal cases. They can often control the most urgent and frightful symptoms. The headache, the obstinate vomiting, the epileptic seizures, are all more or less amenable to one or other of these remedies or a combination of them. Although the vomiting is of centric origin, it is possible that remedies addressed to the stomach might occasionally afford relief, just as we apply medicines to that viscus in reflex irritation, in pregnancy, and in debilitating diseases. The remedies which suggest themselves are the salts of bismuth and cerium, the more stimulating wines, as champagne, in small frequent doses, and cracked ice.

While morphia and bromide of potassium are, on the whole, the most useful remedies for the relief of pain and irritating symptoms of brain tumor, other remedies can often be used with great advantage as adjuvants. Ergot in the form of the solid or fluid extract has a beneficial influence in relieving the congestive symptoms. Cannabis indica in the form of the fluid extract in doses of five to ten minims, or the tincture in doses of fifteen to thirty minims, may be advantageously combined with morphia and a bromide, or sometimes may be tried alone. Hyoseyamus, either the fluid extract or tincture, in somewhat larger doses may also be tried. The great severity of the headache and the imperative demand, however, will usually compel the physician to fall back at last upon morphia in large dose by the mouth or hypodermically.

Leeches to the temples or behind the ears or to the mucous membrane of the nose, either wet or dry cupping to the back of the neck, and bladders or compresses of ice, or very hot water, may be used to the head.

The various serious complications which so often accompany intracranial tumors should be most carefully managed. Among the most important of these are such affections as the conjunctivitis and trophic

corneitis, with anæsthesia, present in a few cases, usually when the trigeminal is directly or indirectly involved. Cystitis and pyelitis must be appropriately treated, and patients must be carefully watched in order to prevent injurious consequences of over-distension of the bladder or enormous fecal accumulations.

TABLE OF ONE HUNDRED CASES OF BRAIN TUMOR.

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|--|--------------|---|---|---|
| <i>Superior Antero-frontal Region.</i> | | | | |
| 1 | M. 35. | Syphilis and traumatism. Headache; vertigo; mental slowness; loss of attention; hysterical. Nystagmus. Tonic spasm of neck and forearm. Movements weak and uncertain. Explosive speech. Gradual blindness; choked discs. Conjunctivitis and corneitis of left eye. Anæsthesia of conjunctiva. Polyphagia. Constipation alternating with involuntary evacuations and urination. Temperature 97°-101°. Head-temperature above normal; highest at frontal station; average, 96.5. | Fibroma. Anterior superior half of second frontal and anterior superior and inner half of first frontal; anterior segment of gyrus fornicatus, and anterior half inch of corp. callosum. | C. K. Mills, <i>Philada. Med. Times</i> , Jan. 18, 1879, and <i>Arch. of Med.</i> , vol. viii. No. 1, Aug., 1882. |
| 2 | M. 50. | Headache, dizziness, and slight right facial paralysis. Dimness of vision. Day before death had an attack of unconsciousness, from which he emerged in half an hour. In two hours had another attack; became comatose; Cheyne-Stokes respiration; temperature 102.3°; pulse 150. Reflexes completely abolished. | Fibroma. One and a half inches in diameter in the left antero-frontal lobe, located so as to involve the middle portions of the first and second frontal convolutions and white substance beneath them almost to the orbital surfaces. White matter softened posterior to tumor. Adherent to pia mater. | C. K. Mills. Not before published. |
| 3 | M. 16. | Frontal headache, vertigo, staggering gait toward right. Later, paresis of sphincter of bladder. Some muscles of right face paretic. Some weakness of mind; emotional. Choreic movements of right arm, increased with mental excitement. No deafness, loss of taste, or of tactile or heat sense. Slight traces of sugar. Blurring of papilla and hyperæmia of retina. Later, vomiting. Urine sp. gr. 1031. Irritability of mind, with erotic conduct. Reduction of pulse—54. Progressive emaciation and mental failure. Tremor in both arms, and in right arm automatic movement. Boil on left hand. Scaphoid abdomen. Later, temperature below normal; also pulse and respiration. Right facial paralysis unchanged. Still later, contracture of both elbows. Pupils react tardily. Apathetic. Very late, small quantity albumen, no sugar. | Glioma. Frontal convolutions flattened; brain-substance doughy; cortex gray-red; medullary substance reddish-white. Corpus callosum arched upward; lateral ventricles enlarged in posterior horns. Tumor in medullary substance of both frontal lobes, springing from septum and radiating toward parietal lobes, almost filling both anterior lobes, and also adhering to walls (apparently) of ventricles. At base extended backward full extent of frontal lobe. | Petrina, <i>Vierteljahrsschr. f. die Prakt. Heilk.</i> , 1 Bd., 1877, p. 126. |
| 4 | M. 36. | History of injury to the head. Frontal and occipital headache. Vomiting and giddiness. Memory much affected. Double internal strabismus with unequal pupils. Double optic neuritis. Hearing unaffected; sense of smell lost. Lies on back. Stumbles on trying to walk. Answers questions with difficulty; speech slow and hesitating. Pain in head, apparently increased by percussion in right frontal region. | Endothelioma. In right frontal lobe anterior portion. Three inches in diameter. Surrounded by soft diffuent cerebral tissue. Right frontal bone had on its internal surface a much greater concavity than the left, and at its upper and outer part was rough, deeper in color, and thin. Dura mater adherent. | Philipson, <i>Medical Times and Gazette</i> , vol. ii., for 1882, Sept. 16, 1882, p. 355. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|---|--------------|---|---|---|
| 5 | F. 32. | History of chancre with secondary and tertiary lesions of syphilis. Frontal node. Constant headache. Epileptiform convulsions. Marked exophthalmus, with impairment of sight in both eyes. Improved under iodide of potassium. Grew worse again. Dimness of vision; pain in head constant, and worse at night. Ophthalmoscope revealed neuro-retinitis with commencing atrophy of optic nerves. | Gumma. From dura mater into the brain-substance at the anterior portion of the anterior lobe of the left hemisphere. Brain-substance softened around tumor. Left ventricle dilated, and filled with fluid. | H. Knapp, <i>Arch. of Ophthalmology and Otolology</i> , vol. iv. p. 245. |
| <i>Inferior Antero-frontal or Orbital Region.</i> | | | | |
| 6 | M. 27. | Loss of sight, increasing to total blindness. Gradually increasing loss of hearing, of smell, and of taste, in order named. No anæsthesia. No paralysis mentioned. | Fibro-sarcoma. Involving inferior portion of right anterior lobe. The first and second pair of nerves were involved, but no other nerves. | L. Howe, <i>Buffalo Med. and Surg. Journ.</i> , xxi. p. 299. |
| 7 | F. 33. | Paralysis and wasting of right leg since childhood. Sudden severe general convulsions with loss of consciousness, followed by paresis of right upper extremity. No facial or ocular paralysis. Special and general sensibility normal. Recurrent convulsions, both tonic and clonic. Severe frontal headache; continued paresis of right arm. Apathetic. Right face partially parietic, and right oculo-motor weakened. | Cholesteatoma. Growing from pia mater at the base between both frontal lobes, extending to anterior margin of corpus callosum and to optic chiasm. | Petrina, <i>op. cit.</i> , p. 126. |
| 8 | F. 20. | Vomiting. Loss of sight and hearing; inability to speak. Somnolence. Pupils widely dilated. Later, all special senses involved. Tongue protrudes to right. Pulse irregular. Right face anæsthetic. Neuro-retinitis in both eyes, worse in right; left eye retained some vision. Hearing and taste perfect; smell impaired. No paralysis. Pain constant over eyes. No convulsions. | Under left anterior lobe and extending from falx cerebri, to which it was adherent, over the cribriform plate of the ethmoid, involving left olfactory nerve, backward and diagonally across the sella turcica to right petrous bone, where the end of it pressed on fifth nerve of right side at its point of exit. Pressed upon optic chiasm. | E. Williams, <i>Med. Record</i> , 1868, pp. 29-31. |
| 9 | M. 49. | Vertigo. Always excessively stupid, allowing himself to be made a fool of. Violent bleeding from the mouth and nose ten years before death, followed by nasal discharge. Frontal headache, especially on left side. Failure of sight. Small tumor in inner upper angle of left orbit, which dislocates left eye outward; right eye also deviated outward without any apparent mechanical reason. Pupils dilated and sluggish. Sight much diminished. Mouth slightly drawn to one side. Speech slow, but not hesitating. Gave replies to questions slowly, and did not usually keep to the point, but clothed his answers in general remarks. A certain amount of self-esteem pervaded his conversation. Continuous headache. Very late, had convulsions which began on the left side and extended to the right. | Tumor the size of a large walnut to the right of the middle line, external to the dura mater at a point corresponding to position of right olfactory bulb. Vitreous table of the frontal bone and crista galli of the ethmoid completely destroyed. On the inner side of dura mater another tumor fills the right anterior fossa and a large portion of the left. | Obernier, <i>Virch. Arch.</i> , vol. xxxvi. p. 155, and <i>Ziemssen's Cycl. Pract. of Medicine</i> , Am. ed., vol. xii. p. 268. |
| 10 | M. —. | Diminution of vision. At first much reduced, without any ophthalmoscopic changes. Slight headache; loss of appetite; restless sleep; rapid pulse. Vision sank rapidly until completely extinguished. Remained thus for nineteen days; then sight began to return, first in the right eye, and then in the left. Increased, so that an examination of the eccentric fields could be undertaken; this showed absence of the external halves of the fields of vision—hemian- | Sarcomata. Two tumors: one about the size of a pigeon's egg between the optic trunks in front of the chiasm, surrounded by the optic nerve in a forked manner, the nerve-fibres being parted by it. A second tumor sit- | Saemisch, <i>Klin. Monatsblätter</i> , 1865, p. 51, quoted by Oberrnier, <i>Ziemssen's Cycl. of the Pract. of Medicine</i> , Am. tr., vol. xii. p. 269. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|--------------------------------------|--------------|--|--|--|
| | | opsia. "The transition of the existing portions of the fields of vision to the lost portions was effected by a region which, by a low light, should be reckoned to the latter, so that then the boundary-line of the defect fell somewhat to the outside of the fixation-point running in the right eye in a vertical direction, and in the left diagonally from the inside and above downward and outward. Within the next four weeks the central vision increased in the right to $V = \frac{1}{2}$, and in the left to $V = \frac{2}{5}$, while the defect in the eccentric vision continued in the way described." Patient died of symptoms of acute meningitis. | uated beneath the pons, raising the dura mater. It had probably originated in cavernous sinus. | |
| <i>Rolandic Region—Motor Cortex.</i> | | | | |
| 11 | F. 38. | History of syphilis. Blows on the head. Headache, with agonizing paroxysms. Top and right side of head sensitive to percussion, and headache severest in these regions. Vomiting; vertigo. Great mental irritability. Severe left-sided spasm, beginning with twitchings in left toes and foot. Partial paralysis of right leg and arm, most marked in leg. Hyperæsthesia. Impaired sight. Choked discs. Head-temperature taken once: right parietal region, 97.2° F.; left parietal region, 96° F. | Gumma. Attached to the fused membranes of the right convexity. Involved the upper fourth of the ascending frontal and a smaller segment of the ascending parietal convolution, crossing Rolandic fissure at its upper extremity. A good example of strictly cortical lesion. | C. K. Mills, <i>Arch. Med.</i> , vol. viii. No. 1, August, 1882. |
| 12 | F. 30. | No history of causation. Headache continuous, sometimes agonizing. Percussion of head caused most pain in right parietal region. Vomiting when headache was most severe. Vertigo. Mind clear, but acted slowly; emotional. Spasm, beginning with twitching of fingers of left hand; most severe on left side, and especially in left arm. Upper as well as lower fibres of left facial nerve partially paralyzed; nearly complete paralysis of left arm; slight paralysis of left leg. Bowels and bladder partially paralyzed. Impaired sensibility in limbs of left side. Left patellar reflex diminished. Sight very imperfect. Choked discs. Hearing defective in right ear. | Carcinoma. The tumor involved the middle portion of the ascending parietal convolution and the upper part of the inferior parietal lobule, pushing aside the interparietal fissure. The anterior extremity of the tumor was about one-fifth of an inch back of the centre of the fissure of Rolandic. On the inner side of the tumor the white matter of the brain was broken down. Adherent to the pia mater; the pia and dura mater were united by strong adhesions. | C. K. Mills, reported at the meeting of the American Neurological Association, June, 1881, <i>Arch. Med.</i> , vol. viii. No. 1, Aug., 1882. |
| 13 | M. 31. | Evidences of tuberculosis. Headache continuous, with severe exacerbations; most severe at vertex. Vertigo. Some irritability and emotionality; hallucination that some one was going to come and take him away. Spasm confined to left arm. Partial paralysis of left arm and leg, and, late in his illness, of left side of face. Left hemianæsthesia, at first partial, but later complete and persistent. Sight impaired; right pupil dilated and left contracted before death. No ophthalmoscopic examination. Hearing defective in left ear; tinnitus aurium. Head-temperature taken once: right frontal region, 98° F.; left frontal region, 96.3° F. Cheyne-Stokes breathing on day of death. | Tubercular tumor. Dura and pia mater adherent over the tumor, which involved the posterior extremities of first and second frontal and upper thirds of both ascending convolutions of right hemisphere. Interior of hemisphere broken down; the parts destroyed included white matter of the parietal lobe, the posterior third of lenticular nucleus, and the adjacent portion of internal capsule. Miliary tubercles in pia mater around and near the tumor. | C. K. Mills, <i>Arch. Med.</i> , vol. viii. No. 1, Aug., 1882. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----|--------------|---|---|--|
| 14 | M. 19. | First symptom, headache; then vertigo. Sudden right brachial monoplegia; possibly some paresis of leg. Recovered use of arm; went to work; was kicked by a mule, and became worse. Headache and right-sided paresis returned. Increasing stupor; paralysis of right arm complete; of leg almost; right facial paresis; ptosis of right side. Partial anæsthesia on right side of face; pain on right side. Slight clonic spasms of right arm. Paralysis of bowels and bladder in last week. Tendency to Cheyne-Stokes respiration. No vomiting. Eyes not examined. | Gumma. A large tumor in the ascending frontal convolution, at junction of middle and upper thirds; one-third of mass on convexity of convolution, the remainder in fissure of Rolando. Smaller tumor at inferior angle of right lobe of cerebellum. Some basal meningitis with effusion. | C. K. Mills, <i>Med. and Surg. Rep.</i> , vol. II., Aug. 2, 1884, p. 119. |
| 15 | M. 56. | Sickness began with an epileptiform seizure lasting about ten minutes; flexing movements of right arm. Next day dragged his right leg slightly. Partial convulsions, without loss of consciousness, followed, and became very frequent. Two months before death convulsions ceased, but absolute paralysis of the arm and paresis of the leg remained. One month later complete palsy of right half of face occurred. Mind became impaired. Complete aphasia. Right-sided anæsthesia. Reflexes of right foot less marked than those of the left. Rectal temperature, 100.4° F. At times deviation of the head and eyes to the left. Left frontal and temporal regions tender to pressure. Very late nystagmus. No headache. | Glioma. In the left ascending frontal convolution, occupying the upper third of this convolution. The tumor extended backward to the fissure of Rolando, and in front was bounded by a vertical line which would meet the upper extremity of the vertical frontal fissure. The inferior boundary was distant about one and three-quarter inches from the longitudinal fissure. Surrounding convolutions flattened and widened. | Samt, <i>Arch. gén. de Méd.</i> , Jan., 1876, from <i>Berlin. klin. Wochenschr.</i> , Nos. 40, 87. |
| 16 | M. 49. | Irritability and loss of memory. Paresis, passing to paralysis, of left arm; paresis of left leg. Slight left-sided paralysis of tongue. No facial paralysis; no optic neuritis. Ankle-clonus and exaggerated knee-jerk on left side. No wasting of muscles or abnormal electrical reactions. Toward end paroxysmal twitchings of left side, including side of face, with left-sided paresis of face. Hebetude. Visual hallucinations. Complete left hemiplegia. Paralysis of sphincter. Vomiting. Strong contraction of pupils. Duration about two months. | Glioma. Involving the middle portion of the right ascending frontal convolution and posterior end of middle frontal convolution, extending as a spheroidal mass downward to roof of lateral ventricle. | A. Hughes Bennett, <i>Brain</i> , vol. v., 1882, p. 550. |
| 17 | M. 30. | Convulsions for twelve years prior to death. Character of fit: first, cramping of right big toe, then twitching of calf-muscles and drawing up of leg and knee. Most of the fits stop here, without loss of consciousness. In some fits the arm is convulsed after the leg, beginning in fingers, and consciousness is lost. Paralysis of right leg. Slight convulsive action of left leg. Sensation of right leg unimpaired. Temporary aphasia at beginning of attack; on one occasion the aphasia was present without fit. The right arm probably paretic after each seizure. No facial palsy. Has as many as thirty fits daily. Marked cessation of seizures at one time. Three days before death became hemiplegic, with exaggerated deep reflexes on paralyzed side; also ankle-clonus. During later years fit sometimes began in hand. No optic neuritis while under observation. | Glioma. Left hemisphere, including posterior half of superior frontal convolution and upper half of ascending frontal convolution, except the extreme end. The superficial area was defined by fissure of Rolando posteriorly, superior frontal fissure externally, and longitudinal fissure internally. Anteriorly, the tumor gradually merged into normal brain. In the longitudinal fissure the growth extended to callosal-marginal fissure. | J. Hughlings-Jackson, <i>Brain</i> , vol. v., 1882, p. 364. |
| 18 | F. 58. | General headache, most marked in the occipital region, and always worse at night. Sore, stiff feeling in neck; at times nausea and vomiting. Trembling | Alveolar carcinoma. An ovoid tumor in the upper part of the ascending frontal con- | E. C. Seguin, <i>Opera Minora</i> , p. 495, and <i>Journal of Nervous and Men-</i> |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----|--------------|--|---|--|
| | | of left hand; later, paresis. Two sorts of movements of left arm—one, a fine tremor; the other, attacks of jerking. Paresis of left arm increasing, with some contracture; slight paresis of left leg. Sight failing; later, semi-stupor; pupils small and fixed, the right larger. Right internal rectus weak. Left lower face paretic. Strong contractures of left arm and hand. Good knee-jerk. Choked discs. Some days bright, others almost moribund. Case advanced to complete paralysis of left arm and leg; involuntary evacuations; divergent strabismus and ptosis; indistinct speech; delirium and coma. | volution and in its subjacent white matter. It extended well across the fissure of Rolando. | <i>tal Disease</i> , vol. viii. No. 3, July, 1881. |
| 19 | M. 50. | History of syphilis and severe fall on the head. Vertigo. Prickling sensation in left foot, extending to thigh, finally to arm and head, followed by unconsciousness and convulsion. Stupor after convulsion. After this, convulsive attacks at intervals. Eighteen months before death an apoplectic attack, in which was unconscious for several hours. Spasmodic attacks, preceded by a peculiar twisting of the fingers of the left hand. Paresis of the right hand and arm. Some diminution of sensation, not well made out. Slight want of use of the left leg. | Gumma. One-third of an inch in thickness at the middle of the ascending frontal convolution. Membranes fused; tumor adherent to them. Edema of the brain. Gumma in the lungs. | H. C. Wood, "Proceedings of the Philada. Neurological Society," <i>Medical News</i> , vol. xlviii. No. 9, Feb. 27, 1886, p. 248. |
| 20 | M. 59. | Gradual loss of speech—aphasia. Gradual paralysis of right side. No headache prior to this. No anæsthesia. Taste, smell, hearing, and sight intact. Apathetic face. Middle branch of facial nerve paralyzed, especially the muscles of the right corner of the mouth. Wrinkles of forehead less strongly marked. Right upper and right lower extremity in strong contracture. Leg swollen. Increasing torpor of bladder. Normal electrical reactions, except speedier and increased reaction of the right facial nerve. Reactions of convulsibility in the right arm with ten to twenty cells. Very late, unconsciousness and paralysis of bowels and bladder. | Myxo-glioma. In front of the left ascending frontal convolution, bounded below by the Sylvian fissure and the upper convolution of the island of Reil; seems to immediately enter into the structure of the island. Left optic thalamus and corpus striatum moist, but completely separated from the tumor. Convolutions flattened. | Petrina, <i>op. cit.</i> |
| 21 | M. 35. | Had epileptic fits for two years before his death. Occasionally the spasms began in the left half of the face and extended to the arm and leg, but did not become general. After such attacks sensation was lost in the left arm, and the arm was paretic for some hours. Toward the close of life the paresis became permanent, and extended from the arm to the leg, and sensibility was somewhat impaired in these limbs. The temperature was 2.5° F. higher over the right parietal eminence than over the left. | Gumma. Arising from the membranes, two inches in diameter, but very thin, involved the gray matter of the posterior extremities of the first and second frontal convolutions, the upper and middle thirds of the ascending frontal convolution, and the adjacent border of the ascending parietal convolution of right hemisphere. | F. H. Martin, <i>Chicago Med. Journ. and Exam.</i> , vol. xlvii. 21. |
| 22 | F. 57. | After excitement lost consciousness. Paresis and heaviness of the right upper extremity. Aphasia; used words inaccurately; short of words and enunciation impaired. Second attack of loss of consciousness. Twitching in right half of body and face. Paralysis of right upper extremity. Severe pains in right arm and leg. Another attack of loss of consciousness, with spasms of right half of body. Right lower extremity and right lower face paretic. Slight trismus; right masseter contracted. Dull headache. Organs of sense not affected. Understands all that is said to her, although aphasic. | Fibro-glioma. Tumor size of fist occupied the whole of the lower and middle portion of the parietal lobe, imbedded in both ascending convolutions. Ascending frontal convolution pushed aside; the annectant gyrus and island of Reil compressed and flattened. Fissure of Sylvius arched over | Petrina, <i>op. cit.</i> |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----|--------------|---|--|--|
| | | Sensibility good. Right-sided pneumonia; œdema of lung. | by tumor. White substance also pushed toward the corpus striatum. Meninges congested. Left parietal bone somewhat excavated. | |
| 23 | F. 39. | Began to suffer with epilepsy two weeks after a blow on the left parietal region. The fits were preceded by formation in the right hand and tongue, and began with spasm in the right hand, which was weak for some hours afterward. A permanent right facial paresis developed one month after the blow, and two months later the tongue, arm, and hand were also paretic on the right side. Disturbance of vision due to choked discs had developed, and temporary attacks of aphasia occurred after the frequent convulsions. She sank into a condition of stupor and aphasia four months after the first symptoms. The skull was then trephined at the seat of the old injury in hopes of evacuating a chronic abscess, but no pus was found. One week after this she died. | Gumma. A gumma one inch in diameter was found on the surface of the left hemisphere, at the junction of the middle and lower thirds of the ascending parietal convolution, and involving also the convolution posterior to this. The membranes were adherent to the gumma. | H. B. Sands, <i>Med. News</i> , April 28, 1883. |
| 24 | M. 25. | Four years previous to death had received a blow on the left side of the head. A year later, twitching in the tongue and the left side of the face. Twitching of the left arm. Twitching increased. Paroxysmal spasm and general convulsions, with loss of consciousness. Paresis, and then slowly-developed paralysis, of the forearm and hand. Some paresis of left leg. Double optic neuritis. Violent headache. This patient was in charge of Hughes-Bennett at the Hospital for Epilepsy and Paralysis, London. He diagnosed brain tumor, and suggested its removal. Rickman Godlee trephined over suspected region, and removed a glioma of the size of a walnut. The operation was performed November 25th. The patient did well until December 16th, when he was seized with a rigor, followed by fever, sickness, and pain in the head. A hernia cerebri of large dimensions supervening, he died December 23d. | Glioma. Meningitis was found at the lower border of the wound, spreading downward toward the base of the brain. | Hughes - Bennett and Rickman Godlee, <i>British Medical Journal</i> , Nov. 29, 1885. |
| 25 | F. | Syphilitic history. Tingling sensation and numbness of the left arm and leg, which increased until it ended within six weeks from its commencement in complete motor paralysis, with a deficiency in the perception of touch. Left side of the face also slightly paretic. Mental confusion and loss of memory. | After antisyphilitic treatment and counter-irritation, trephining was performed over the middle of the ascending parietal and frontal convolutions. Internal table of the disc removed was found softened and thicker than usual, having on its internal surface projections or roughnesses. A second opening was made over the occipital region, and a similar thickening was found. Opposite first opening the dura mater pale and thickened. It was elevated, and a false membrane of yellow color was removed. An incision was made in the direction of the paracen- | Macewen, "Proceedings of Path. and Clin. Soc. of Glasgow," <i>Glasgow Med. Journ.</i> , vol. xxi., 1884, p. 142. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|--|--------------|--|--|---|
| | | | tral lobule, when a gush of grumous, red-colored fluid escaped. Day after the operation much better; on third day moved her toes; within a week lifted her leg; fingers moved within a week. Mind greatly changed for the better. | |
| <i>Centrum Ovale—Fronto-parietal Region.</i> | | | | |
| 26 | F. 16. | Fell when sixteen months old from the table on her head. Left hand, five months later, noticed at times to be stiff and firmly closed. Three months later the leg became similarly affected, and two months later general paroxysms. Many seizures for periods of weeks or months, then intervals of freedom. Spasm began by contraction of the left hand; she would lie down and jerk for a half minute or minute, laughing or talking all through it, never losing consciousness. In about six years left leg became paretic. Seizures became much worse and more frequent; unconscious for six weeks, and fifty to eighty spasms in twenty-four hours. Ten months without spasms until a week before death, when they returned with great violence. Spasms always began in the left hand; appeared to extend to the leg first, and then to the face. Intellect clear. | Fibro-glioma. In the white matter, but touching upon the gray at several spots at the position of the upper end of the ascending frontal convolution of the right hemisphere. The tumor occupied largely the anterior portion of the paracentral lobule. | Osler, <i>Medical News</i> , vol. xliii., Jan. 19, 1884, in "Proceedings of Medico-Chirurgical Society of Montreal;" also, <i>Am. Journ. Med. Sci.</i> , N. S. vol. lxxxix., Jan., 1883, p. 31. |
| 27 | M. —. | Severe fall, followed by insensibility. Paralysis of the left side followed injury, but improved. Three years later, epileptic convulsions: sudden fall, general spasm, biting tongue. These attacks replaced by partial or localized epilepsy without loss of consciousness: tonic-clonic spasm of muscles of left side of face and neck and of left upper extremity, especially of the thumb and index finger. Left pupil a trifle larger than right; left cheek paretic, left arm and forearm absolutely paralyzed; left leg weak. Marked tactile anaesthesia on left side. Ophthalmoscope showed fulness of veins, but no neuro-retinitis. Late, some opisthotonos. Deafness in right ear; axillary temperature, 36.4° C. Pain in right arm and leg and in posterior part of head on right side. Conjugate deviation of head and eyes from palsied side. No neuro-retinitis. Localized and general convulsions recurred from time to time. | Sarcoma. Larger than a hen's egg in white substance of right hemisphere, occupying the whole thickness of the hemisphere above the opto-striate bodies. Exerted much pressure upon these bodies, on convulsions near, and even upon the inner surface of the left hemisphere. Adherent to the dura mater. Right half of the brain much enlarged, and lateral ventricle and septum lucidum forced over to the left. Two depressions on the top of the skull; dura mater depressed and adherent to convulsions. Some pachymeningitis. | E. C. Seguin, <i>Opera Minora</i> , p. 215; reprinted from the <i>Transactions of the Amer. Neurol. Ass.</i> , vol. ii., 1877. |
| 28 | M. 34. | Attacks of right-sided epilepsy every four or six weeks; later, every week or oftener. Spasms wholly restricted to the right arm or leg; the slightest attacks only momentary shocks on the right side of the body. No spasm in the face. Only very rarely lost consciousness. Never frothed at the mouth, bit his tongue, or micturated in the attacks. In intervals had good use of his right hand and leg up to a late period. Paresis of right limbs came on with indefinite numbness of right leg. Diffused headache, mostly frontal. No facial palsy; no anaesthesia. Knee-jerk absent on left side and strong on right. | Sarcoma. In centrum ovale, underneath the left cortical motor area, and completely undermining it, was a large cavity which contained a large amount of coffee-red serum, and also a tumor lying on its inner side near the paracentral lobule. The tumor was connected behind with | E. C. Seguin, <i>Opera Minora</i> , p. 459, and <i>Journ. of Nerv. and Mental Dis.</i> , July, 1881. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|---------------------------------|--------------|--|--|--|
| | | Later, complete paralysis of right arm and leg, with oedema. Violent headaches, more to the left of the median line at the vertex; photophobia, nausea, and vomiting. No neuro-retinitis. Still later, paresis, and then paralysis of right face. Atrophy; contractures; bed-sores; semi-coma; profuse sweating; high temperature; conjugate deviation of the eyes to the right; head straight. | the falx cerebri in the region of the paracentral lobule. | |
| 29 | M. 22. | First symptom was a fit, which was followed by a rigor. After this fit paresis of right arm and leg, with inability to articulate properly. Could not raise the affected arm, but could grip objects weakly. Paralysis of right side of face and tongue. Was quite rational. No loss of sensation. Later, violent headache, followed by vomiting. Slight amelioration of many symptoms, soon followed by second attack of violent headache, which could not be localized; complete right hemiplegia and aphasia. Later, dysphagia. Death rather sudden. Patient had had amputation of thigh about six months before for sarcomatous enchondroma of head of the tibia. Had also had chancre four years before. | Enchondroma. In left hemisphere, between anterior part of corpus striatum and "surface of frontal lobe." The cortex over tumor and the outer and anterior portion of corpus striatum were softened and broken down. | T. P. Pick, <i>St. George Hosp. Rep.</i> , vol. ix. p. 663. |
| 30 | F. 16. | Patient was a wayward, hysterical girl of neurotic family, precocious, and with abnormal sexual instincts and indulgences. Had a sudden attack of total blindness, then sudden recovery; sudden blindness again, and deafness; then restoration of hearing; loss of power in lower limbs, ending with total blindness, deafness, and paraplegia. Had dilated pupils and some hyperæsthesia; also marked hysteroid attacks, becoming at last maniacal. Negatively, no constant headache or affection of ocular, facial, or lingual muscles, no convulsions or vomiting; no abnormal ophthalmoscopic appearances (except slight choked disc). The case had been diagnosed by many doctors and one of the "first authorities in Europe" to be hysteria. | Tumor in right hemisphere, size of hen's egg, translucent, and nodulated, soft, highly vascular, with small extravasations of blood on its surface, occupied medullary substance of middle lobe superior to lateral ventricle causing bulging of roof of ventricle. | A. Hughes-Bennett, <i>Brain</i> , 1878, vol. i. p. 114. |
| <i>Postero-parietal Region.</i> | | | | |
| 31 | M. 25. | Kicked on the head. Headache, nearly continuous, with violent paroxysms. Vomiting at intervals, most when headache was most violent. Vertigo. Mental confusion; sometimes maniacal. Left convergent strabismus. Partial right hemianæsthesia. Patellar reflexes slightly exaggerated; slight ankle-clonus on the right side. Blind in both eyes; sight of right eye lost first. Choked discs, and eventually optic atrophy. Hearing defective in right ear. Constipation. Head-temperatures taken once; right parietal region, 98° F.; left parietal, 97.8° F. | Fibroma. Adherent to membranes, and involving the left postero-parietal and occipital region to within half an inch of longitudinal fissure. The brain-tissue around softened and broken down, the parts disintegrated being chiefly the white matter of the postero-parietal and occipital lobes. | C. K. Mills, <i>Arch. Med.</i> , vol. viii. No. 1, August, 1882. |
| 32 | M. 49. | Dropping of left hand at intervals, with power regained in about an hour. Brief attacks of loss of speech, and numbness in lips and tongue on both sides. Numbness in tips of his fingers and the left hand. Slight paroxysms of general rigidity. Severe frontal headache. No vomiting. Loss of sight, gradually increasing to total blindness. Involuntary micturition. Increasing hebetude. Slow but probably correct intellect. Left upper extremity, toward last, parietic. Was able to stand, but could scarcely walk. Hearing and taste preserved. | Carcinoma. It occupied nearly exactly the site of the right "postero-parietal lobule" (superior parietal). It was clear of the ascending parietal convolution in front, and behind did not quite touch the external parieto-occipital fissure; below it extended just | James Russell, <i>Brit. Med. Journ.</i> , 1876, ii. p. 709. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----|--------------|--|---|---|
| | | Some doubt as to smell. Later, imbecile. After a severe fit of general convulsions he died. Duration, about four months. | short of the intraparietal fissure, and on inner face of hemisphere reached for half an inch into quadrilateral lobe. Below tumor toward ventricle brain-substance softened. | |
| 33 | F. 36. | Right-sided temporal and orbital neuralgia. Anæsthesia of left arm. Epileptic attacks. Slighter attacks of spasm, without unconsciousness, in left face, left arm, and hand. Paresis of left arm. Blindness. Optic neuritis. Pupils dilated and immobile. Later, loss of smell and taste. Mental depression. | Gummata. In right supramarginal lobule two tumors size of pea, lying superficially. | Broadbent, <i>Lancet</i> , Jan., Feb., 1874, quoted by Bernhard, p. 68. <i>Beiträge zur Symptomatologie und Diagnostik der Hirngeschwülste</i> , von Dr. M. Bernhard, Berlin, 1881. |
| 34 | | Left hemiplegia with some anæsthesia. Deafness developed in the left ear, with a total inability to localize the origin of sounds. | Tumor size of an apple in middle of ascending parietal convolution and backward. Around the tumor white softening, which extended forward as far as the fissure of Rolando, and backward throughout the right parietal lobe, and beneath almost into the central ganglia. | Strümpell, <i>Neurolog. Centralb.</i> , Aug. 15, 1882. |
| 35 | M. 54. | Middle finger of the right hand began to jerk violently, also some of the flexor tendons. Twenty minutes after this he had a fit, in which he became unconscious and beat himself violently on the chest with the right arm. Had three of these fits. Aphasic after this for two weeks. Had high fever at the time of the seizures; was rubbed all over the body with ice. The fingers became paretic, not the forearm or arm. Arm became numb at times, especially after exertion. With dynamometer, left hand, 75; right hand, 55. Headache, which ceased after some months. Right optic disc abnormally red, but not choked; left disc normal. Had a convulsive attack in the Philadelphia Hospital, in which the four fingers of the right hand rapidly vibrated, contracting and extending without pain; no loss of consciousness or other disturbance. The tongue was also affected, so that speech was impossible. Later, the patient had a general convulsion, preceded by a drawing sensation in the face; convulsive movements began in right hand. Tongue bitten. Attack preceded by severe headache. Had another attack without loss of consciousness or convulsion, preceded by a sensation as of a knife cutting through the flesh, which travelled up from the left hand to the shoulder, and then to the head. Increasing loss of sensation in the fingers of the right hand. Increasing difficulty of speech, with spells of melancholia and crying. Right side of face markedly paralyzed. Right arm almost entirely paralyzed and much swollen. Speech much affected; difficulty in swallowing. Paralysis involves the right leg. | Gliomata. A small tumor occupies the lower end of the left supramarginal convolution, just where it joins the foot of the ascending parietal convolution. The latter convolution was not involved in the tumor, but was distinctly pressed upon in its lower third. The ascending frontal convolution was entirely healthy. In right hemisphere a similar gliomatous growth in the foot of the angular convolution where it runs into the middle temporo-sphenoidal convolution, involving also the upper part of this convolution, and to a slight extent the deepest portions of the superior temporo-sphenoidal convolution. | H. C. Wood. Not before published. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|--|--------------|--|--|---|
| <i>Occipital Region.</i> | | | | |
| Occipital lobe—cortex and centrum ovale. | | | | |
| 36 | M. 57. | Headache. Vertigo. Paresis of left side. Left facial paralysis, especially middle branch. Vomiting. Right pupil dilated. Tongue not involved. Uvula directed to left. Left velum palati relaxed. Taste, smell, sight, and hearing normal; sensibility of whole body normal. Reaction of degeneration on left side of face. Left side of body shows reaction of convulsibility. Slight quantity of albumen. Paresis declined with exception of facial nerve. Apathetic. Oedema of lung. | Glioma. In middle of right occipital lobe; lobe softened. Right lateral ventricle narrowed and left dilated. Right posterior horn and right thalamus opticus compressed. | Petrina, <i>op. cit.</i> |
| 37 | M. 27. | Dysphagia, most marked with liquids, caused by paresis of pharynx, more marked on left. Left hemiparesis for three years. Headache (frontal and temporal), which is of a boring, tearing character. Failure of memory. Speech guttural and monotonous. Puriform expectoration. Later, feeble voice, hiccup, yawning, somnolence. | Fibroma. On posterior face of left petrous bone and inferior occipital fossa, extending behind occipital foramen and to right of cerebellar falx. A prolongation involving the pneumogastric, glosso-pharyngeal, and spinal accessory. Also cerebellar abscess. | Cruveilhier, <i>Bull. de la Soc. Anat.</i> , 1855, xxx.475-479. |
| 38 | F. 20. | Headache. Dimness in right eye, then in left; finally, blindness in both. Convulsions. External strabismus; right pupil dilated, left contracted. Coma, alternating with consciousness. Vertigo. Optic discs congested, presenting small hemorrhages; exophthalmus. Paresis of right arm and leg; partial anæsthesiæ on same side. Earache. Vomiting, not frequent. Coma and death. Duration, about three months. | Sarcoma? Occupied all the posterior part of right hemisphere of cerebrum, pressing upon and indenting opposite hemisphere and right half of the cerebellum. | S. O. Habershon, <i>Guy's Hosp. Rep.</i> , 3d S., xx. 330-334. |
| 39 | M. 18. | Periodical headaches. Pains in the neck and vertebral column. Points of exit of trigeminal nerve sensitive. Staggering gait. Diplopia. Confused sounds in right ear. Tetanoid contractions of neck. | Echinococcus. In right occipital lobe. | Visconti, <i>Annal. Univer.</i> , Oct. 1869, quoted by Bernhardt, p. 98. |
| 40 | F. 21. | Right hemianopsia. Central vision good. Other symptoms: headache, dysarthria, anæsthesia of the right half of the face. No paralysis, no mental symptoms. Choked discs. Duration seven months. | Cystic glioma. In the left occipital lobe; had reached and destroyed the cortex of the lobe at its apex, and had extended inward, nearly reaching the inferior cornu of the lateral ventricle. The entire inner half of the occipital lobe was thus destroyed. | Jany, <i>Knapp's Archiv f. Augenheilk.</i> , vol. xi. p. 190, quoted by Starr, <i>Am. Journ. Med. Sci.</i> , N. S., lxxxvii., Jan., 1884, p. 72. |
| 41 | M. 42. | Right hemianopsia. Central vision good. Other symptoms: aphasia, right complete hemiplegia, with facial paralysis. | In left occipital lobe, surrounded by a zone of softening, reaching inward to and involving the pulvinar of the left optichthalmus. Optic tracts normal. | Hirschberg, <i>Deut. Zeitsch. f. Prakt. Med.</i> , 1878, No. 4, quoted by M. Allen Starr, <i>Am. Journ. Med. Sci.</i> , N. S., lxxxvii., Jan., 1884, p. 69. |
| 42 | M. 42. | Right hemianopsia, not quite reaching the point of fixation. Central vision good in both eyes. Ophthalmoscopic examination negative. Other symptoms: vertigo, loss of memory, aphasia, and partial aphasia, with temporary right hemiplegia. | Gelatinous sarcoma. In the left occipital lobe, involving all three of its convolutions, as well as the præcuneus. Softening extended inward through the white substance to the posterior cornu of the lateral ventricle. Thalamus and optic tracts normal. | Jastrowitz, <i>Arch. f. Augenheilk.</i> , 1877, p. 254, quoted by Starr, <i>Am. Journ. Med. Sci.</i> , N. S., lxxxvii., Jan., 1884, p. 71. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----------------------------------|--------------|--|--|---|
| 43 | M. 40. | For seven years epileptic seizure, beginning with spasm of left leg and going on to general convulsions; motions more violent on left side. An aura consisting of a darkness, coming gradually over the field of vision from the left side, always preceded the attack. During the intervals left-sided headache was the chief symptom. It seems probable that a temporary left hemianopsia preceded the attack. | Cyst filled with serum. In white matter of the right occipital lobe, surrounded by a zone of softening which did not involve either the cortex or the wall of the lateral ventricle. | Traube, <i>Gesammt Beitrage zu Pathologie</i> , ii. 1083, quoted by Starr, <i>Am. Journ. Med. Sci.</i> , N. S., vol. lxxxvii., Jan., 1884, p. 73. |
| 44 | M. 52. | Headache. Numbness down right arm. Later, paroxysms of headache lasting twenty to forty minutes, generally preceded by pain and numbness in right hand and arm, ascending to head, and so intense as to produce profuse perspiration. Delirium (lasting two days) during these attacks. No paralysis or previous fit, nor vomiting. Few hours before death had convulsions. The pain and numbness were in right arm, although tumor was in right hemisphere. | Malignant tumor. Size of pullet's egg at inferior portion of posterior lobe on right side in substance of cerebrum, approaching within a few lines of surface. | J. C. Langmore, <i>Trans. Path. Soc. Lond.</i> , iii. pp. 246-248. |
| <i>Temporo-sphenoidal Region.</i> | | | | |
| <i>Temporo-sphenoidal lobe.</i> | | | | |
| 45 | M. 33. | History of syphilis. Blows on the head. Headache, continuous, usually dull, occasionally severe. Occasional vomiting. Stupidity, want of energy, drowsiness. One general convulsion a few hours before death. Partial anæsthesia on the right side. Hyperæsthesia of left side. Sight impaired. No ophthalmoscopic examination. Hearing defective in right ear. Constipation. | Gumma. One and a quarter inches in diameter, attached to adherent membranes, and involved the middle portions of the first and second temporal convolutions of left hemisphere. A layer of brain-substance both anterior and posterior to the tumor was softened. The tumor grazed the ascending parietal and inferior parietal convolutions. A large foyer of greenish-yellow pus was found to the inner side of the tumor. | C. K. Mills, <i>Arch. Med.</i> , vol. viii. No. 1, August, 1882. |
| 46 | M. 42. | At first an attack of vertigo which lasted over twenty-four hours: some unconsciousness for a time. Continued headache; loss of memory; giddiness and vomiting, the latter occurring without connection with the state of the stomach as to food. Partial bilateral deafness, which the patient stated was of long duration. No paralysis, but right hand a little weaker than left. Distinct mental failure during last two weeks of life; incoherence and faulty memory. | Epithelioma. Ovoid tumor about one and a half inches in diameter in the central portion of the temporo-occipital region. Hippocampal convolution grazed. Some surrounding softening and meningitis. One corner of tumor had produced a small spot of softening in the cerebellum. | H. C. Wood, "Trans. of Path. Soc. of Philada.," 1880, <i>Med. Times</i> , vol. xi., Jan. 29, 1881. |
| 47 | F. 40. | Suffered from a light form of epilepsy dating from tenth year, which resulted, it was believed, from a fall. Rarely bit her tongue, but usually frothed at the mouth. No history of one-sided spasms. Always had an aura of a peculiar character. She suddenly perceived a disagreeable odor, sometimes of smoke, sometimes of a fetid character, and quite unaccompanied by other sensory warning. Developed phthisis, her attacks occurring from time to time until her death. | At lower part of right temporo-sphenoidal lobe a shrinking and induration involving the uncinate gyrus and parts of the adjacent convolution. The olfactory nerves were not involved. A form of low-grade hemorrhagic pachymeningitis present. | Allan McLane Hamilton, <i>New York Med. Journ. and Obstet. Review</i> , vol. xxxv., June, 1882, p. 575. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|---|--------------|--|--|---|
| 48 | F. 39. | Attacks of convulsion seven weeks before her death. In two weeks mind affected; drowsy and stupid; condition of dementia. Passed into a state of semi-consciousness. No eye symptoms. No paralysis. Percussion on left side of head painful. | Sarcoma. Occupied the posterior part of the fourth and fifth temporal convolutions, and the third convolution was atrophied. Did not involve the lateral ventricle. Under surface flattened and resting partly upon the left lobe of the cerebellum. | W. H. Draper, <i>New York Hosp. Histories</i> , N. S., vol. x. p. 445, quoted by M. Allen Starr, <i>Am. Journ. Med. Sci.</i> , N. S., vol. lxxxvii., April, 1884, p. 383. |
| <i>Basal Ganglia and Adjoining Regions.</i> | | | | |
| 49 | M. 59. | Contractures of right arm and leg since childhood. Death from accident. The arm was atrophied and shortened, flexed at elbow and wrist; disappearance of some cartilages at wrist and wasting of joint-surface of radius. Femur flexed at hip; knee-joint flexed; ankle-joint in position of equinus. Other bone-changes. Right leg shortened. | Osteoma. Tumor in left corpus striatum on "surface of anterior thick half," projecting outward into white substance of brain, and inward into anterior portion of optic thalamus. | A. Bidder, <i>Arch. f. Path. Anat. und Physiologie, und f. Klinische Med.</i> Virchow, 1882, p. 91. |
| 50 | M. 30. | Right frontal and occipital headache. Vertigo. Paresthesia of the toes, particularly the right. Face drawn to the right. Left face paretic. Right eye smaller than left. Weakness and fatigue of limbs. Convulsions. Vomiting. Slow pulse. | Myxo-sarcoma. In right corpus striatum protruding into right lateral ventricle and cortex. | Schüppel, <i>Arch. d. Heilk.</i> , p. 357, 1867. |
| 51 | M. 34. | Walked a mile to an infirmary, and in less than one hour went into a series of severe epileptic attacks, which continued for four hours. The spasms were clonic, and chiefly in upper extremities, with violent contortions of face; the latter most marked on left side and in zygomatici. Between the fits there was deep coma, especially three hours before death, when, after another violent fit, he died, seven hours after first seizure. No paralysis, and report says nothing about any previous fits. | Myxomatous glioma. It exactly occupied the place of right nucleus candatus, extending outward as far as white fibres, but not involving them. Brain-tissue in proximity normal. | Dowson, <i>Med. S. and Gaz.</i> London, 1878, p. 333. |
| 52 | | Partial anæsthesia of right half of trunk. Hyperæmia of retina, and capillary hyperæmia of left optic disc. Left pupil dilated; left ptosis; left diverging strabismus. Paralysis of right side and extremities. Paralysis of muscles around right corner of mouth. Incontinence of feces and urine. Redness of face. Variations in temperature. | Tubercle. In left optic thalamus. Partial destruction of left peduncle of cerebrum. | Fleischmann, <i>Wien. med. Wochenschrift</i> , 6, 7, 8, 9, 1871, quoted by Petrina. |
| 53 | F. 44. | Severe headache on left side. Sensibility lessened in left extremities, at same time frequent pain. Intelligence diminished. Speech retarded. Strabismus of left eye. Amblyopia. Left pupil alternately dilated and contracted. Left lagophthalmos. Chattering of the teeth. Twitchings on the left paralyzed half of the face. Tongue and uvula tending toward the left. | Sarcoma. Right optic thalamus. Corpora quadrigemina compressed. | Friedreich, quoted by Petrina, <i>op. cit.</i> |
| 54 | F. 38. | Headache. Creeping sensations in right arm and leg. Right facial paresis. Paresis of left extremities. Convulsions. Dimness and confusion of sight. Diplopia. Hardness of hearing. Failure of memory. Difficulty in speaking and swallowing. Improvement under iodide of potassium. | Glioma. Left optic thalamus. | Bruzeliuss and Blix, 1870, quoted by Bernhardt, 153. |
| 55 | F. 14. | Headache, vertigo. Epileptic attack. Right hemiplegia. No anæsthesia. Slight dilatation of pupils. | Sarcoma. In left optic thalamus. The right optic thalamus also affected. Corpora quadrigemina enlarged and pushed backward. | Rusconi, <i>Gaz. Med. Ital.</i> , 1874, No. 11. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----|--------------|--|--|--|
| 56 | M. 30. | Headache. Left ptosis; fixation of left eyeball. Drowsiness. Retarded speech. Gait unsteady. Paresis of right hand and foot. Emaciation; incontinence of urine. | Serous tumor. Large as a nut, in posterior half of right optic thalamus. | Troschel, <i>Med. das ver. für Heilk. in Preussen</i> , xliii., 1839, quoted by Petrina. |
| 57 | F. 36. | Imbecile. Speech inarticulate. Pupils contracted. Spasms in arms, but light in limbs. | Cancer. Left optic thalamus and corpus striatum without definite boundary, extending into brain-mass. | Brenner, quoted by Petrina, <i>op. cit.</i> |
| 58 | F. 33. | Headache and vomiting for three weeks; for one week had been maniacal. Convulsions. Apoplecticiform attack, marked by unconsciousness, general muscular flaccidity, and stertorous breathing. Paralysis of left face; twitching of right face. | Glioma. Between left optic thalamus and hippocampus minor, extending from the ventricle to the under surface of the brain. Corpus striatum and optic thalamus unaffected. Hemorrhage on under surface. | Owen, <i>St. George's Hosp. Rep.</i> , ix., 1877-78, p. 150. |
| 59 | M. 45. | Vertigo, headache, and tinnitus. Five years before attack had fallen and struck the back of his head. Much exposed to the sun. One day in August a general feeling of numbness came over him. This was followed by vertigo, etc., as above. Staggered and stumbled in walking as if intoxicated. Unable to maintain his balance in the dark or with his eyes closed. Some numbness in legs and arms, but no actual loss of sensibility. No neuro-retinitis; no paralysis. When erect had a constantly increasing tendency to stagger backward. Divergent squint and diplopia appeared. Potassium iodide blisters, and seton were used. Noises and headaches disappeared. During last two or three weeks some difficulty in swallowing. Involuntary evacuations. Occasional hallucinations. | Glio-sarcoma. Tumor size of walnut in third ventricle, moulded to the interior. Extending to base of brain just above corpora albicantia, and forward as far as anterior commissure. A caudate prolongation completely blocked up the Sylvian aqueduct. Owing to this obstruction, a large quantity of serum had been imprisoned, enormously distending the fourth and lateral ventricle. The growth invaded left optic thalamus. Superior surface of cerebellum softened from median line to middle of right hemisphere. | F. Woodbury, <i>Am. Journ. of the Med. Sci.</i> , N. S., lxxvi., July 1, 1878. |
| 60 | M. 15. | Epileptic from childhood; had had no fits for last three years. Had tremors and was dull. Short-sighted, and had a habit of absurdly frequent winking. Nothing else wrong with eyes. Suddenly, after a mental disturbance, had intermittent pulse. Cold surface, dulness, head and face swollen and flushed. Then tonic spasms, loss of consciousness, involuntary micturition. General tremors, dilated pupils, stupor. Next diffused dusky-red flush of both cheeks, also over back of hands and forearms. Temperature depressed to 92° in axilla. Automatic repetition of words. Taste and smell normal. He recognized himself in looking-glass on the day he died. | Sarcoma. In third ventricle, lying between corpora striata and optic thalami of opposite sides. It completely enveloped optic commissure, and partially involved track of optic nerves issuing from front. The sole organic connection of tumor was with the commissure. The tubercineum was distinct from its tissue. | Russell, <i>Med. Times and Gaz.</i> , 1873 (1), p. 522. |
| 61 | M. 19. | Periodical headaches. Unsteady gait. Left hemiparesis. Peculiar swelling of face. Delirium. Convulsions and sudden death. Bad-smelling discharge of the nose. | Echinococcus. In left lateral ventricle; the whole of the ventricle a sac. | Yates, <i>Med. Times and Gazette</i> , Aug., 1870. |
| 62 | M. 14. | Convulsions; vomiting; internal strabismus of right eye; gradually increasing paresis of left leg and arm. Reeling toward left side. Occipital headache. Pain and numbness in left arm. Lat- | Glioma. Involved right anterior tubercle of corpora quadrigemina; also right optic | David Ferrier, <i>Brain</i> , vol. v. p. 123. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|--------------------|--------------|--|--|--|
| | | eral movements of eyes lost; paralysis of accommodation; nystagmus. Oscillation of left hand. Left leg ataxic. Patellar reflex exaggerated, and ankle-clonus present on left side. Superficial reflexes increased on right side. Partial anæsthesia on left side. Sight good; double optic neuritis. Left-sided hearing impaired. Taste and smell normal. Toward end, increasing torpor; left hemiplegia, except slight power retained in face, with anæsthesia and analgesia. Tonic fits. Right pupil dilated, and external strabismus in right eye. Slow respiration. Ankle-clonus and increased knee-jerk in right. | thalamus, posterior part of internal capsule, and tegmentum of crus cerebri. The enlarged optic thalamus pressed back upon right anterior portion of cerebellum and middle peduncle, and exerted some transmitted pressure upon medulla oblongata. | |
| 63 | F. 29. | Cervico-occipital headache. Vertigo. Convulsions. Right facial paresis. Tendency to fall backward. Uncertain gait. Optic neuritis. Double amblyopia. Difficulty in moving both eyes toward the left. Diminished intelligence. Vomiting. | Glioma. In corpora quadrigemina. Cerebellum not involved. Tumor lay upward and outward from the left cerebellar crus ad pontem. | Annuske, <i>Von Graef's Arch.</i> , 1873, Bd. xix., quoted by Bernhardt, 167. |
| 64 | M. 21. | Right temporo-frontal headache. Vertigo. Pains in right leg. No anæsthesia. Right leg paretic. Tinnitus. Atrophy of the right optic nerve. Abnormal somnolence. Sexual inclination diminished. Vomiting. Blindness, first of the right and then of the left. Right divergent strabismus. Pupils dilated. | Lipoma. Tumor compressed corpora quadrigemina and geniculate bodies. | Hirtz, <i>Bull. de Société Anat.</i> , Mars and April, 1875, quoted by Bernhardt, 168. |
| 65 | F. 3. | Right hemiparesis. Right-sided tremor. Contraction of the right elbow. Late, loss of sight in left eye. Ptosis, dilatation of the left pupil. Stupidity. Peculiar movements when seated from right backward to the left. | Tubercle. At site of corpora quadrigemina, springing into the third ventricle. Left cerebral peduncle compressed. | Pilz, <i>Jahrbuch. für Kinderkrankh.</i> , iii., 1870, 2, 133, quoted by Bernhardt, 168. |
| 66 | M. 25. | Cervico-cephalic pains. Vertigo. Uncertain gait. No paralysis. Tension of muscles of neck. Optic neuritis. Double amaurosis. Tinnitus. Diminution of hearing. Intelligence clear until within fourteen days of death. Insensibility, delirium, coma. Small irregular pulse. | Glioma. Tumor displaced corpora quadrigemina and pineal gland. Projected into the third ventricle through aqueduct of Sylvius and into fourth ventricle. | Duffin, <i>Lancet</i> , June 17, 1876. |
| 67 | M. 7. | Occipital pains. Staggering gait toward right and backward. Hydrocephalic cries. Tendency of head forward. Alternating diverging strabismus. Double optic neuritis. Sudden death in paroxysm of pain. Paresis of bladder. Vomiting. | Tumor took the place of posterior part of corpora quadrigemina and velum. Cyst in the midst of the cerebellum, reaching the fourth ventricle. | Kohts, <i>Virch. Arch.</i> , Bd. lxxvii., 1876, quoted by Bernhardt, 168. |
| <i>Cerebellum.</i> | | | | |
| 68 | M. 1. | Frontal headache. Slight control over arms and legs. Stiff neck. Dilated pupils. Sopor. Vomiting. Duration, one year. | Glioma. Size of an orange in the middle of cerebellum. Chronic hydrocephalus. | H. Green, <i>Trans. Path. Soc.</i> , vol. xx., 1870. |
| 69 | F. 21. | Fall from a swing upon the head, followed by loss of consciousness for a few minutes. Occasional headache during eleven years, always located at the occipital region. Eight months before death severe paroxysmal headaches, increased to one every five or six days, and lasting three to four days. Great hyperæsthesia of the head. Choked discs in both eyes. Complete blindness. Slight paresis of left side of body; twitching of muscles of left side of face. Staggering gait; sometimes complained of a momentary swinging or rotary sensation. Intellect clear. During last few days of life loss of power of deglutition, and also of taste, smell, and hearing. | Tubercle. In left and middle lobe of cerebellum, involving the pia mater. Over the tumefaction leptomeningitis. | H. F. Formad, <i>Tr. of Philada. Path. Soc.</i> , 1879-81, vol. x. p. 178. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----|--------------|--|--|---|
| 70 | F. 27. | History of syphilis. Headache, with paroxysmal exacerbations. Vomiting, frequently recurring; for four weeks before death vomited almost incessantly. Vertigo; impossible to sit or stand because of vertigo late in illness. Slowness of mind and hebetude. General muscular weakness. Right partial hemiplegia and hemianæsthesia. Trigeminal neuralgia. No ophthalmoscopic examination, but sight impaired. Marked slowness of respiration; respirations ran down as low as four and five per minute two weeks before death. | A. nodulated mass involved the right middle cerebellar peduncle and the adjacent region of the right cerebellar hemisphere. The right upper half of the floor of the fourth ventricle superficially softened. A small area of softening was also found involving the under outer surface of the left optic thalamus, the breadth of the internal capsule, and a small segment of the lenticular nucleus. | C. K. Mills, <i>Arch. Med.</i> , vol. viii. No. 1, August, 1882. |
| 71 | F. 13. | Tubercular history. Headache, with severe paroxysms; most marked in frontal and occipital regions. Vomiting; vertigo; attacks of reeling and falling. Mental dullness. Weakness of limbs, but no distinct paralysis. Hyperæsthesia; severe pains in limbs. Gradually went blind, first in left eye, and then in right. Descending neuritis determined nearly a year before death; marked optic atrophy observed a month before death. Constipation. | Tubercle. A large nodulated mass occupied the lower two-thirds of the right cerebellar hemisphere; one small nodule extended across the posterior extremity of the superior vermiciform process, destroying altogether about one-third to one-half of a cubic inch of its substance. Internal hydrocephalus. | C. K. Mills, <i>Arch. Med.</i> , vol. viii. No. 1, Aug., 1882. |
| 72 | F. 20. | Headache. Occasional vomiting, but only upon a full stomach and at the beginning of a paroxysm of headache. No impairment of intellect; no paralysis; no convulsion; no inco-ordination. During last few days, when in paroxysms of headache, her face would be drawn toward left side, accompanied by a rigid drawing backward of the head, by pain in left shoulder and arm, and by a marked diminution of sensation in the same shoulder and arm. Head-pain excruciating, at first involving the whole cranium, afterward only the forehead and temples, but finally only the back of the head and nape of the neck. Died of sheer exhaustion. Symptoms and physical signs of phthisis. | Tubercle. In right lobe of cerebellum. Tubercular disease of both lungs with pleuritic adhesion. Fatty liver. | L. S. Clark for A. S. Gerhardt, <i>Tr. of Philada. Path. Soc.</i> , 1878-79, vol. ix, p. 144. |
| 73 | M. 45. | Occipital headache. Movements weak; gait staggering. Inability to fix eyes; sight retained. Pupils unequal. Partial deafness in both ears. Vomiting. Sopor. Sudden death. History of fall upon head at twenty years of age, since which time much headache. | Tumor size of nut, compressing cerebellum and pons, situated between pons, middle peduncle of cerebellum, the cerebellum, and brain. Corpora quadrigemina atrophied. | Luyt, <i>Gaz. des Hôp.</i> , 1867, 105, quoted by Bernhardt, p. 225. |
| 74 | F. 52. | Violent and continuous headache. Gradual loss of sight. Very irritable. Psychic pain and complaints. Incoherence of ideas. In three to four years some anæsthesia of left leg; the left hand became rebellious to the will. Paralysis progressed; symptoms increased very slowly. Intense coryza, with running from the nose, accompanied with a feeling as if a strange body filled up this cavity. Great appetite. Had an attack of unconsciousness, preceded by violent pains and creepings in the left hand, and presenting the following conditions: Dorsal decubitus; flushed face; head strongly retracted; | Tumor size of hen's egg lodged between the superior surface of the cerebellum and cerebrum. | M. Bouliet, <i>Gaz. méd. de Par.</i> , 1834, 2d S., vol. ii. p. 264. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----------------------------------|--------------|--|--|--|
| | | frowning; respiration difficult, but not stertorous; pupils large and insensible to light; the left eye widely opened, the right shut; very marked contraction in the orbicular muscle; stringy mucus in large quantities from right nostril; the left commissure of the lip strongly carried downward and backward. Tongue white, not deviated. Limbs of the right side not anæsthetic or paralyzed; the hand strongly shut. On the left arm painful pricking; the elbow flexed at a right angle, hand completely paralyzed. Motion diminished in left leg; sensibility not altered; intelligence obtuse, but the patient responds to questions. Nausea; hiccough. Finally, diaphragmatic breathing; asphyxia by strangulation. | | |
| 75 | F. 64. | History of a fall down stairs. Headache. Frequent vomiting. Stupor, and when admitted to the hospital three weeks before death could not give any account of herself or of her complaint. Semi-comatose. No definite paralysis. She could move both arms and legs, but could not stand. Involuntary evacuations. No deviations of the eyes; apparently saw well. Pupils equal and moderately contracted; right disc a little redder than the left, but no swelling of the disc. Died in a convulsion, the right side being most affected. | Tumor size of a green-gage plum, sprang from the dura mater just under the tentorium cerebelli on the left side. It had caused the deep depression of the left lobe of the cerebellum. Also a small clot, partly decolorized, just outside the right corpus striatum. | B. Bramwell, quoted in <i>Med. and Surg. Rep.</i> , vol. xxxiv., Mar. 11, 1876. |
| 76 | F. 32. | Headache first. Then pain in right eye and numbness in right arm and leg; vision poor in right eye, with improvement. The left soon similarly affected, without improvement. Vomiting (patient was pregnant); vertigo. Ataxia marked. Patellar reflexes diminished. Tongue protruded to left. Right pupil dilated. Taste abolished on right side. The left field of vision showed hemianopia of the temporal side. Both eyes showed optic neuritis. Later, shooting pains in legs and left arm. Mind clear, but hysteroidal excitement frequent. Surface-temperature of head elevated. Toward end mental aberration, then unconsciousness. Died during labor. | Sarcoma. A nodular tumor, size large horse-chestnut, on upper surface of right lateral hemisphere of cerebellum. | J. T. Eskridge, M.D., <i>Journ. of Nerv. and Ment. Dis.</i> , vol. xii, No. 1, Jan., 1885. |
| <i>Floor of Fourth Ventricle.</i> | | | | |
| Directly or indirectly involved. | | | | |
| 77 | F. —. | Vertigo only on standing. Sensibility normal. Walking and standing impossible. Ataxia of legs. No paralysis. Facial and trigeminus intact. Dysphagia. Double amaurosis. Eyeballs fixed, directed forward. Symmetrically dilated pupils. Hearing, smell, and taste normal. Consciousness clear. | Tumor of whole anterior part of vermi-form process of the cerebellum, lying on floor of fourth ventricle. Corpora quadrigemina compressed to thinness of paper. | Curschmann, <i>Berlin. klin. Wochenschrift</i> , 1877, p. 237, quoted by Bernhardt, 227. |
| 78 | M. 6½. | Fell from a bench, striking the occiput. Headache for a day or two afterward. Slight irregularity in gait. For weeks restlessness, headache, and motor ataxia the chief symptoms. In three months speech became indistinct. "He screamed his words." Defective memory. Apparent exophthalmus; ataxic movements of the head, and a look of profound stupidity; epistaxis; bulbar conjunctiva anæsthetic; left pupil dilated; vomiting. Ophthalmoscopic examination showed congestion of right optic nerve and left descending neuritis, going on to progressive atrophy. | Glioma. Anterior portion of the fourth ventricle occupied by a rounded swelling of the pons; from under surface of the pons enlargement about equal on both sides. The anterior pyramids at entrance of pons seemed abnormally elevated, with the point of entrance also deeper than normal. Corpora quadrigemina much smaller than usual, and seemed pushed upward and flattened. | V. P. Gibney, <i>Am. Journ. of the Med. Sci.</i> , N. S., vol. lxx., July, 1875, p. 142. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|--|--------------|--|---|---|
| 79 | M. 11. | Fronto-occipital headache. Vertigo. Staggering gait. Falls often, and to right. No paralysis. Diminution of sight. Irregularity of movements of eyes. Right strabismus (?). Vomiting. | Tubercle. Size of hazelnut, in middle of vermiform process, above fourth ventricle. Some softening of surrounding tissue. | Capozzi, quoted by Bernhardt, p. 224. |
| 80 | M. 25. | Fronto-occipital headache. No anæsthesia. No paralysis; staggering gait. Loss of consciousness, with trembling of upper extremities. Vertigo. Falls to right. Double optic neuritis; amaurosis; nystagmus. Dementia; moroseness. Vomiting. Sudden death. | Between the amygdalæ of cerebellum; in front of cerebellum, bulging into fourth ventricle, merging with floor of fourth ventricle. Medulla oblongata pushed forward to right. | Annusk, <i>V. Graefe's Arch.</i> , Bd. xix., 1873, quoted by Bernhardt, 223. |
| 81 | M. 58. | Headache, vertigo, diplopia; vomiting. Left facial paralysis. Ptosis of both eyes, worse in left. Contracture of left masseter. Speech nasal. Sense of pharyngeal obstruction. Both eyes diverted to right; on looking toward left the right eye turns to middle line, and left eye does not follow. Pupils contracted, left more than right. Anæsthesia of right face. Left ear slightly deaf. Smell and taste normal. Head movable, with deviation. Trunk and extremities not anæsthetic or paralytic. Later, smell of left side diminished. Reactions of degeneration in left face. | Floor of fourth ventricle to left of median line, involving motor root of fifth and nuclei of sixth, seventh, eighth, and ninth nerves on that side. | C. Wernicke, <i>Arch. für Psychiatrie und Nervenkrankh.</i> , vii. Bd. 5, iii. Heft., 1877, p. 513. |
| 82 | F. 61½ mo. | Symptoms of tubercular meningitis with a few irregular symptoms; conjugate deviation of the eyes to the left and upward. Cheyne-Stokes breathing. | Tubercular granulation about the size of a large pea springing from the left side of the fourth ventricle, just inside the posterior pyramid, midway between the cerebellar peduncle and calamus scriptorius; touched the under surface of the middle lobe of cerebellum. Head hydrocephalic. Miliary tubercles along Sylvian fissure, and a few elsewhere. | Morris J. Lewis, <i>Trans. of Phil. Path. Soc.</i> , 1879-81, vol. x. p. 172. |
| <i>Pons Varolii and Medulla Oblongata.</i> | | | | |
| 83 | F. 8. | Right external strabismus, with contraction of the right corner of the mouth; contraction disappeared, but squint remained. Persistent cough, with stringy mucous expectoration. Staggering. Left hemiparesis, with left partial hemianæsthesia. Severe constipation. Bowels opened only about once in five days. Water passed voluntarily once every two days. Difficulty of articulation. Squint had almost disappeared, but later returned for a few days, and then disappeared entirely. Became unable to walk, or even to sit, unsupported. Also became unable to speak, but produced strange inarticulate sounds. Difficulty in swallowing. A marked feature in this case was the absence of headache. The only pain suffered was the pain of dull character referred to the left ear, but which lasted only two days. | Occupied the lower half of the pons and the upper half of the medulla oblongata, bulging most at the lower border of the pons at the right side, and extending a little lower and higher at the right side than on the left. Floor of fourth ventricle bulged slightly, and appeared to be expanded in all directions, so that the median fissure was pushed decidedly to the left. Incision revealed the tumor to be a large cyst filled with bloody fluid and detritus. The lower part of the ventricular floor not involved. | C. K. Mills, not before published. |
| 84 | M. 32. | Thrown from a horse and kicked on the head. History of syphilis; headache, severe at first, always came on at night; became less severe later. Vertigo. De- | Gumma and fibroma. (1) Gumma, half an inch in diameter, distinctly limited to the | C. K. Mills, reported at the meeting of the Amer. Neurol. Assoc., |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----|--------------|--|--|---|
| | | fective memory; apathy. Right hemiparesis; helplessness of all the limbs before death; partial ptosis of the right side. Sensation diminished in the left side of the face and in the right limbs. Pupils small before death. Descending optic neuritis. Conjugate deviations of the eyes and rotation of the head to the right. Persistent epistaxis; tendency to hemorrhage from mucous membranes. Constipation. | left upper quarter of the pons. (2) Fibroma, no larger than a pea, between the dura and pia mater, causing a slight depression in the first temporal convolution about the junction of its middle and posterior thirds, and halfway between the parallel fissure and the horizontal branch of the Sylvian fissure. Microscopical examination of the optic nerves showed a descending neuritis of subacute character. | June, 1881, and published in the <i>Journ. of Nerv. and Mental Dis.</i> , July, 1881; and <i>Arch. Med.</i> , vol. viii. No. 1, Aug., 1882. |
| 85 | M. 35. | History of syphilis. Wounded in head by glancing bullet. Headache of great severity at intervals. Vomiting at time of headache. Vertigo. Failure of memory and depressed spirits. Epileptiform attacks. In the spasms lifted up the right side of his body and worked over toward the left. Occasional cramps in stomach and legs. Temporal and orbital neuralgias. Descending neuritis, and eventual atrophy of both optic nerves. Constipation. Died at the close of a series of convulsions, death being preceded by general paralysis. | Gumma. A rounded mass, quarter of an inch in diameter, attached to the pia mater, just to the left of the centre of the anterior surface of the pons. The entire anterior central portion of the pons was softer and more doughy than usual. At the junction of the pons with the medulla oblongata was a recent hemorrhage, which had spread downward to about the middle of the latter. | C. K. Mills, <i>Brain</i> , Jan., 1880, and <i>Arch. Med.</i> , vol. viii. No. 1, Aug., 1882. |
| 86 | M. 5. | At first left internal squint and nightly paroxysms of excessively silly laughter. Slight paralysis of right arm, with rigidity. Paresis of right leg, increasing to paralysis, with rigidity. During sleep arm and leg became relaxed. Difficulty in swallowing. Paralysis of left orbicular palpebrarum and left external rectus muscles. Sensibility not impaired. Electro-muscular contractility present in all the paralyzed muscles (?). Speech lost, apparently from difficulty in articulation. Intelligence preserved till near the close. Sight, smell, and taste good. Later, suffered from intense headaches and frequent attacks of palpitation of the heart, with flushing of face and injection of left conjunctiva, and with increased rigidity of right arm and leg. Death from paralysis of the pneumogastric. | Glioma. Gliomatous transformation of the pons, but no distinct separable neoplasm. Had encroached somewhat on cerebellum, particularly in region of left pneumogastric lobe. | W. Pepper, <i>Trans. Phila. Path. Soc.</i> , 1878-79, vol. ix. p. 136. |
| 87 | M. 2. | Dysphagia; paresis of left arm and ptosis of left eye, which improved, followed by same symptoms on right side. "Legs affected." Head very large. Dribbling. Paralysis of articulation. Contraction of orbicular muscle, causing ptosis (?). Clonic spasm of right side of mouth, and rhythmical jactitation of right arm on attempted movement. Unable to stand or sit. Optic discs normal. Evacuations involuntary. Left side of face paralyzed. Tonic spasms of right sterno-mastoid. Later, left arm jerked like right, and rigid contractions of legs. Retraction of head and occasional spasm of left sterno-mastoid. Impossible to gauge sensation. | Tubercle. Tumor of left side of lower part of pons and central and posterior part of upper half of medulla. Cerebral fluid increased. Medulla oblongata was twice the normal size. | J. M. Hobson, M.D., <i>Brain</i> , vol. iv. p. 531. |
| 88 | M. 12. | Slight paresis of right side (arm and leg). He spoke thickly and swallowed badly. Slight headache. Was depressed. Delirious at night. Slight paresis of left face. | Glioma. Membranes of base congested. Tumor, which appeared to | Hughlings - Jackson, <i>Med. Times and Gaz.</i> , Lond., 1874, i. 151. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|-----------------------|--------------|---|---|--|
| | | Irregularity of pulse. Choked discs. Later, paralysis of sixth nerve. Sudden death, probably in a fit. | occupy the whole left half of pons varolii. No trace of fifth nerve on left side. | |
| 89 | F. 60. | Headache frontal, severe and almost constant. Paresis of right arm and leg. Painful spasm of right arm. Paresis gradually extended to left half of body. Persistent pain in right arm, with tremor; later, same symptom, less marked, in left arm, simulating paralysis agitans. Atheromatous arteries. Melancholic; talks to herself; very hard of hearing. Head directed constantly to right. Tremor increased on voluntary motion. Atrophy of muscles of arms. Flexors of legs contracted. Electro-muscular contractility reduced, especially on right side. Later, pain on touch in right arm. Febrile intermitting symptoms, simulating malaria. Still later, distinct contracture of neck. Conjunctivitis of left eye, with corneal dullness, followed by kerato-iritis, with ulceration of cornea. Dysphagia; swelling of submaxillary glands. Edema of lungs. | Sarcoma. Tumor of left side of pons and left cerebellar crus, extending toward transverse sinus. | Petrina, <i>op. cit.</i> |
| 90 | M. 54. | Severe continuous headache. Eyes constantly turned to the right. No diplopia. Eyes, moved together, could not turn beyond the median line of the left, though the right eye alone could be turned for some distance to the left beyond the median line. Pupils equal and mobile. No paralysis or loss of sensation. Some dizziness and stagger in walking. Died of pneumonia. After the autopsy the position of the head was regarded not as compensatory for the position of the eyes, but as due to a severing of fibres joining the rotatory muscles of the head with their reflex centres. | In the pons at a level one centimeter below the apparent origin of the fifth nerve on the left side. It was so situated in front of the eminentia teres that it involved the course of the fibres of the left abducens, and by a little prolongation across the raphé toward the right side interrupted the fibres of communication between the centres for the sixth and third nerves. It did not involve the common nucleus of the sixth and seventh. It interrupted the posterior - anterior longitudinal bundle and the adjacent part of the raphé. No other lesion was found. The tumor was the size of a small nut. | Quioe, <i>Lyon Méd.</i> , 1881, July, Nos. 19 and 20, quoted by M. Allen Starr, <i>Journ. of Nerv. and Mental Dis.</i> , vol. xi., July, 1884, p. 377. |
| <i>Crura Cerebri.</i> | | | | |
| 91 | M. 25. | No headache. Staggering some days before death. Apoplectic seizure, with right-sided hemiplegia. Ptosis of left side (some days before death). Loss of consciousness for three or four days. No vomiting. | Glioma. In left crus cerebri, including also portion of right. | Sutton, <i>Brit. Med. Journ.</i> , Feb., 1870, quoted by Bernhard, p. 163. |
| 92 | M. 9. | Awkwardness in using right hand; soon almost complete paralysis in the right arm. Headache; nausea; vomiting; double vision, followed by strabismus, due to paralysis of the left abducens. Occasional twitchings in right hand, but no convulsions. Paralysis extended to the right leg; staggering gait. Ataxia and rigidity in the fingers of the paralyzed hand. Pain in the legs. Optic neuritis. | Sarcoma. Pressing upon the left crus cerebri and the pons. | E. C. Seguin, <i>Journ. of Nerv. and Ment. Dis.</i> , Jan., 1882. |
| 93 | M. 3. | Headache; unnatural drowsiness. Ptosis of right eye, with very marked divergent strabismus and fully-dilated pupil; similar paralysis in left eye, not quite so | Tubercle. Size of a walnut in right crus, almost destroying the crus just | S. Browne, <i>Dublin Q. J. Med. Sci.</i> , 1849, vii. 496-499. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Pathology and Location. | Remarks. |
|---|--------------|---|---|---|
| | | marked. Paresis of left leg. Very late, unconsciousness, constant motion of tongue and lips, and clonic spasms of left arm and leg. Twitching of right face. Convulsions, death. Duration, about one year. | at its junction with pons; making pressure on left crus. Third pair of nerves diminished in size and softened. Recent inflammatory changes at base. Increased cerebral fluid. | |
| <i>Middle Region of Base of Brain and Floor of Skull.</i> | | | | |
| 94 | F. 35. | History of syphilis. Headache severe, at first with long intermissions; later, continuous, and often agonizing. Vomiting with paroxysmal headache, coming on late in illness. Vertigo, usually with headache. Excitable and irritable. Slight twitching of mouth, hands, and forearms. Left hemiplegia; upper as well as lower fibres of facial nerve paralyzed. Left internal strabismus. Electro-contraction diminished. Difficulty in enunciation. Sensibility diminished in left leg. Later, hyperæsthesia and great pain in paralyzed limbs. Conjunctivitis and necrosis of cornea of left eye; conjunctiva and cornea insensitive. Sight impaired. Descending optic neuritis. Hearing impaired on left side. Smell defective. Profuse perspiration, more marked on right side than on left. Constipation. Temperature, taken in right and left axilla for eleven weeks before death, gave the following averages: Right axilla, 99.1°, M.; 100°, E. Left axilla, 99.4°, M.; 101.4°, E. On some days remarkable falls in temperature to 96°, 95°, and even 94° and 93°. Average head-temperatures above the normal: for stations on right side of head averaging about 97°; on left side, about 94.3° F. | Gumma. A twin-tumor, each mass about two-thirds of an inch in diameter, in front of the optic chiasm. The growths involved the basal termination of the corpus callosum, the peduncles of the corpus callosum, the lamina cinerea, and anterior perforated spaces. They also probably encroached upon the roots of the olfactory nerves, the optic nerves and commissure, and the anterior portions of the circle of Willis, which seemed to have been broken in front. The base of the brain, from the posterior line of the tumor backward to the pons, was markedly softened. Microscopical sections of optic nerves showed the appearances peculiar to descending neuritis in a somewhat advanced stage. | C. K. Mills, <i>Philadelphia Medical Times</i> , March 23, 1879, in "Proceedings of the Pathological Society of Philadelphia;" also, <i>New York Medical Record</i> , Aug. 9, 1879, and <i>Arch. Med.</i> , vol. viii. No. 1, Aug., 1882. |
| 95 | F. 21. | Suffered for three years from excessive thirst and polyuria, with occasional vague pains in the head. A constant relation existed between the amount of fluid imbibed and of urine passed. Specific gravity of urine, 1002. No albumen nor sugar. Eight liters of urine passed in the twenty-four hours on an average. Slight headache and dimness of vision shortly before death; no other nervous symptoms. No ophthalmoscopic examination was made. | Sarcoma. About the size of a chestnut at the base of the brain, at a spot corresponding to the sella turcica. It had caused complete degeneration of the optic chiasm, and had encroached considerably on the circle of Willis. | F. Fazio, <i>Il Morgagni</i> , quoted in <i>Med. and Surg. Rep.</i> , vol. xlii., May 8, 1880, p. 415. |
| 96 | F. 73. | Suffered for several years from post-nasal catarrh, with enlargement of tonsils and granular pharyngitis. Fulness in right side of throat; muco-sanguinolent discharge from post-nasal space; bulging of soft palate. Severe pain through the right side of the head. Deafness of right ear and dimness of right eye. Mental failure. Paresis of levator palpebræ superioris and orbicularis; complete paralysis of external rectus; possibly slight paresis of the muscles supplied by the third nerve of the right side. Diminished sensibility of right half of face and cornea, and conjunctiva of right eye. Cornea opaque; conjunctival catarrh; vision almost nothing; ophthalmoscopic examination could not be made. Left | Lobulated epithelioma. Involved the cribriform plate of the ethmoid bone, the whole of the body of the sphenoid, and the anterior part of the basilar process of the occipital bone. These were softened to the consistency of cheese. Membranes and cerebral substance firmly adherent to the base of the skull at the inner portion of the bot- | W. Pepper, <i>Trans. of Philad. Path. Soc.</i> for 1878-79, vol. ix. p. 138. |

TABLE (concluded).

| No. | Sex and Age. | Clinical History. | Location and Pathology. | Remarks. |
|-----|--------------|--|---|---|
| | | eye showed some diminution in acuity of vision, with concentric narrowing of visual field; pigmentation. | tom of the right cerebral fossa. Blood-clot in one of the large arteries of the optic papilla. Sclerosed blood-vessels. Atrophy of optic nerve and retina. | |
| 97 | F. 25. | Headache (for six years), with vomiting. For three years had dimness of vision. For a year had blindness. Exophthalmus, with dilated pupils and fixation of eyeballs. Painful spasm of right face occasionally. Occasional paresis of left arm and leg, with pain. Severe vertical headache. Anosmia. Involuntary discharge of urine and feces. Convulsions. Stupor. No local paralysis of face or extremities. Death happened unexpectedly. | Cancer. Tumor apparently springing from pituitary body, passing through infundibulum into right lateral ventricle. Tumor was "almost the shape and size of goose-egg." It occupied anterior half of ventricle, and flattened out thalamus and corpus striatum. By pressure it had flattened the olfactory and optic nerves. The growth extended into the sphenoidal fissure, causing absorption of bone. | Habershon, <i>Med. Times and Gaz.</i> , 1864 (2), pp. 463, 464. |
| 98 | M. 44. | No symptoms during life indicating any brain disease. The patient had died of phthisis. | Osteoma. Consisting of true bone with Haversian canals, occupying position of infundibulum and corpora albicantia, which were totally absent. Not connected at all with dura mater. The pituitary body was apparently healthy. | Bristowe, <i>Tr. Path. Soc. Lond.</i> , vi. 25. |
| 99 | F. —. | Intense supraorbital neuralgia. Paralysis of the parts supplied by the third, fourth, fifth, sixth, seventh, and eighth nerves of the left side. The muscles moving the tongue not affected. No interference with respiration or the action of the heart; no choked discs. External tumors on each side of the neck, with a protuberance of the left eye. | Involved the petrous portion of the temporal bone, with a portion of the sphenoid bone of the left side, size of walnut. | James H. Hutchinson, <i>Philada. Med. Times</i> , vol. xiii., Sept. 22, 1883. |
| 100 | F. 66. | One-sided convulsions; first left leg, next left arm. Slow, syllabic speech, not aphasic. Abnormal, prolonged somnolence, followed by voracious appetite. Later, incontinence of urine. Apathetic. Muscles of left half of body, especially arm and leg, contracted. Pupils contracted. No facial paralysis. Slight ptosis upon right side. Conjugate deviation of eyes to right; fixed and immovable. Head drawn to right and backward. Extremities cyanotic and cold. Accentuated aortic sound; abdominal tympanitis. Taste, smell, hearing doubtful. Sensibility retained. Electric irritability rapidly exhausted; reflexes diminished. Unable to stand; constant tendency to turn to right. No albumen or sugar. All symptoms intensified; exhaustion; temperature below normal; death. | Sarcoma. Growing from right half of fossa of body of sphenoid bone, and extending outward and backward along petrous bone, only closely adherent at basilar portion of sphenoid. Slight depression of middle peduncle of cerebellum near entrance to pons. Basilar artery pushed to left. Vessels thick and rigid. Gyrus fornicatus of right side, temporal aspect, compressed. Right peduncle of cerebrum compressed. Brain-substance dense; numerous serous cysts in brain and ganglia. | Petrina, <i>op. cit.</i> |

TUMORS OF THE SPINAL CORD AND ITS ENVELOPES.

BY CHARLES K. MILLS, A. M., M. D., AND JAMES HENDRIE LLOYD, A. M., M. D.

DEFINITION.—Under Spinal Tumors will be included the growths or adventitious products which arise in the substance of the spinal cord or spring from its envelopes, membranous or bony, in such manner as to directly or by pressure involve the spinal cord. Tumors strictly confined to the cord are extremely rare. First in order of frequency are the new growths which develop from the spinal membranes, either the dura mater or pia mater, most frequently the former. Tumors originating in the bony spine, like those of the substance of the cord, are comparatively rare.¹

ETIOLOGY.—Under the predisposing causes of spinal as of intracranial growths are such diatheses or constitutional affections as cancer, tuberculosis, and syphilis. Under Pathology a table will be given from which it appears that of 50 tabulated cases, 3 were cancerous, 5 syphilitic, and 4 tubercular.

Traumatisms, such as a fall from a height, a blow on the back, a wrench or twist of the spine, or a sudden concussion as in a railway accident, sometimes serve as exciting causes of spinal tumors. Even when a diathetic or infectious predisposition exists, the patient might frequently escape from the special intraspinal localization of the disease were it not for the accidental infliction of direct injury to the axis. When no special predisposition is present, an injury is more likely to produce an osteoma, fibroma, or sarcoma than some of the other forms which will be mentioned, such as a glioma, myxoma, neuroma, or psammoma.

Spinal tumors are said by most authors to occur much more frequently in the male than in the female sex. Our tabulated cases, however, gave 22 cases among males, 21 among females, and 7 in which the sex was not given.

Fifty cases of spinal tumor gave the following result as to age :

| | |
|-------------------------------|-----------------|
| Under 10 years | 4 cases. |
| From 10 to 20 years | 3 " |
| " 20 to 30 " | 7 " |
| " 30 to 40 " | 12 " |
| " 40 to 50 " | 10 " |
| " 50 to 60 " | 6 " |
| " 60 to 70 " | 1 " |
| Age not given | 7 " |
| | <hr/> 50 cases. |

¹A "Table of Fifty Cases of Spinal Tumor" (which will be frequently referred to) is appended to this article.

SYMPTOMATOLOGY.—Can tumors of the spinal membrane be separated by a study of symptoms from intramedullary tumors? While this may be theoretically possible, in practice it will be found difficult, and of little value even when it can be done. The spinal canal is of such narrow calibre that a growth of any size either in the membranes or the cord itself will soon directly or indirectly involve both. On this subject Erb¹ speaks as follows: "The attempt has thus far been made in vain to secure, from amongst the individual symptoms, at least a few fixed points on which to base the diagnosis of intramedullary tumors. The following have been claimed as such: A somewhat long antecedent history of active local manifestations of irritation, belt-like pains, eccentric pains, definite paræsthesiæ, local paralysis, as in meningeal tumors; early and well-marked atrophy, which points to a larger involvement of the gray substance; striking fluctuations in the course of the disease, spontaneous improvement, and equally spontaneous growing worse again (Schueppel); and, finally, Schueppel has also tried to connect the occurrence of scoliosis (curvature of the spinal column to the side on which the tumor is situated) with the presence of a tumor. In this he is doubtless wrong, as this manifestation merely depends on unilateral paralysis of the muscles of the back, which may depend on all sorts of causes."

In the discussion of symptomatology and diagnosis which follows therefore no effort will be made to separate the phenomena of meningeal and intramedullary growth. In most cases the symptoms indicate involvement early of the membranes, and later compression of the cord.

The symptomatology will differ according to the stage of the affection. The symptoms can be arranged into those of a first or early, a middle, and a late stage. As a rule, but not invariably, the symptoms of the early stage are those of beginning irritation—such sensory phenomena, for instance, as pain in the parts supplied by certain nerves in the neck, arms, hands, abdomen, legs, or feet. This pain is sometimes associated at an early period with more or less stiffness, which later may become well-marked contracture. Pain in the back is occasionally an early symptom. Paræsthesiæ, as numbness, formication, constriction or girdle sensations, coldness or heat or alternations of hot and cold feelings, are sometimes early symptoms, but occur in a more positive manner in the middle stages of the progress of the spinal growth. Hyperæsthesia is more likely to be pronounced in the middle stage of the disease. A slight paresis, which may vary a little from day to day for a time, slight twitchings or spasms, usually localized to certain muscles or groups of muscles, are also present, in some cases as an incipient manifestation. The presence of these motor symptoms will depend largely upon the location of the incipient growth with reference to the columns of the cord.

One general point of differentiation between intramedullary and membranous tumors is the fact that irritative phenomena, such as pain in the back and along nerve-tracts, spasmodic twitchings, etc., are not likely to appear as early in the intramedullary cases as in the meningeal or mixed forms.

In the middle period of the progress of a spinal tumor the irritative phenomena, such as pain, paræsthesiæ, hyperæsthesia, twitchings, cramps, stiffness, and paresis, will be found to persist and increase, and in addi-

¹ *Ziemssen's Cycl. Prac. Med.*, Am. trans., p. 754.

tion other manifestations will appear, chiefly those of compression of the cord. Anæsthesia frequently develops, and, when the posterior segment of the cord is the one chiefly implicated, soon becomes profound; it is, however, often variable in distribution for a time, and sometimes shows peculiar areas. One leg or one arm may be partially involved, or both lower or both upper extremities, or certain portions of any one of the limbs. Anæsthesia dolorosa—that is, absence of sensation to objective tests, although the patient suffers pain or distress in the affected part—is common. Hyperæsthesia, best observed in this middle period, is sometimes cutaneous, but in other cases follows certain nerve-trunks, probably indicating a neuritis descending from the seat of the spinal growth. In this and in the last stage the paresis advances to more or less complete paralysis, which is also variable in distribution according to the localization of the growth. Contractures and rigidity come on and changes in the reflexes now become important symptoms. These may be increase of knee-jerk with ankle-clonus, or diminished or abolished knee-jerk, according to the position and the extent of the lesion.

The late symptoms of spinal tumors, especially of those which are slowly developed, are—usually profound anæsthesia and paralysis of the limbs, with rigidity and contractures, atrophy, marked changes in the spinal reflexes, bed-sores, paralysis of bowels or bladders or their sphincters, impotence, cedema, dyspnoea, vomiting, cardiac palpitation, cystitis, and pyelitis, and, when the lesion is near the medulla oblongata, dysphagia and certain intracranial symptoms, as amblyopia, diplopia, deafness, contracted pupils, affections of speech, etc.

The size of the growth and the rapidity of its development will of course influence the character and the time of appearance of certain symptoms. According to the position of the growth, either as to its level in the spinal axis or as to its relative position to the various longitudinal segments of the spinal cord, the symptoms will also differ at special stages. These differences will appear as symptomatology and diagnosis are now further considered.

Pain in the back occurs, but is not as frequent a symptom as eccentric pain. Unlike headache in intracranial tumors, it is not a constant symptom. The headache of brain tumors is due in part at least to the conditions of tension which are produced by the growth interfering with the balance of pressure within the skull. Headache is also, as has been pointed out in the article on Brain Tumors, frequently due to the irritation of the membranes; but in this case the one great nerve through which pain expresses itself is the trigeminal, which has its distribution both within the skull and outside of it to all parts of the head. In spinal tumors the pains are more likely to be eccentric, because of the limited character of the lesion and the almost exclusively peripheral distribution of the nerves. Twisting the trunk or jarring the spinal column by blows on the head will sometimes cause pain along the spine, most frequently when the bone is involved. It sometimes cannot be elicited.

Leyden¹ pointed out the fact that the movement of the spinal column is often difficult and painful in a certain direction, because this motion brings a greater pressure upon the tumor.

¹ Quoted by Erb.

Pain on percussion over the spinal column might be expected from the character of the affection, but has not been frequently reported. Like spinal hypersensitiveness and inflexibility with muscular rigidity, it is much more to be expected in those cases in which the vertebral bones and cartilages are implicated.

Constriction or girdle sensations are of comparatively frequently occurrence. When the cervical cord is involved, choking sensations or a sense of constriction about the neck are common. Tumors located in the lower cervical and dorsal region give girdle sensations most frequently in the chest or abdomen. So far as the assistance afforded by such sensations toward localizing the exact level of the growth is concerned, however, it must not be forgotten that curious and unexpected conditions sometimes occur. Thus, in one case (Case 16) a myxoma at the level of the sixth and seventh cervical vertebræ caused constriction sense about the legs and abdomen, and in another (Case 44), a glioma of the filum terminale, constriction of the chest.

The paralytic phenomena of spinal tumors have certain peculiarities which are not exhibited by any other spinal or by cerebral affections. A glance at the clinical history of a number of cases shows that many of them began with paresis of a single limb or part of a limb, in addition to the irritative phenomena. This paresis deepens after a time into complete paralysis, or before this occurs one or more of the other extremities become parietic. The progress toward bilateral paralysis may be comparatively rapid. The appearance and progress of the paresis or paralysis vary somewhat according to the level of the cord at which the tumor is located. In tumors of the cervical cord the paresis usually, but by no means invariably, first attacks the upper extremity. The fact that the arms are first the seat of irritative phenomena and paresis is in a case of spinal tumor indicative of a cervical location or a location in the upper dorsal region; but, on the other hand, not a few cases are recorded in which in tumors in these locations the loss of power first exhibited itself in one or both of the lower extremities. These cases are to be explained by the manner in which the descending motor tracts are affected directly or by pressure. In mid-dorsal tumors and those below this level the paresis shows itself first in the legs, and generally becomes before long a complete paraplegia.

To Brown-Séquard, more than to any other observer, we owe our accurate practical knowledge of unilateral lesions of the spinal cord, both in the cervical and other regions. When the lesion is localized in one lateral half of the cord and is situated in the cervical region, we have the affection known as spinal hemiplegia. The main symptoms of this affection are motor paralysis of the arm and leg on the side of the lesion and anæsthesia of the opposite limbs. Sensory fibres decussate in the cord soon after entering it, while the motor tracts cross at the anterior pyramids of the medulla oblongata; in which physiological facts we have a simple explanation of the peculiar motor and sensory phenomena presented by such a case. When the lesion is below the cervical portion of the cord, instead of spinal hemiplegia we have the affection known as spinal hemiparaplegia, in which the paralysis and hyperæsthesia in one lower extremity stand out in strong contrast to the anæsthesia and retained muscular power in the other. With a lesion so strictly localized as a spinal

tumor it might be expected that these crossed phenomena would present themselves in some cases. They are recorded, more or less distinctly, in Cases 4, 16, and 38, and it is probable that they would have been more frequently observed if they had been anticipated and looked for carefully.

Ataxia does not seem to have been a frequent symptom in reported cases. It has probably been sometimes overlooked or confounded with paresis. In a case of myxoma of the dura mater in the left dorsal region ataxia of both leg and arms was present; but in this case, however, the dura mater of the brain contained fluid and lymph. In the light of the commonly accepted views as to the physiology of the spinal cord regarding the posterior columns, as related in function both to co-ordination and sensation, ataxic manifestations might be frequently expected. Owing, however, to the narrowness of the spinal canal, compression of the entire cord takes place so early as to make paretic symptoms displace those of ataxia.

Atrophy which varies in distribution according to the extent of the destructive involvement of the cord is frequently present. In a few instances the atrophy will be of certain muscles or muscular groups. When true atrophy is present the anterior horn will be involved directly or indirectly, and accompanying changes in the electrical reactions will also be found.

The electrical condition of the atrophy of the paralyzed parts will vary with the extent of the trouble produced by the tumor. In a case of tumor of the cervical enlargement, for instance, producing more or less paralysis both of the upper and lower extremities, reactions of degeneration will be present only in the muscles supplied by the nerves which spring directly from the seat of lesion.

Spontaneous twitchings or spasms due to irritation of motor-centres or tracts are comparatively frequent. More or less permanent contracture in a limb or part is of frequent occurrence, particularly after the growth has advanced. Forms of torticollis or retraction of the head, strong flexures of the arms or legs, and, late in the history of many cases, complete and extremely painful drawing up of the limbs upon the body, may occur. Persistent subultus was observed in one case, a gliomyxoma involving the gray columns from the medulla oblongata to the cauda equina. Fibrillary twitching is rare, and in our tabulated cases was observed only in one instance, a glioma of the filum terminale. General convulsions with unconsciousness are exceedingly uncommon. In one case, however, a round-celled sarcoma at the level of the seventh, eighth, ninth, and tenth cervical vertebræ, the patient is recorded as having died in a fit. Nystagmus was observed once, but probably had no significance so far as the spinal affection was concerned, as the cerebral dura mater exhibited evidences of inflammation.

The condition of the reflexes, both cutaneous and tendinous, is often peculiar and almost diagnostic, but varies greatly according to the position and extent of the lesion. Increase of reflex action is sometimes a marked symptom. The slightest irritation of the soles of the feet, the calves of the legs, palms of the hands, or other special regions will often produce decided contractions, and sometimes that symptom which has been designated by Brown-Séquard as spinal epilepsy, in which both lower extremities are thrown into violent clonic spasms, which may last

for many seconds or even minutes. In tumors of the dorsal region causing marked compression and preventing cerebral inhibition, clonus and knee-jerk are also markedly exaggerated. The so-called diplegic contractions—that is, contractions in one extremity from irritation of the other—are observed, especially when a transverse area of the cord, large or small, is involved in an irritative or inflammatory process. They probably result from the abnormal facility of transmitting impressions which has been acquired by the cord. When the cervical or the lumbar enlargement of the cord is completely compressed or destroyed by a tumor, reflex activity is diminished or abolished in the region supplied by nerves originating at the seat of lesion.

Alterations in the body-temperatures have been frequently noted in lesions of the spinal cord, such as fractures of the vertebræ and inflammatory changes in the cord and its membranes. Some of the observations are almost incredible, as that of J. W. Teale,¹ who records an axillary temperature of 122° F. The subject has been somewhat obscured by physiological speculations. Thus, it has been asserted that paralysis of motor centres and strands causes an increase of temperature, while paralysis of sensory tracts produces a diminution. The accepted clinical facts apparently are as follows: after crushing the cervical cord a uniform rise in temperature occurs if peripheral cooling is prevented. This rise is caused by a paralysis of the vaso-motor nerves, which permits a paralysis of the vessels and floods the parts with blood. This assumes, of course, that mere increase of blood in a part means increase of heat. After a variable period this increase is followed by a decrease which is permanent. Hutchinson records² a case of fracture of the cervical spine at the fifth vertebra in which the patient's body felt almost as cold as a corpse and the rectal temperature was only 95° F. In Cases 4 and 16 the affected parts are recorded as cold, just as in atrophic and other lesions of the cord. The tabulated cases do not show many exact thermometric observations, but in Case 8 the average temperature for two weeks before death is given as slightly below normal, while Case 7 shows a sudden rise on the day preceding death. It is probable that the permanent decrease following crushing and compressing lesions would also be found in cases of spinal tumors. The following exact observations, made by one of us³ upon a case of injury to the cervical cord, are directly illustrative of this subject. The case was of several months' standing. The patient could walk imperfectly, and the right arm was more paretic than the left. The observations were made at 10 o'clock A. M. on six successive days:

| | Right Axilla. | Left Axilla. |
|-----------------------------|---------------|--------------|
| First observation | 98.2° | 97.3° |
| Second " | 99.8° | 98.2° |
| Third " | 96.4° | 96.2° |
| Fourth " | 95.6° | 96.4° |
| Fifth " | 97.2° | 96.8° |
| Sixth " | 95.2° | 93.8° |

It will be seen that the temperatures range higher in this series on the more paretic side; but this did not hold in a series taken a few weeks

¹ *Lancet*, March 6, 1875.

² *Ibid.*, August, 1875.

³ *Hôpital Gazette*, Nov. 7, 1879.

later. The fact is to be noted that all these temperatures, with one exception, are below the normal.

Cystitis, pyelitis, and pyelo-nephritis are usually secondary symptoms, due to retention of urine, distension of the bladder, etc. in consequence of paralysis of this viscus. Bed-sores result in two ways: in the first place, they may be due to emaciation and immobility and the uncleanness which it is almost impossible to prevent; or, in the second, trophic eschars may arise because of the involvement of nutritive regions of the cord. The so-called sacro-ischiatic eschars are of this character. Febrile phenomena, such as chills, increased temperature, increased respiratory action, are frequently secondary phenomena due to bed-sores, cystitis, continued pain, exhaustion, or septic infection.

Priapism was recorded in two of the fifty cases, both tumors of the cervical cord. Impotence was only recorded once, a dorsal myxoma. It is probable that both priapism and impotence, particularly the latter, were present, but overlooked in other reports.

Headache was present in three of fifty cases. One of these was a fibro-sarcoma at the level of the fourth cervical nerve; the other two were low down in the spinal axis, one in the lumbar enlargement, and the third, strange to say, in the filum terminale. Vertigo is a rare symptom in the spinal tumors. In one case in which the growth was located at the position of the third cervical vertebra its presence was recorded.

Out of five cases in which vomiting was present, two were in the cervical regions, one in the dorsal, one in the lumbar, one in the filum terminale.

Tumors involving the upper cervical and bulbar region of course will give rise to special symptoms indicating more or less involvement of cranial nerves.

Unfortunately, very few ophthalmoscopic observations have been made in cases of spinal tumor. Optic neuritis has been found in a few cervico-dorsal cases, and in other cases located in the same region no ophthalmoscopic alterations have been discoverable.

Mental disturbances were only especially recorded in four of the fifty cases. Such symptoms were certainly not of frequent occurrence, except those emotional manifestations which were due to the great suffering which the unfortunate patient was called upon to endure. These emotional disturbances, as in all forms of painful disease, varied according to the mental stamina of the patient. In one case the mental symptoms, in association with other phenomena and a probability of dog-bite, led to the suspicion of hydrophobia.

In one case (31) an interesting observation was made of an anal sphincter reflex, with frequent stools. The tumor in this case is reported at the level of the tenth dorsal vertebra, which would be at the level of the eleventh dorsal segment. The tumor was tubercular, and therefore probably meningial, so that the irritation to the anal centre, which is in the lumbosacral segment, may have been caused by extension of inflammation along the meninges.

PATHOLOGY.—We present in tabulated form the various kinds of tumors as found in the fifty cases which have been collected:

| | | | | | |
|----------------------------|---|--------------------------|---|------------------------|---|
| Aneurism | 1 | Glioma | 5 | Osteoma | 1 |
| Cancer (?) | 2 | Gumma | 5 | Phlegmon | 1 |
| Carcinoma | 1 | Myo-lipoma | 2 | Psammoma | 2 |
| Cysticercus and hydatids . | 3 | Myxoma | 2 | Sarcoma | 7 |
| Cyst (dermoid ?) | 1 | Neuroma | 1 | Tubercle | 4 |
| Fibroma | 5 | Organized blood-clot . . | 1 | Unclassified | 6 |

It will be observed that the predominance in this list is decidedly in favor of the sarcomata and structures which are likely to be associated with or to graduate into them, such as the gliomata, myxomata, and the psammoma. In one instance the resemblance (Case 15) to psammoma is referred to by the reporter. The comparatively large number of unclassified, and the two cases referred to vaguely as cancer, would probably, on more exact report, have added several more to the group of the sarcomata. The table shows that next in frequency come the fibromata and gummata, while the carcinomata have but a single representative in the group. Tubercular tumors occurred with comparative frequency, no less than 8 per cent. being recorded. Although the exact origin of only somewhat more than one-half (29) of all the tumors is given, it is stated of this fraction that 17 sprang from the membranes, while of the remainder 8 were located in the cord itself and 4 in the vertebræ. Of the 3 cases of parasitic invasion, it is recorded of one (Case 43) that a hydatid cyst was also found in the liver; and it is probable that in any given case the spinal cord would not be the only part to suffer. Cobbold's work refers to one case of hydatid of the spinal cord. Erb refers to 13 cases, all but 2 external to the dura mater. In Case 43 of the table pains in the back and hip, simulating rheumatism, were present early.

The dimensions of the spinal tumors of whatever character are never very great, for the reason that they have but little space in which to enlarge, and that their presence soon causes such grave changes as to be incompatible with life. They rarely exceed an inch in their longest diameter, and not unfrequently are smaller than this. There is usually about them a more or less marked meningitis and an area of vascular fulness. Edema of the membranes is sometimes noted. The substance of the cord beneath is compressed, atrophied, or softened, and this softening sometimes extends for a considerable distance both above and below the neoplasm. These changes were reported in Case 8, in which there was the addition of an abscess. Secondary degenerations would probably be found in all cases, unless very recent; and these changes, following the Wallerian law, would ascend the posterior and descend the lateral columns. Such degenerations are reported in some of the cases. The spinal nerves are sometimes compressed and atrophied. Old or recent hemorrhages are found, as in Case 18. Among the changes which occur, probably at a late stage, are the formation of cysts, either large or small, either in the substance of the cord or consisting simply of a dilatation of the central canal of the cord. This condition is known as syringo-myelia, and is of exclusive pathological interest. In Case 1 is recorded, apparently, a well-marked dilatation of the central canal (hydromyelus), and cyst-formation is recorded with gliomata, sarcomata, and gummata in other cases. Caries of the vertebræ is recorded in a number of cases, and occurred both in cases of gumma (Case 8) and in carcinoma (Case 14). These cases were, however, exceptions to the general rule that the bony envelope of the cord does not furnish external

evidence of the location of the tumor. It is worthy of note that the one instance of phlegmon or inflammatory exudate (Case 20) also presented infiltration of the tissues of the throat and mediastinal space. A case of organized blood-clot (Case 39) has been included in the list, although, properly, a spinal hemorrhage, because it became and acted as a tumor. The location of the single case of aneurism (Case 48) is not given. The symptoms were those of tumor in the dorsal spine.

As sequelæ of tumors of the cord may be mentioned especially bed-sores, which sometimes commit frightful ravages, as in a case (37) in which the spinal canal was laid open. The bronzing of the skin and diseased condition of the suprarenal capsules, as recorded in Case 41, were mere coincidences, and not probably at all connected in pathological sequence with the spinal lesion. Cystitis, pyelitis, and pyonephritis are not uncommon in cases of tumor of the cord, just as they are observed in other compressing and destructive lesions of that organ. In those cases in which the tumor is the result of a general taint, as in gummy and tubercular growths, the evidence of this taint is not usually wanting in other organs; thus in Case 37, of tubercle of the cord, tubercles were also found in the lungs, bowels, and uterus. In gummata of the cord it would not be likely to escape careful inquiry that the patient's history or his body presented evidence of the disease.

In a case (47) of congenital sacral neuroma amylinicum the infant was also hydrocephalic and had a bifid spine—conditions of faulty development with which the patient cannot long survive.

In one case of psammoma (Case 5) a resemblance to endothelioma is noted, while in another (Case 15), already referred to, a sarcoma is said to have resembled a psammoma.

Vascular changes are usually notable. In addition to the congestion already spoken of, it is recorded in one case (No. 14) that the right vertebral artery was obliterated. This was a carcinoma which had partly destroyed one vertebra.

Virchow's case (No. 50) of a stillborn child with a large tumor of the size of the head of a child of two years, and containing bone, has some analogies in three cases, referred to by that author, in which both hair and bone were found.

In several cases a brown or yellow exudate (plastic lymph?) is mentioned as extending along the cord far beyond the immediate neighborhood of the tumor.

The histology of tumors of the whole cerebro-spinal axis will be found described in the article on Tumors of the Brain.

DIAGNOSIS.—The diagnosis of tumors of the spinal cord presents itself naturally under two heads—the differential, or general, and the local diagnosis. The conclusions reached in this paper are based on a careful study of the cases appended, two of which were personal observations, and the remainder were collected from American, English, French, and German literature. It cannot be denied that much obscurity rests upon the diagnosis of tumors of the spinal cord, and that the doubts expressed by Erb and other writers have much to support them. It is hoped that the systematized study presented in this table will do something to dispel this obscurity.

(1) General Diagnosis.—The differential diagnosis has regard first to

certain general phenomena which are broadly indicative of a spinal disorder as distinct from a cerebral or peripheral one. Thus, mental symptoms are absent, or if present are an accompaniment of tumors high up in the spinal axis, are the results of suffering, or appear very late in the disease because of progressive weakness. Briefly stated, the phenomena which point with comparative certainty to the existence of spinal tumors are symptoms of meningeal irritation gradually increasing, and symptoms of slow compression of the cord. These have been sketched at the beginning of Symptomatology. As to duration, the data in the cases studied were somewhat meagre. The usual duration is from six months to three years.

The differential diagnosis of spinal tumors will be considered in reference to the following affections: congestion, hemorrhage, meningitis (simple and specific), caries, traumatism, sclerosis, aneurisms, neuritis, metallic and infectious disorders, and hysteria. Spinal tumors, it will be recalled, are from constitutional or special causes, as syphilis, cancer, and tuberculosis. The onset is gradual and irregular. The duration is comparatively long. The progress is by irregular advances toward a fatal termination. The symptoms are inclined to be at first unilateral or local; later, bilateral. Special symptoms, as paralysis, spasm, sensory and visceral disorders, occur irregularly as to time. Decubitus and trophic changes are common late in the history. Reactions of degeneration are often present. Gowers refers to the fact that two morbid processes often occur, one consecutive upon the other, as a secondary degeneration or a hemorrhage, after the establishment of the morbid growth, with characteristic increase of symptoms.

In spinal congestion a constitutional cause is not likely to be present. The onset is usually sudden and after exposure. The duration is shorter than in tumors, and is from a few days to four months. The disease is stationary for a while; then retrogression of symptoms toward recovery occurs. The symptoms are more uniformly bilateral, and motor and other symptoms develop about the same time. Decubitus is rare. Reactions of degeneration are rare (?). It is desirable that cases of so-called spinal congestion should be differentiated from the forms of peripheral neuritis above referred to, the most characteristic symptom of which appears to be tenderness of nerve-trunks.

In spinal hemorrhage there is no special history, or a history and signs of cardiac and vascular degeneration may be present. The onset is quite sudden and the progress of the case regular. The first symptoms persist, and secondary degenerations follow, and differ according to the extent and location of the lesion, but are most likely to be uniformly bilateral.

In meningitis the symptoms of localized compression are absent. The girdle symptom is absent. The affection is sometimes curable, and especially so if it has been of syphilitic origin. The reactions of degeneration are not marked.

In caries of the spinal vertebræ deformity is rarely absent, especially if the case has continued a few months. Rigidity of the muscles of the back is an important symptom, which, however, is occasionally found with a tumor. Jarring of the spinal column by tapping upon the head or jumping from a chair or stool is more likely to elicit pain in caries than

in tumors. Strumous symptoms and evidence of tubercles in the lungs or other organs are often present.

In traumatism usually a history of the injury can be obtained. The symptoms are those of caries, myelitis, meningitis, or of combinations of these, according to the character of the case.

In sclerosis the symptoms are usually those of progressive systemic affections, with absence of compression symptoms. The duration is longer. The progress is gradual and more regular.

Aneurisms are only to be distinguished when extra-spinal, causing erosion and compression.

In neuritis there is the soreness of the nerve-trunk already referred to, while compression symptoms and visceral disorders are absent. The motor and sensory symptoms are confined to the area of distribution of the affected nerve. It is amenable to treatment. In advanced stages the reactions of degeneration are marked. In the form of general peripheral neuritis, the existence of which, as a distinct disease, is being at present claimed, the characteristic symptoms are as yet not sufficiently determined or the pathology demonstrated by post-mortem research to admit of much discussion.

In metallic and infectious disorders a history of definite causation is present. Metallic disorders may present special distinctive signs, such as lead-line, wrist-drop, etc.

In hysteria a precedent characteristic history is usual. The onset is often sudden and an emotional element is present. The symptoms are bilateral and protean. Trophic changes are absent. No reactions of degeneration are present.

(2) Local Diagnosis.—It may be said of spinal tumors in a modified sense, as it can be said of brain tumors, that they are not good pathological experiments for illustrating the functions of the exact areas which they occupy. The spinal canal has such narrow limits, the tumor itself soon attains such a relatively large size and causes such wide vascular engorgement, and the different tracts and systems of the cord are so closely packed together, that the tumor does not often invade only one functional area and escape another. Hence the regional diagnosis presents special and greater difficulties than the diagnosis of the level of the cord at which the tumor presents itself. A tumor which destroys the trophic centres for the arm in the anterior cornua might exert sufficient backward pressure to paralyze the motor tracts running to the leg; or a cervical tumor, as in Case 5, might produce symptoms which are almost wholly observed in the legs. It will be seen, however, by reference to the table, that in Case 3, reported by Wilks, we have a tumor whose exact anatomical seat could have been predicted, and which seems to have reproduced almost the upper-arm paralysis of Remak. When we compare these two cases, in which the pathological conditions are so similar, it will be observed that the paralyzed arm is much wasted, which indicates a lesion of its trophic centre, whereas the affected legs in the other case are irritated by pressure and by isolation, but are not wasted, because their trophic centres are far below the point of lesion. The invasion of the trophic centres, and the accompanying wasting of particular groups of muscles, especially when this occurs early in the case, with the consequent reactions of degeneration in these muscles, would furnish very valuable indications

both as to the region and the level of the cord involved (Case 29). Unfortunately, the exact observations are wanting in most of the cases as reported.

M. Allen Starr, in a recent paper,¹ has devoted much labor to the elucidation of the functions of different segments and regions of the cord. He demonstrates the existence of groups of cells in the gray matter, especially in the anterior horns, each of which he believes constitutes a physiological unit. He affirms that these cell-groups preside over certain associated movements or combinations of certain muscles, and, quoting from Spitzka, says that "the nearer a muscle is to the ventral aspect of an animal the nearer will its nucleus be to the median line of the cord; and the nearer the muscle is to the dorsal aspect of the animal the nearer will its nucleus be to the lateral cornua of the cord. Flexor nuclei are therefore in internal, extensor nuclei in external and posterior, cell-groups." The only light that such a theory throws upon the subject of diagnosis is by affording a possible explanation of the fact that spastic flexion is much more common than spastic extension, and may be due to the fact that the cell-groups for flexion lie deeper and are more protected than those for extension; and the additional fact above referred to, that a paralysis of associated muscles or groups of muscles, with degeneration, as in the types of Remak, would indicate with great clearness the destruction of the cell-group which presides over them. Starr, in his article, also tabulates the various reflexes and their seats in the cord. As this subject is of much importance in any exact study of spinal-cord diseases, we will state here some of the facts as given in that article: The neck-pupil reflex (dilatation of the pupil on irritation of the neck) has its seat from the fourth to the seventh cervical segment; the elbow-tendon reflex in the fifth and sixth cervical; the wrist tendons from the sixth to the eighth cervical; the palmar in the seventh and eighth cervical; the epigastric and abdominal skin reflexes in the fourth to the eleventh dorsal segments; the cremasteric reflex in the first to the third lumbar; the patellar tendon in the second to the fourth lumbar, and bladder and sexual centres in same; the rectal centre in the fourth lumbar to the third sacral; the foot-clonus and Achilles-tendon reflex in the first sacral. A destructive lesion, such as a tumor, at any one of these points would cause abolition of that particular reflex, and this would probably occur early in the case. Our table of cases does not present any such observation, whereas exaggerated reflexes, such as occur from a compressing lesion above the seat of the excited centre, are recorded in abundance. Many of these deductions are of course only possible early in the history of the case, as at a late stage the secondary degenerations have caused too widespread havoc to admit of any exact localization. The distinction must also be sought for between a destructive lesion and the symptoms of irritation which it may project to distant parts. Fürstner's cases of syringo-myelia,² in which were marked vaso-motor changes, such as pallor, flushings, copious sweat, and trophic disorders in the integument and its appendages, seem to show that a lesion in the gray matter just posterior and external to the central canal is necessary for such phenomena. Similar vaso-motor changes may be observed in some of the tabulated cases, as in No. 4, in

¹"Localization of the Functions of Spinal Cord," *Am. Journ. Neur. and Psych.*, 2-3, p. 443.

²Quoted by Starr.

which there were islands of heat and cold in the leg, with a hydromyelia in the cord. Sensory symptoms are very common in cases of spinal tumor, but they furnish indications rather of the exact level of the lesion than of its region.

Before considering briefly the indications which point to the various levels of the cord as a possible seat of spinal tumor, it will be necessary also to make plain a few anatomical facts. It must be borne in mind, first, that the nerve-origins in the cord are never at the same level as their exits from the spinal canal, or, in other words, that the spinal segments do not correspond with the bodies of the same numerical vertebræ, and that there is, in fact, one more cervical segment than there are cervical vertebræ. The tendency is for the nerve-trunks to run downward before passing out of the canal, so that in every instance, without exception, from the medulla oblongata to the filum terminale the segments of the cord are above the corresponding vertebral body. This discrepancy increases as we descend the cord; whereas it is approximately correct to say of the cervical and dorsal regions that every segment is opposite the vertebral body which is numerically just above it, this difference be-

Diagram of Spinal Column, Cord, and Nerve-exits (after Gowers).

Sarcoma compressing Cervical Cord, Case 17 of Table (E. Long Fox).

comes much greater in the lumbar and sacral regions. The cord itself terminates in the lumbar enlargement which ends opposite the interval between

the first and second lumbar vertebræ. All the remainder of the canal is occupied by the descending trunks of the lumbar, sacral, and coccygeal nerves as they pass to their respective foramina, constituting the cauda equina. It must be recalled, however, that the vertebral bodies, lying very deep, cannot serve as guides, but that we are dependent upon the spinous processes as landmarks in diagnosis. These again differ in their levels from their respective vertebral bodies, as they are deflected at somewhat different angles at different regions of the spine. Gowers has illustrated these facts by a very graphic wood-cut¹ (Fig. 45), from which the general rule may be drawn that each vertebral spine is about opposite the spinal segment which is numerically two places below it; thus the eighth dorsal spine is opposite the tenth dorsal segment, etc. The indications afforded by this exact anatomical knowledge have reference largely to the existence of pain on pressure and to any deformity of the bony structures. The cases as reported do not indicate that this method of research has been utilized, and it may possibly be of only theoretical importance; but it has been considered worthy of reference as an indication in diagnosis.

It will be seen by reference to the table that usually certain general features in the symptomatology indicate the seat of the lesion. Thus

FIG. 47.

FIG. 48.

FIG. 49.

FIG. 50.

Sarcoma of Lower Cervical Cord, Case 13 of Table (Adamkiewicz).

in tumors of the cervical region pain and stiffness of the neck occur, while the first appearances of paresis and sensory disturbances are usually observed in the arms and about the chest. The centres for the forearm and hand lie in the lower portion of the cervical enlargement; that for the upper arm, including the supinator longus, in the upper portion. Mental symptoms are more marked, and in Case 4 several of the cranial nerves were implicated. In the lower cervical and upper dorsal region there are symptoms of dyspnea, fixation of the chest (Nos. 20, 22, 24), and cough. The girdle symptom is an important indication at any level,

¹ *Diagnosis of Diseases of Spinal Cord*, p. 6.

as it is due to irritation of the nerves at the lowest level of healthy cord just above the transverse lesion. It has already been discussed under Symptomatology. In many of the dorsal cases (Nos. 32, 37, 38, 39, and 45) the symptoms are almost entirely confined to the legs and lower trunk, the arms escaping entirely. The condition of the bladder is usually given in the table as one of paralysis; this does not indicate whether automatic evacuation existed at the beginning of the case; which condition would indicate that the centre for micturition was below the lesion, and intact. It is probable that later in these cases the bladder is actually paralyzed by destruction of its centre in the cord, and this even when the tumor has been situated some distance above.

FIG. 51.

Fibroma of Lower Dorsal Cord, Case 32 of Table (W. Cayley).

FIG. 52.

Tumor of Cauda Equina, Case 45 of Table (W. W. Fisher).

With reference to tumors of the cauda equina, Erb¹ says that they have in every respect a great resemblance to those which are situated higher and affect the cord proper. "They are hard to distinguish from the latter, but may be in many cases perhaps, if it is borne in mind that tumors of the cauda produce exclusively nerve-root symptoms, and that the signs of compression of the cord, of secondary myelitis, etc. are absent. The higher the tumor, the nearer it approaches the lumbar por-

¹ *Op. cit.*

tion of the cord, the harder will it be to draw the distinction. In respect to tumors seated lower the following points may be attended to: the seat of the pains (which in such cases often attain enormous violence) is strictly localized in certain nerve-districts; all nerves leaving the spinal canal above the tumor are free; thus in myxo-sarcoma telangiectodes of the cauda I observed the pain strictly limited to the district of the sciatica, while the crural and the dorsal nerves were perfectly free; constant violent pain in the sacrum. If palsy occurs the reflex actions necessarily

Fig. 53.

Fig. 54.

Psaumoma of Dorsal Cord, 38 of Table (after Charcot).

cease at once. Spasms are seldom observed, more frequently contractions. Atrophy of the muscles occurs rather frequently. The palsy and anæsthesia by their localization often give us the opportunity of fixing the upper limit of the lesion. Increase of the reflex acts and marked tendinous reflexions do not occur. Paraplegia, palsy of the bladder, bed-sores, etc. may develop exactly as in tumors occupying a higher seat,

but the symptoms of paralysis do not seem to belong necessarily to the disease, as is shown in my case (just mentioned), which terminated fatally before paralysis or anæsthesia occurred."

PROGNOSIS.—The prognosis of spinal tumors is generally very unfavorable. Syphilitic cases are of course the most hopeful, but even in these cases it is only when they are recognized early that much can be expected. A gumma that has grown to any dimensions will have so compressed the cord that even when the tumor is melted away by specific treatment its effects will remain.

DURATION AND TERMINATION.—Most cases of spinal tumor last from about six months to three years. Occasionally death may result, as from a rapidly-developing sarcoma, in less than six months, and somewhat more frequently in slowly-developing tumors, or in those which are held more or less in abeyance by treatment the sufferings of the patient are prolonged to four or five years or more. Hemorrhages into or around the growths sometimes take place, and are the cause of death, or more frequently of a sudden aggravation and multiplication of severe symptoms. Death sometimes takes place from the complete exhaustion which results from the disease and its accompanying secondary disorders, such as bed-sores, pyelitis, etc. Occasionally death results from intercurrent diseases, such as pneumonia, infectious fevers, etc., whose violence the weakened patient cannot well withstand. Sometimes the symptoms of a rapidly-ascending paralysis appear, probably due to an ascending myelitis or meningo-myelitis.

COMPLICATIONS AND SEQUELÆ.—Spinal tumors are sometimes complicated with other similar growths in the brain or the evidences of the same constitutional infection in other parts of the body. In one case of cysticercus of the cord sclerosis of the posterior columns was also present.

TREATMENT.—The treatment of spinal tumors can be compressed into very small compass. In cases with syphilitic history, or when such history is suspected, although not admitted, antisyphilitic remedies should be applied with great vigor. It should be borne in mind, however, that even in syphilitic cases after destruction of the cord by compression or softening specific remedies will be of no avail. In tubercular cases and in those in which the system is much run down tonics and nutritives are indicated. Bramwell¹ advises an operation in any case in which the symptoms are urgent, in which the diagnosis clearly indicates the presence of a tumor, when there is no evidence of malignant disease, when the exact position of the growth can be determined, and when a vigorous antisyphilitic treatment has failed to produce beneficial results. As some meningitis, meningo-myelitis, or myelitis is usually present in cases of spinal tumor, treatment for the complication will assist in relieving the torments of the patient. Anodynes, particularly opium and its preparations, should be used freely in the later stages of the affection. Bromides and chloral are of little value except in association with opiates. Operation offers even less hope than in brain tumor, but in very rare cases should be taken into consideration.

¹ *Diseases of the Spinal Cord*, Edinburgh, 1884.

TABLE OF FIFTY CASES OF SPINAL TUMOR.

| No. | Sex and Age. | Clinical History. | Path. Anat. and Location. | Remarks. |
|-----|--------------|--|--|---|
| 1 | M. 33. | Paresis of forearms, left worse. Paraplegia, then paralysis of all limbs; paralysis of intercostals. Contractures of hands, then of feet. Pain and stiffness of neck on motion. Wasting of interosseal. Diplegic contractions of legs. Only partial paralysis of sphincters. Sensation perfect. Bed-sores. Duration, thirteen months. | Glioma; syringomyelus. Dilated lymphatics. Entire length of cord, and involving medulla oblongata. Upper four inches of cord greatly enlarged. | T. Whiphham, <i>Trans. Path. Soc. London</i> , 1881, xxxii. 8-12. |
| 2 | F. —. | Constricting pains about abdomen. Paresis of legs. Persistent subsultus. Temporary improvement after labor. General paralysis. Scoliosis. | Glio-myxoma. In gray columns from medulla oblongata to cauda equina. | Schueppel, <i>Arch. d. Heilk.</i> , viii. Bd., 1867 (quoted by Rosenthal). |
| 3 | M. 15. | Paresis of left arm. Pain back of neck. Later, paralysis of left arm, and wasting of arm, shoulder, and neck muscles. Slight paresis of right arm. Prolonged vomiting. Constriction of neck; dysphagia; paralysis of chest. | Gelatinous tumor left side of cord, and involving in some parts the gray matter. From medulla to sixth cervical vertebra. | S. Wilks, <i>Lectures on Dis. of Nervous System</i> , p. 266. |
| 4 | M. 18. | Paresis of left leg, increasing; some atrophy. Weakness in left arm. Later, numbness in both legs. Contracture of fingers. Some mental confusion. Left hand and leg livid and cold. Hyperæsthesia of left leg; anæsthesia of right leg, perineum, penis, scrotum, rectum, and inguinal region, and of left arm. Right arm normal. Islands of heat and cold in leg, and of cold in arms. Left ankle clonus. Left pupil contracted. Vomiting. Dysphagia. Occipito-cervical pain and contracture of cervical muscles. Leg contractures and tremor. Later, hyperæsthesia disappeared. Incontinence of urine. Patellar and skin reflexes increased. Facial spasm. Amblyopia, optic neuritis, diplopia, deafness, paralysis of left abducens; pupils contracted. Sacral bed-sores. Thick speech. | Round-celled sarcoma or glio-sarcoma, growing from ependyma of central canal, causing hydro-myelia, softening, and secondary degeneration. Dura mater thickened. Brown exudate in cord and base of brain. From medulla oblongata to dorsal cord. | Schultze (F.), <i>Arch. f. Psychiat.</i> , Berlin, 1878, viii. 367-393, 1 pl. |
| 5 | F. 48. | Pain in abdomen and down legs, worse on left side. Tonic spasm in flexors and adductors of thighs. No anæsthesia. Two months before death paralysis of sphincters. Great emaciation. | Tumor (psammoma), growing from dura mater on right side in cervical region. Upper part of cervical region. | J. Hutchinson, Jr., <i>Tr. Path. Soc. Lond.</i> , 1881-82, xxxiii. 23, 24. |
| 6 | | Pain in arms. Contracture of fingers of right, then left side. Numbness in right foot, then upward, then left foot. Girdle feeling. Priapism and dysuria. Complete anæsthesia, later, up to third rib, with paralysis of legs and paresis of fingers. Respiration diaphragmatic. Legs very jerky. Later, arms paralyzed. | Sarcoma of left post. aspect of cord; adjacent cord compressed and soft. Belt of yellow substance enveloped cord to cauda equina. Between cervical bulb and second cervical vertebra. | E. Long Fox, <i>Bris. Med.-Chir. Journ.</i> , 1883, i. 100-106, 2 pl. |
| 7 | F. 31. | Pain, stiffness in neck; pain radiating, aggravated by jarring. Sudden paralysis of both arms; next day paralysis of legs, incomplete. Partial anæsthesia. Marked skin reflexes in legs. Patellar reflexes retained, weaker on right than left. Dyspnoea. Profuse perspiration. Cardiac irregularity. Day before death temperature in right axilla 100°; left, 102.2°. | Gumma of dura mater two inches long, with intercurrent hemorrhage; flattening and softening of cord, with secondary sclerosis. From first to fifth cervical vertebra. | Charles K. Mills, <i>Philada. Med. Times</i> , Nov. 8, 1879, p. 58. |
| 8 | M. 34. | Pain in back of neck, with stiffness and torticollis. Paresis of arms; later, of legs. Anæsthesia of arms, then of legs; also paræsthesia of legs. Late symptoms: shortening and great rigidity of neck, with choking sensation (girdle sensation at neck). Dimness of vision. Atrophy of arms and less of legs. Complete paralysis of arms, almost complete of legs. Electro-contractility preserved. Violent skin reflexes in legs. Involuntary evacuations and incomplete priapism. Severe pains in knees and ankles. No acute bed-sores. | Gumma of dura mater; caries, probably syphilitic, of vertebrae. Abscess. Total (almost) transverse sclerosis of cord. Secondary degeneration. Some softening above and below tumor. Cervical nerves compressed and atrophied. | Charles K. Mills, <i>Philada. Med. Times</i> , Nov. 8, 1879, p. 58. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Path. Anat. and Location. | Remarks. |
|-----|--------------|---|---|---|
| 9 | M. 43. | Paroxysms of dyspnœa. Average temp. for two weeks before death, M. 97.9°, E. 98.3°. Pain between shoulders. Numbness in right hand and arm, with weakness and swelling. Numbness in left arm, which spread over chest and abdomen. Unable at first to lie down. Felt as though encased in armor. Pain in back of neck. Tongue protruded to right. Exaggerated reflexes in legs. Right arm and leg weaker than left. Vertigo. Dysphagia. Sense of constriction about neck. Breathing impaired. | From second to fifth cervical vertebra; most in front. At third cervical vertebra, to right of front of cord. Destruction of opposite vertebra. | E. H. Clark, <i>Bost. Med. and Surg. Journal</i> , 1859-60, lxi. 209-212. |
| 10 | | No record of symptoms especially referable to the cysticercus. Symptoms of tabes dorsalis. | Cysticercus in substance of cord. Lesions of tabes dorsalis. On level with third cervical nerve. | Geo. L. Walton, <i>ibid.</i> , vol. cv. p. 511. |
| 11 | M. 25. | Pain in back of neck; stiffness. Numbness of left hand. Gradual loss of power of left arm. Jerking of arm. Paresis of left leg. Constriction of upper chest. Right limbs involved, and eventual complete paralysis of trunk and extremities. Severe headache. Last three days absolute anesthesia of arms and legs. No ophthalmoscopic changes. Constipation and dysuria. | Fibro-sarcoma at level of fourth cervical nerves. Cord compressed. | H. A. Lediard, <i>Tr. Path. Soc. Lond.</i> , 1881-82, xxxiii. 26-27. |
| 12 | F. 25. | Œdema of ankles; pain in legs; afterward numbness, formication, and stiffness of legs. Painful contractures in upper extremities. Slight left scoliosis. Abdominal pains. Paresis of arms. Fingers flexed. Fever. Respiration became involved, and bowels and bladder paralyzed. Mind clear. Died in attack of suffocation. Duration, two years and three months. | Fibroma, size hazelnut, under pia mater. Between fourth and fifth cervical vertebrae. | Bernhuber, <i>Deutsch. Klin.</i> , Berlin, 1853, v. 406. |
| 13 | M. 16. | Restlessness. Cramps in pharynx on swallowing. Excitability. Delirium. Hallucination. Pain in the neck. On touching neck general cramps. Grimaces. Salivation. In three days complete paraplegia. No fever. Sudden change. Pulse 120. Pupils alternating. Blepharospasm. Irregular respiration. Pulmonary œdema. Suspicion of hydrophobia, because patient had been with hydrophobic dog; when offered coffee had symptoms simulating rabies. | Sarcoma. Extending from fifth to seventh cervical nerve on antero-lateral face of cord, compressing left half and penetrating into right half, so that anterior longitudinal fissure described arc of circle around it. | Adamkiewicz, <i>Arch. de Neurol.</i> , Paris, 1882, iv. 323-336, 1 pl. |
| 14 | F. | Paresis and partial anesthesia in all limbs for many months, most marked on left side. Brain and special senses unaffected. Had a tumor at bottom of right side of neck. Extensive bed-sore. | Carcinoma. Tumor caused partial absorption of sixth cervical vertebra. Cord compressed and twisted. Right lateral aspect especially affected. Cord atrophied. At level of sixth cervical vertebra. | J. W. Ogle, <i>Tr. Path. Soc. Lond.</i> , 1885, 6, vii. 40, 41. |
| 15 | F. 34. | Pain in right foot, and paresis increasing to paraplegia. Paresis of arms. Contractures of legs. Hyperesthesia in both legs up to crest of ilia. Later, great pain; paralysis of sphincters. Bed-sores. | Sarcoma, growing from dura mater; nerves passing through and over tumor. Cord congested and pushed to one side. Thin, but not softened. Growth resembled psammoma. Between sixth and seventh cervical nerves of left side. | T. Whipple, <i>Tr. Path. Soc. Lond.</i> , 1873, xxiv. 15-19. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Path. Anat. and Location. | Remarks. |
|-----|--------------|--|---|--|
| 16 | M. 57. | Pain in right arm. Numbness in hand, and paresis. Paresis and coldness of left leg. Some anaesthesia and wasting of right leg. Later, paraplegia. Diminished reflexes. Contractures. Constriction sense about legs and abdomen. Triceps, deltoid, and serratus magnus of right side paralyzed. Incontinence of urine, difficult defecation, decubitus, fever. Abdominal muscles paralyzed. Later, other muscles of arms paralyzed. Complete anaesthesia of legs. Dyspnoea, cedema of lungs. | Myxoma from arachnoid. Cord compressed and softened on right postero-lateral side. Secondary degeneration. Some cedema of brain. At sixth and seventh cervical vertebra on postero-lateral surface of cord. | Pel (P. K.), <i>Berlin Klin. Wochensh.</i> , 1876, xiii.461-463. |
| 17 | F. 35. | First, pain in right arm, weakness in right hand. Then paralysis almost complete in arms, and impaired sensation. In legs paralysis complete, sensation impaired. Alternate incontinence and dysuria. Ankle clonus and increased knee-jerks and plantar reflex. Tapping biceps causes reflex in little and ring fingers. No atrophy or bed-sores. Cold on one side, hot on other. Pain and little swelling over sixth cervical vertebra. No eye symptoms. Brain clear. Inability to turn head. Before death respiratory paralysis and bed-sores. Duration, fifteen months. | Spindle-cell sarcoma, springing from arachnoid and destroying cord by pressure, except posterior columns. Cord below tumor soft. At sixth cervical vertebra. | E. Long Fox, <i>Bris. Med.-Chir. Journ.</i> , 1883, i, 100-106, 2 pl. |
| 18 | M. 50. | Paresis in right arm. Stiffness in neck and back. Paralysis of all extremities gradually developed. | Glioma in right half of cord. Old hemorrhages in adjacent parts and in medulla oblongata. A more recent hemorrhage in dorsal cord. In lower cervical region. | Schneepel, <i>Arch. d. Heilk.</i> , viii. Bd., 1867 (quoted by Rosenthal). |
| 19 | | Coldness, numbness, violent pains, first in left arm, later in both legs. Paralysis of all limbs and muscles of trunk. Atrophy. Reactions of degeneration. Violent leg reflexes. | Tubercle, large as hazelnut. Consecutive myelitis of adjacent parts and left anterior horn. In lower cervical region. | Chvostek, <i>Med. Press</i> , 33-39, 1873 (quoted by Rosenthal). |
| 20 | M. 45. | Interscapular pain. Chest-pressure and dyspnoea. Paraesthesia and pain in legs. Spastic paralysis. Difficulty in stools; bloody urine and dysuria. Cedema of legs. Bed-sores. Kypho-scoliosis. Pain on pressure over spine. Paralysis of left leg, paresis of right, some anaesthesia of both. Broncho-pneumonia, fever. | Phlegmon of dura mater, compressing cord. Some infiltration of tissues of throat and mediastinal space. From seventh cervical to second dorsal vertebra. | Mankopff (E.), <i>Berl. Klin. Wochensh.</i> , 1864, i. 33-46, 58, 65, 78. |
| 21 | M. 22. | Pain in back and side of neck and in limbs. Marked pain in sternal region on coughing. Pressure and jarring cause pain. Rapid loss of power in both arms. Feeble and slow movements of thighs, legs, and feet. Right deltoid and flexors of fingers much wasted. No paralysis of face. Knee-jerks exaggerated. Later, complete paralysis, including bladder and rectum. | Tumor of membrane. Cord beneath compressed and degenerated. Lower cervical and upper dorsal region. | H. C. Wood, "Proceedings of Philadelphia Neurological Society," <i>Medical News</i> , vol. xlviii. No. 9, Feb. 27, 1886. |
| 22 | F. 50. | Pain in neck, shoulders, and chest. Stiffness of neck, back, and arms. Chest fixed; breathing diaphragmatic. No paralysis or altered sensation. | Secondary cancer of vertebrae. Cervical region. | Gull, by Wilks, in <i>Lect. on Dis. of Nerv. System</i> . |
| 23 | F. 40. | Severe pain in back. At height complete paralysis in legs, some paresis in arms. Variable anaesthesia. Girdle sensation and mammary pain. Lively and distressing reflexes. Contractures in legs. Bed-sores and paralysis of sphincter of bladder. Toward close rigors (pyæmia?). | Fibro-cyst on right side, between cord and dura, and between anterior and posterior nerves. Top of dorsal region. | Risdon Bennett, <i>Tr. Path. Soc. Lond.</i> , 1855-56, vii. 41-45. |
| 24 | M. 30. | Cough, dyspnoea, wasting, simulating phthisis. Pain in back of neck and shoulders. Pain in joints; paresis of legs and bladder. Pain in chest. Paresis of arms. Later, increased paralysis, bed-sores, sweating. | Tumor, size of hazelnut, inner anterior surface of dura mater. Flattening and softening of cord. Top of dorsal region. | Gull, in <i>Guy's Hosp. Rep.</i> (quoted by Wilks in <i>Lectures on Dis. Nerv. Syst.</i> , p. 264). |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Path. Anat. and Location. | Remarks. |
|-----|--------------|--|--|---|
| 25 | F. 43. | Pain in shoulders, chest, and sides. Contractures of legs; heels to nates. No anæsthesia. Later, retention of urine and bed-sores. Incessant pain in back and abdomen. | Fibro-nucleated tumor from inner surface of dura mater. Opposite third dorsal vertebra. | Gull, by Wilks, <i>ibid.</i> |
| 26 | F. 43. | Pain in chest and shoulder, then in legs. Paresis of legs. Contractures and jerking of legs. Spasm of abdominal muscles. No anæsthesia. Paresis of bladder and rectum. Wasting and bed-sores. Finally, paresis increased, but never complete paralysis. Duration, nine months. | Fibro-nucleated tumor, size of a bean, from dura mater. Cord compressed backward, and softened. Opposite third dorsal vertebra. | Wilks, <i>Trans. Path. Soc. Lond.</i> , 1855-56, vii. 37-40. |
| 27 | M. 24. | Paraplegia. Depressed reflexes; girdle symptom. Partial anæsthesia. Dysuria. Vomiting. Pulse weak and intermittent. Partial recovery from paralysis, and anæsthesia in left leg, and reflexes in right foot regained. Later, complete paraplegia, anæsthesia, and bed-sores. Duration, five months. | Probable gumma. Middle dorsal region. | B. G. McDowell, <i>M. D., Dubl. Q. J. Med. Sci.</i> , 1861, xxxii. 299-303. |
| 28 | F. 44. | Paresis in legs. Spine hypersensitive and inflexible; least attempt at bending causes great cervico-brachial pain. Paræsthesia; sense of falling out of abdominal viscera through abdominal walls. Pains in extremities increasing, and involving right shoulder, intercostals on both sides, and lumbar region. Paralysis of right arm (first); complete paralysis of leg. Excessive spinal tenderness. Loss of sensation (partial) in legs, body, and right arm. Later, dyspnoea, then dysuria, then complete inability to empty bowels or bladder. Great tympanites. Girdle sense above umbilicus, and finally complete paralysis and anæsthesia below this band. Sense of twisting of legs and feet, so that latter seemed close to face. Œdema. Later, paresis of left arm. One small bed-sore. | Alveolar sarcoma. Eighth and ninth dorsal vertebrae. | G. W. H. Kemper, <i>Journ. Nerv. and Ment. Dis.</i> , xii. No. 1, Jan., 1885. |
| 29 | F. 42. | Projection of seventh, eighth, ninth, tenth, and eleventh dorsal vertebrae. Numbness below ankles, and early girdle sensation. Peronei and anterior tibial muscles first involved; then all leg-muscles, then sphincters, then arms. Died in a fit. | Round-celled sarcoma. The anterior columns soft opposite tumor. Bodies of seventh, eighth, ninth, and tenth vertebrae soft. Opposite seventh, eighth, ninth, and tenth dorsal vertebrae. | E. Long Fox, <i>Brit. Med. Journ.</i> , 1871, p. 566. |
| 30 | F. —. | Ill-defined hemiplegia; later, paraplegia, with contractures and rigidity. | Gumma and syringomyelus. Small cavities in anterior cornua. At ninth dorsal vertebra anterior aspect. | Taylor, <i>Lancet</i> , 1883, p. 685. |
| 31 | M. 7. | Paraplegia, except adductors and rotators of thigh. Reflex contractures; most intense from irritation of penis and scrotum. Rigidity of legs. Complete anæsthesia of lower half of body. Later, anuria, incontinence of feces. Anal sphincter reflex; figured stools. Cystitis. Pain on percussion in dorsal region. Pain in back. Complete paraplegia. Very late, brain symptoms. Duration, nine months. | Tubercle (?). Cord soft for two inches. Tenth dorsal vertebra. | Geoghegan, <i>Dublin Med. Press</i> , 1848, xix. 148-151. |
| 32 | F. 46. | Fixed pain in left iliac region. Paresis in left leg, increasing to paraplegia. Formication. Girdle sensation. Incomplete, increasing to complete, anæsthesia of legs. Spontaneous twitchings. Bladder and sphincter ani paralyzed. Bed-sores. Duration, one year. | Fibroma (?) from inner surface of dura. Cord hollowed out and softened. Interval between tenth and eleventh dorsal vertebrae. | William Cayley, <i>Tr. Path. Soc. Lond.</i> , 1864-65, vol. xvi. 21-23. |
| 33 | M. 30. | Hyperæsthesia; later, anæsthesia in legs; then complete paraplegia. | Tubercle size of pea. Adjacent myelitis. In lower dorsal region. | Chvostek, <i>Med. Presse</i> , 33-39, 1873 (quoted by Rosenthal). |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Path. Anat. and Location. | Remarks. |
|-----|--------------|--|---|--|
| 34 | M. 31. | Ataxia; stiffness of legs and cramps in abdomen and legs. Slight nystagmus. Difficulty in forming words. Ataxia of arms. Slight wasting of legs, especially of left. Lumbar pains; abdominal cramps. Dysuria. Impotence. Later, increased spastic state of legs. Mind depressed and emotional; attempts at suicide. Anuria. Bed-sores. Urine albuminous. Duration, one year. | Myxoma of dura mater 3 inches long. Dura mater of brain contained fluid and lymph. Dorsal region, left side. | Shearman, <i>Lond. Lancet</i> , vol. ii. 1877, p. 161. |
| 35 | F. 50. | Pains in limbs (thought to be rheumatic). Paresis in legs. Hyperæsthesia in right leg; burning pains alternating with sense of coldness. | Cancer of vertebrae (sarcoma?). Dorsal region. | Gull, by Wilks, <i>Dis. Nerv. Syst.</i> |
| 36 | F. 35. | Paresis of left leg; soon of right leg. Pain in back and left side. Tonic spasms of legs. Darting pains in knees. Partial anæsthesia. Exalted plantar reflexes. Dysuria. Later, complete paraplegia and anæsthesia; violent reflexes; severe pain in back. Bed-sores. Duration, seven and a half years. | Tumor, osseous or fibrous, three-fourths of an inch long, growing from dura mater. Cord flattened, and softened below tumor. Lower part of dorsal cord. | H. Ewen, <i>Tr. Path. Soc. Lond.</i> , 1848-50, i. 179. |
| 37 | F. 28. | Weakness in legs. Aching and shooting pains in legs. Numbness and formication. Slight spasm in legs. "Felt as if ground was some distance below feet." Oedema of ankles. Later, numbness extended to abdomen. Paralysis of bladder. Hyperæsthesia in right leg. Obstinate constipation. Bed-sores. Some paralysis of respiratory muscles. Duration, fourteen months. | Tubercle the size of cherry, which had almost obliterated cord. Tubercles in lungs, bowels, and uterus. Bed-sore had opened spinal canal. Lower part of dorsal cord. | S. O. Habershon, M.D., <i>Guy's Hosp. Rep.</i> , London, 1872, 3d S., xvii. 428-436. |
| 38 | M. 63. | Progressive paresis of left leg for five years. Right leg then paretic. Paralysis then in left leg. Rigidity on extension of right leg. Paroxysms of clonic spasms in right leg. Joint pains, sciatic pains. In left leg, hyperæsthesia. In right leg, anæsthesia. Plantar reflex retained; other reflexes exaggerated. Diplegic contractions in right leg from irritation in left. Late symptoms: purulent urine, with retention; chest and lumbar pains like bone pain; extension changed to flexion; swelling of legs and ecchymosis; sacral and other eschars. | Psamomma adherent to dura mater. Cord softened. Ascending degeneration in posterior columns, and descending degeneration of lateral columns. In dorsal region just above lumbar enlargement, anterior left side. | Charcot, <i>Arch. de Physiol.</i> , Paris, 1869, ii. 291-296. |
| 39 | M. 20. | Paralysis of lower extremities; tremor; exaggerated reflexes, hyperæsthesia of trunk; bed-sores. Oedema of feet. Fever. Pus in urine. | Organized blood-clot exterior to dura mater. Cord compressed and softened. Opposite lower dorsal and upper lumbar. | C. B. Nancrede, <i>Am. Journ. Med. Sci.</i> , O. S., lxi. 156. |
| 40 | F. 38. | Pain around abdomen, in back, and legs. Paraplegia. Anæsthesia and tingling of feet and legs. Paralysis of bladder. | Hydatid cysts of vertebrae(?) and spin. canal. Lower part of spinal canal (probably lumbar region). | S. Wilks, <i>Dis. Nerv. Syst.</i> , p. 265. |
| 41 | F. 23. | Bronzing of skin for two years; then headache, giddiness, fever. Choreic movements in left arm, then in leg, then general. Bronzing increased. Vomiting after meals. Duration, two years and two months. | Tumor, consisting of granular matter, with a few nerve-fibres and cells, springing from centre of cord backward to posterior fissure. Cord slightly widened. Suprarenal capsules large and nodulated. Lumbar enlargement. | W. H. Broadbent, <i>Trans. Path. Soc. Lond.</i> , 1861-62, viii. 246. |
| 42 | 10 ms. | Twitching and convulsive movements of right leg. After removal of exterior tumor the movements ceased. Child died of peritonitis. | Tumor outside of sacrum, and also protruding through sacral opening. Reported to have been behind and pressing upon cord (?). Fatty growth within membranes. | Arthur Johnson, <i>ibid.</i> , 1856-57, viii. 28, 29. |

TABLE (continued).

| No. | Sex and Age. | Clinical History. | Path. Anat. and Location. | Remarks. |
|-----|--------------|---|--|--|
| 43 | F. 54. | Paresis, first of left arm and leg; then paralysis of these and of right arm and leg. Pain in back and hips early; then, suddenly, darting pains and incontinence of urine. Paræsthesia of left arm and leg; no anæsthesia. Coma. | Hydatid cyst. Cyst also in liver. Fluid beneath membranes of cord and brain. At first and second left sacral foramen, opposite last lumbar and upper three sacral vertebrae. | H. S. Wood, <i>Australian Med. Journ.</i> , 1879, N. S., i. 222. |
| 44 | M. 46. | Fibrillary twitching. Increased patellar reflexes. Paræsthesia and hyperæsthesia in legs, disappearing. Constriction of chest (?). Headache. Dysuria for two years. Straining at stool. Indigestion. Bloody vomiting. Cardiac palpitation; intracardial murmurs; slow pulse. Swollen inguinal glands. Variations in temperature. Bed-sores. | Glioma. At filum terminale, upper part. | Lachman, <i>Arch. f. Psychiat.</i> , Berl., 1882, xiii. 50-62, 1 pl. |
| 45 | M. 38. | Pain in legs. Oedema. After two years could not lie down; rested on hands and knees. Paralyzed in legs; pain in seat. Anæsthesia in legs, not complete in right. Paræsthesia in left. Dysuria and constipation. Before death had incontinence with hæmaturia, and was able to lie down. | A lobulated tumor from pia mater at lower end of spinal canal, surrounded by nerves of cauda equina. Structure not made out. At cauda equina. | W. W. Fisher, <i>Tr. Prov. M. and S. Ass.</i> , 1882, x. 203-208. |
| 46 | | This case had symptoms of posterior spinal sclerosis, which possibly had no relation to growth, according to reporter. | Myo-lipoma attached to conus medullaris. Crescentic, clasping cord from anterior to posterior fissure. Nerve-roots of cauda equina imbedded in it. Contained striated muscular fibres. | W. R. Gowers, <i>Tr. Path. Soc. Lond.</i> , 1875-76, xxvii. 19-22. |
| 47 | Und. 1 yr. | Spina bifida (?); hydrocephalus; convulsions, bloody stools; partial paraplegia. (Above symptoms came on after closing of sacral opening by surgical operation.) | Congenital sacral neuroma amylinicum. | W. F. Jenks, M.D., <i>Trans. Path. Soc. Philada.</i> (1871-73), 1874, iv. 190-192. |
| 48 | M. 30. | Pain in back; abdominal girdle sensation. Pain in legs; paraplegia; nearly complete anæsthesia; paralysis of bladder; bed-sores. | Aneurism, eroding vert. and compressing cord. Location not given. | Wilks, <i>Dis. Nerv. Syst.</i> |
| 49 | M. 54. | Paralysis of both legs, of sphincter ani, and of bladder; urine alkaline, with pus and blood. Partial anæsthesia. Pyonephritis. | Gumma from inner layer of dura mater and involving pia mater. Location not given. | Delafield, <i>N. Y. Med. Rec.</i> , 1875, x. 131. |
| 50 | Still-born. | | Tumor, size of head of child two years old, projected between legs from spinal column. Nerves of cauda equina over anterior part. Some bone in tumor (dermoid cyst?). | Virchow, <i>Monatsschr. f. Geburtshk.</i> , Berl., 1857, ix. 259-262. |

INFANTILE SPINAL PARALYSIS.

By MARY P. JACOBI, M. D.

SYNONYMS.—Essential paralysis of childhood (Riliet and Barthez); Myogenic paralysis (Bouchut); Acute fatty atrophic paralysis (Duchenne); Atrophic paralysis (Ferrier); Acute anterior poliomyelitis (Kussmaul, Erb, Seguin); Regressive paralysis (Barlow); Tephromyelitis (Charcot).

DEFINITION.—Of all the titles which have been given to the disease it is our purpose to describe, two alone may be considered irreproachable. In the present state of our knowledge it is unnecessary to argue that this disease is not essential—*i. e.* destitute of characteristic anatomical lesions. Neither can the theory of its myogenic origin be maintained; nor even is fatty degeneration invariably present in the paralyzed muscles. Finally, the disease cannot longer be regarded as peculiar to childhood,¹ since cases in adults have been in these last years quite numerously reported²—four with autopsies demonstrating the identity of the lesion. But there are two definitions in our list of synonyms which embrace between them the most striking characteristics of the disease, yet contain no error of fact. Atrophic paralysis describes at once the two most salient symptoms; acute anterior poliomyelitis defines at once the seat and nature

¹ W. H. Barlow, *On Regressive Paralysis*, 1828. See *Brain*, April, 1879.

² In Dec., 1873, I quoted 14 cases of adult spinal paralysis, as follows: Duchenne, 4 cases; Charcot and Petitfils, 3; Moritz Meyer, 2; Bernhardt (*Archiv Psych.*, 1873), 1; Cumming (*Dublin Quart. Journ.*, 1869), 1; Lucas Championnière (by Hallopeau, *Archives gén.*, 1861), autopsy, 1; Gombault (*Archives de Psych.*, 1873), 1; personal, 1.

In 1874, Seguin published a summary of all the foregoing cases except the last, and added 6 personal observations, also 3 from Duchenne and 1 from Hammond. In the enlarged edition of his essay in 1877, Séguin increased the list to 45—by new personal cases, 3; cases related by Frey (*Berlin. Wochens.*, 1874), 4; cases by Erb (*Arch. f. Psych. u. Nervenkrank.*, v.), 4; case by Cornil and Lépine (*Gaz. méd.*, 1875), autopsy, 1; case by Soulier (*Lyon méd.*, 1875), 1; case by D. H. Lincoln (*Boston Med. and Surg. Journ.*, 1875), 1; case by Lemoine (*Lyon méd.*, 1875), 1; case by George M. Beard, 1; case by Leyden (*Klinik Rückenmarks Krankheiten*) Bd. iv. 1; case by Hammond (6th ed. *Treatise*), 4; case by Courty (*Gaz. méd.*, 1876), 1; case by Dejerine (*Arch. de Phys.*, 1876), 1.

To these may be added—case by Goltdammer (*Berl. klin. Wochens.*, 1876), 1; case by Webber (*Trans. Amer. Neurol. Ass.* for 1875, vol. i.), autopsy, 1; case by Klose (*Diss. Breslau*, 1876), 1; case by Schultze (*Virchow's Archiv*, Bd. lxxviii.; also Bd. lxxiii.), autopsy, 1; case by Bernhardt (*Archiv für Psych.*, Bd. ix., 1879); case by Sinkler (*Amer. Journ. Med. Sci.*, Oct., 1878), 5; case by Althaus (*ibid.*, April, 1878), 2; case by Ross (*Dis. Nerv. Syst.*, vol. ii. p. 139), 1—total, 57 cases.

Morton (*St. Bartholomew's Hospital Reports*).

Others have doubtless been published since this date, but, as they do not immediately concern our subject, need no further citation.

of the lesion, classes it with the systematic diseases¹ of the spinal cord, and notes the peculiarity in the mode of invasion by which it is so remarkably distinguished from nearly all the organic diseases of this centre.

SUMMARY OF CLINICAL HISTORY.—The clinical features of an acute attack of infantile paralysis are well known. The children affected are usually between eighteen months and four years of age (Henoch). The attack is more likely to occur in summer than in winter, as Sinkler² found that 47 out of 57 cases began between May and September, and Barlow noted 27 out of 53 in July and August.³

The onset of the paralysis is either really sudden, occurring in the daytime, while the child is under competent observation, or apparently sudden, being discovered in the morning after a quiet night, the child having gone to bed in health (West); or is preceded by some hours or days of fever or of nervous symptoms, especially convulsions, or both. The paralysis is almost always at its maximum of extent and intensity when first discovered, and from this maximum begins, within a few hours or days, to retrocede. The improvement may, however, be delayed much longer. A variable number of muscles remain permanently paralyzed, and in these, within a week (thirty-six hours, according to some observers), faradic contractility is first diminished, then abolished; galvanic reaction is exaggerated, ultimately is characterized by the degeneration signs (entartungs reaction). The temperature of the paralyzed limbs falls; the muscles waste; the atrophy may rapidly become extreme. The paralysis and loss of faradic contractility are complete, however, while the atrophy is only incipient and progressing. The absence of lesions of sensibility, of visceral disturbance, of trophic lesions of the skin, or of sphincter paralysis is as characteristic of the disease as are the positive symptoms above enumerated.

In the third or chronic stage the paralyzed limbs often become contracted and deformed. At other times, and with more complete paralysis, the growth of the bones is arrested, the muscles remain flaccid, the entire limb shrivels, and dangles so loosely from its articulations that it may be dislocated by slight effort (*membre de Polichinelle*). The general health of the patient remains remarkably good, the intelligence clear, the disposition lively. The duration of life seems to be in nowise shortened by the paralysis. Thus, suddenness of development, intimate association of trophic, motor, and electrical disturbance, absence of cerebral or sensory lesion, peculiar localization and grouping of the permanent paralyses, —such are the salient characteristics of this remarkable disease.

SYMPTOMS IN DETAIL.—Three well-defined stages exist—the initial, the paralytic, and the chronic.

¹ Vulpian, *Leçons sur les Myelitis*, 1880.

² *Amer. Journ. Med. Sci.*, April, 1875.

³ *Loc. cit.*, p. 75. Among Sinkler's 57 cases, only 6 furnish autopsies, thus:

Case by Cornil and Lepine and case by Webber (quoted and accepted by Erb in *Ziemssen's Handbuch*, Bd. xi.); case by Gombault (rejected by Erb and Westphal); case by Schultze; cases by Dejerine and Lucas Championnière (quoted by Hallopeau).

The influence of heat is perhaps shown in the case related by Dyce-Duckworth in the *Lancet* of 1877: a child two and a half years, after exposure to great heat on a steamboat-landing, became paralyzed in all four limbs, but the paralysis was subsequently confined to the lower extremities. Coincidentally, the patient became delirious; suffered from anæsthesia and temporary paralysis of the sphincters. The paralyzed muscles wasted rapidly and lost faradic contractility. Treatment by faradization was begun in a month from the date of the attack, and recovery was complete three months later.

Initial Stage.—Seeligmüller¹ signalizes three principal varieties in this stage. The first is characterized by fever; the second by nervous symptoms, principally convulsions, sometimes delirium or coma; in the third no symptoms either precede or accompany the local disease—"la paralysie est toute la maladie."²

Mode of Invasion.—I have elsewhere³ described eight different modes of invasion: absolutely sudden, coming on in the daytime; morning paralysis (West), discovered after a quiet night, preceded by fever or by vomiting alone (?), or by another typical disease, especially one of the exanthemata, or, finally, by a traumatism, generally slight. An interval of time almost always elapses between the occurrence of the traumatism and the development of the paralysis—a fact which already indicates that a definitely-evolved morbid process must intervene between the two occurrences. An exception is related by Duchenne fils;⁴ and some apparent exceptions, in which recovery occurred rapidly, seem to belong to the temporary paralysis of Kennedy,⁵ more recently described again by Frey.⁶

PRODROMATA.—There is rarely any lengthened period of prodromata. Seeligmüller has noticed in some cases an indisposition on the part of the child to stand or walk during several weeks before the occurrence of the paralysis. He does not say whether such children were rachitical. In marked contrast with cases of cerebral paralysis is the habitual absence of generalized nervous symptoms. Thus in only 1 case of Seeligmüller's (total of 75) did the child suffer, and that during six months preceding the paralysis, from intermittent muscular contractions, and also from attacks of laryngismus stridulus.

The fever is usually of moderate severity (Seeligmüller), but sometimes extremely high (Erb)⁷—as much as 41° C. (Henoch),⁸ or 104° F. (Barlow).⁹ Duchenne fils observed 7 cases alleged to be entirely without fever, and Laborde counts 10 cases out of 50 as apyretic.¹⁰

The duration of the fever usually varies from a single night to forty-eight hours; much more rarely does it last six, eight, twelve, or fourteen days, or even, but quite exceptionally, three or four weeks. According to Duchenne, its intensity and duration increase with the age of the child, perhaps indicating greater resistance on the part of the nerve-tissues which are the seat of the morbid process of which it is symptomatic. Rarely does it last after the paralysis has once occurred,

² *Rilliet et Barthez, Traité des Maladies des Enfants*, ii. p. 551.

³ *Am. Journ. Obstet.*, May, 1874.

⁴ *Archives gén.*, 1864. A father pulled his child from a table by the right arm, and set it rather roughly on the ground. Immediate pain, almost immediate paralysis of arm, which persisted, and was followed by atrophy of its muscles.

⁵ *Dublin Quarterly*, 1850.

⁶ *Berlin. klin. Wochens.*, 1874. Frey considers these cases to be identical in nature with, though differing in severity from, anterior poliomyelitis.

⁷ *Ziemssen's Handbuch*, Bd. xi. Abh. 12.

⁸ *Vorlesung. über Kinderkrank.*, 2d Aufl., 1881. Seeligmüller (*Jahrb. für Kinderheilk.*, 1878, p. 345) quotes another case from Henoch's clinic where the fever lasted thirty-six hours, the temperature on the first evening being 39.2°, the following morning 39.6°, the second evening 39.5°; the second morning, at which date the paralysis was discovered, it was normal. The author states this to be the only case known to him in which thermometric measurements were taken.

⁹ *Loc. cit.*

¹⁰ *De la Paralysie de l'Enfance.*

but ceases then with an abruptness which recalls the defervescence of pneumonia when the exudation process is once completed.¹

There is no proportion between the intensity of the fever and the extent of the subsequent paralysis; nor is there any marked contrast between the fever in children and that in adults in those rare cases in which the disease, instead of being subacute, is sudden as in children.

Erb considers the fever to be purely symptomatic of an inflammatory process in the spinal cord.² But Vogt regards it rather as an essential factor in the development of a spinal lesion, and thus explains the occurrence of this in the course of febrile diseases which at the outset have no special relation to the cord.

Convulsions, usually accompanied by fever, were observed in 11 of Seeligmüller's cases out of 67; Duchenne had 13 out of 70; Heine, 9 out of 86;³ thus a total of 33 cases of convulsions in 223 cases of infantile paralysis—nearly 15 per cent. The paralysis may set in after a single brief convulsion, or this may be repeated several times at variable intervals before the paralysis is definitely declared (Ross).⁴ The convulsive movements are apt to be particularly intense in the limbs destined to become paralyzed (Vogt).

The convulsion may be very slight—an isolated spasm of a limb or even a single group of muscles. Whether, on the other hand, it can ever be so intense that the child succumbs to it before the development of paralysis, is a question which could only be decided by repeatedly examining the cord in the cases of convulsion which have terminated fatally. In a case of Seeligmüller's the child was affected for eight days preceding the paralysis by tremblings generalized through all his muscles.

The convulsion is usually followed by a soporous or even comatose condition, or this may replace the convulsion. Delirium may take the place of either.

Special interest attaches to those cases where the paralysis develops in the course of an acute specific disease; for then becomes most plausible the suggestion of Vogt, that a fever excited by some cause remote from the spinal cord may itself become a cause of lesion in this centre. In Roger's first and most celebrated case, paraplegia developed suddenly during the course of a fatal scarlatina in a child already suffering from paralysis of the left deltoid of two months' standing.⁵ The scarlatina was hemorrhagic, and, as will be shown farther on, the autopsy showed traces of a hemorrhagic extravasation in the cord. Thus a double influence was presumably exerted by the scarlatina, while, moreover, the previous and recent occurrence of a deltoid paralysis indicated a morbid predisposition in the spinal cord. Of Seeligmüller's 75 cases, 1 occurred during scarlet fever, 1 with measles, 1 in the course of an erysipelas, and 1 of pneumonia.

Apyretic diseases, especially of the gastro-intestinal tract (Brown-Séquard), also seem to have an influence on the development of infantile paralysis. Two of my own cases occurred during an attack of

¹ See p. 1144 for pathogenic inferences to be drawn from this fact. Seguin (*New York Med. Record*, Jan. 15, 1874) seems to throw some doubt on the existence of apyretic cases; but, as Seeligmüller remarks, there is too much testimony to this possibility to render it really doubtful.

² *Loc. cit.*, p. 279.

⁴ *Loc. cit.*, p. 107. The author is quoting Laborde.

³ *Die Spinale Kindertahmung.*

⁵ *Gaz. méd.*, 1871.

cholera infantum; another in a child who had been for several weeks in bed with a purulent conjunctivitis. Study of these varied antecedents is of interest in connection with the obscure question of the etiology of infantile paralysis. In this latter connection we will refer to them again.

Vomiting, or even the entire symptom-complex of gastric fever, not infrequently ushers in the paralysis. Fever is then usually present, but I have recorded one case of vomiting where, according to the mother's assurance, no fever at all existed.

At the moment that the symptoms of the invasion subside, and the child seems to enter upon convalescence, the terrifying discovery is made that an arm or a leg or all four limbs, or even they and the muscles of the trunk, are paralyzed.

In the severest form the child lies motionless, unable to stir hand or foot, or even a finger or toe. Yet, singularly enough, this extensive paralysis is sometimes overlooked, especially in very young children, as the immobility of the patient is attributed merely to weakness caused by previous illness. General paralysis, during at least the first few hours of the paralytic stage, is probably more common than appears from our present statistics. Not only, as has just been noted, may this condition be overlooked, but it may exist during the hours of sleep which precede the cases of morning paralysis. Seguin¹ speaks as if the paralysis were at first always generalized, but this statement seems to me somewhat exaggerated. Referring merely to the statements of the parents, a considerable number of paralysees would be found limited from the beginning. Heine's third table of partial paralysis is entirely composed of cases so limited. In 16 out of the 19 cases of hemiplegia (monoplegia) the original limitation of the paralysis is also specified; similarly with 7 out of the 20 cases of paraplegia contained in the first table.

Paralysis of one or both lower extremities is often first detected when the child gets out of bed and attempts to walk; or in children too young to walk the flaccid immobility of the limb attracts attention as soon as they are again carried on the mother's arm. Paralysis of the upper extremities is discovered early in proportion to the liveliness recovered by the child, leading him to occupy himself with his toys as usual. In unilateral paralysis of the trunk the child will fall over to one side when placed in the sitting position; in bilateral paralysis it cannot be made to sit up at all.

From lack of competent observation during the initial stage it is really not quite certain whether any degree of paresis precedes the paralysis; but from the testimony at present accumulated the paralysis is nearly always complete when first observed. This is in striking contrast with adult spinal paralysis. In some few cases the paralysis has been observed to creep on slowly, and not reach its maximum for several days (Ross). Laborde relates a case where recovery from a first attack of paralysis was followed by two relapses in the same limbs at intervals, each ushered in by fever. After the second relapse the paralysis remained permanent.

Significance of Original Extent of Paralysis.—The question of the

¹ *Ibid.*

original distribution of the paralysis is of special interest in connection with that of the original distribution of the morbid process in the spinal cord. The real effect of the latter cannot be adequately measured by the permanent paralyses; for, as will be seen, it is not unusual to find traces of an extensively diffused process in the cord in cases of quite partial paralysis.

It is interesting to notice that certain muscles are always exempt from paralysis. With the exception of a single case of paralysis of one temporal muscle, cited by Seguin,¹ the muscles of the head, eyeballs, ears, larynx, and pharynx are always exempt, as are also the diaphragm and intercostals. The arrest of the spinal lesion below the medulla explains the immunity of muscles supplied by the vagus and spinal accessory nerves. But since the cervical plexus is often involved, the constant escape of the diaphragm, innervated by the phrenic nerve which comes from this plexus, is remarkable. Still more so the immunity of the intercostal muscles, whose nerves arise in the dorsal region—a position of the cord frequently affected. This fact tends to confirm Ross's hypothesis, that the nuclei of the intercostal nerves lie in the vesicular columns of Clarke—columns confined to the dorsal region of the cord, and which are invariably found intact at autopsies of atrophic paralysis.

The immunity of these respiratory nerves explains the absence of the dyspnoea which is so marked in Landry's ascending paralysis. In the adult case described by Schultze and Erb² dyspnoea was present for a short time. The disease terminated fatally twenty months from the time of invasion. In this case traces of myelitis were found extending through the dorsal region of the cord, and including not only the anterior nerves, but, to a less degree, the columns of Clarke.

The facial nerve (itself a respiratory nerve) shares the immunity of the phrenic and intercostals. In the cases in which facial paralysis has been noted the limb paralysis has been hemiplegic, as in Seeligmüller's twentieth case. A cerebral origin is then always to be at least suspected.

Barlow³ has seen 6 cases of paralysis of the facial, but the histories render a cerebral paralysis more probable in 4 out of those 6. Henoch⁴ gives a case of paralysis of left arm, accompanied by paralysis of corresponding facial nerve. The latter rapidly recovered, but the paralysis of the arm persisted and was followed by atrophy. Ross⁵ implies that the sides of the neck, face, and tongue are always at first implicated in spinal hemiplegic paralysis, but do not remain permanently affected.

That the facial should be affected while the other medullary nerves escape probably depends on the more anterior position of its nucleus.

The regression of the original paralysis is characteristic, indeed almost pathognomonic, of the disease. It is on this account that Barlow has proposed the name regressive paralysis.⁶ This author quotes the case of a boy who at five months was affected with a universal paralysis, even affecting the neck, but entirely recovered except in the extensor longus digitorum of the foot. This improvement constitutes a second apparent convalescence, as deceptive as that which immediately succeeds the pyrexia. Only in rare cases do all the

³ *Loc. cit.*

⁶ *Brit. Med. Journ.*, 1882.

muscles at first paralyzed remain so permanently (Seeligmüller); nor, on the other hand, do all entirely recover (temporary paralysis of Kennedy and Frey). Even when an entire limb appears to be paralyzed, careful examination will usually detect certain muscles that retain their faradic contractility. Thus the order of frequency of paralysis in the different limbs must be distinguished from that observed for different muscles.

Duchenne fils¹ and Seeligmüller² have tabulated, for lists of 62 and 75 cases respectively, the general locality of the permanent paralyses in their order of frequency. The cases of monoplegia are by far the most numerous. Thus in the table quoted below there are 97; in Heine's tables (86 cases), 47; in Sinkler's tables (86 cases), 29—total, 173 from a total of 309, or nearly one-half:

| | Duchenne. | Seeligmüller. | Total. |
|---------------------------------------|-----------|---------------|--------|
| Left lower extremity | 7 | 27 | 34 |
| Right " " | 25 | 15 | 40 |
| Right upper " } | 10 | 13 { 9 4 | 23 |
| Left " " } | | | |
| All four extremities | 5 | 2 | 7 |
| Both upper " | 2 | 1 | 3 |
| Both lower " | 9 | 14 | 23 |
| Left over and under extremity | 1 | 1 | 2 |
| Right " " " | 0 | 1 | 1 |
| Right over and left under " | 2 | 1 | 3 |
| Muscles of trunk and abdomen . . . | 1 | 0 | 1 |
| | 62 | 75 | 137 |

This limitation is all the more noteworthy when compared with the frequency of general paralysis at the outset.

The next peculiarity is the great preponderance of paralysis of the lower over that of the upper extremities. This is noticeable even in the monoplegias. In Sinkler's cases only two of these affected an arm. But in bilateral paralysis the predilection is still more remarkable, paraplegia of the lower extremities being among the most frequent, paraplegia cervicalis the rarest, form of paralysis. This is not because a lesion situated in the cervical spinal cord must interfere with the motor tract going toward the lumbar, and hence nearly always paralyze all four extremities, if any. Because when this does happen the upper extremities alone exhibit the atrophic changes characteristic of anterior poliomyelitis: the lower, though paralyzed, do not atrophy and retain their faradic contractility. Heine denied the existence of paraplegia cervicalis. But in the table of Duchenne-Seeligmüller 3 cases are recorded; Rosenthal³ relates 1; Lockhart Clarke, 1.⁴ This is the somewhat famous case, described by Clarke as a progressive muscular atrophy, which contributed one of the earlier autopsies.

Seeligmüller's case⁵ is remarkable in several respects. The paralysis, occurring after a brief fever in a child seventeen months old, exclusively attacked the two arms at the moment of invasion, and never retreated from them, thus offering a double exception to the usual rule. At four years of age the arms were much atrophied, and faradic contractility was lost in their muscles, the legs being sturdily developed. Nevertheless,

⁴ *Med.-Chir. Trans.*, li. p. 219.

⁵ *Jahrbuch*, loc. cit., p. 349.

the child constantly fell in walking, because, observes Seeligmüller, he was unable to balance himself with his arms, as is habitual with little children learning to walk.

The hemiplegic variety of paralysis is again very rare. The Duchenne-Seeligmüller table contains (out of 137) 3 cases; Sinkler records (out of 86) 4; West, 5; Heine (out of 86), 1; Leyden, 1; Duchenne, 1. West's 5 cases all present certain peculiarities, at least unusual in spinal paralysis. In 2 the paralysis came out gradually; in 1 succeeded to remittent fever (pigmentary embolism?); in 1 was preceded by heaviness of the head for several days; and in 1 the leg was paralyzed fourteen days after the arm.¹ It is probable that in almost all, if not in all cases, hemiplegic spinal paralysis is the residue of a paralysis originally generalized to all four limbs, if only for a few hours.²

The question of hemiplegia is closely connected with that of paralysis of the facial nerve, inasmuch as the existence of the latter often serves to suggest a cerebral paralysis—a suggestion confirmed later by the absence of atrophy and of characteristic electrical reactions. However, in some cases of undoubted spinal paralysis the facial does really seem to have become involved. Thus in the case just quoted from Seeligmüller (Case 20 of his table) Henoch³ relates a case of paralysis of the left facial coinciding with paralysis of the left arm. Rapid recovery from facial paralysis: arm atrophied. Barlow⁴ records temporary facial paralysis in six cases, but only two of these seem to be really spinal. Such temporary paralysis is not altogether infrequent in the poliomyelitis anterior of adults (Sinkler, Seguin). Ross⁵ implies that the sides of the neck, face, and tongue are always implicated at first in hemiplegic spinal paralysis, but do not remain so.

Crossed paralysis is extremely rare. There are 3 cases in the Duchenne-Seeligmüller table; Leyden⁶ has one. But paraplegia of the lower extremities, coinciding with paralysis of one upper extremity, is by no means so rare, especially as a residual paralysis.

Finally, as in cerebral paralysis, the muscles of the trunk, though often paralyzed at the outset, rarely remain so in children—much more often in adults. Eulenburg⁷ relates one interesting case of complete paralysis and atrophy of the extensors of the back. Even the interspinous muscles were involved, as shown by the divergence of the spinous processes. The paralysis was observed in a girl of fifteen affected since the age of three, and was completely cured in five months by daily faradizations of ten minutes each, and two gymnastic séances, each lasting two hours.

¹ In three cases of hemiplegia observed by myself, and previously diagnosed as spinal paralysis by other physicians, I doubted the diagnosis from the coincidence of unusual cerebral symptoms. In the first case the hemiplegia appeared after coma, during cerebro-spinal meningitis; in the second, after a violent convulsion the face was drawn to the opposite side, and the patient, a child of seven, remained for a month in a state of intense maniacal excitement. In a third case, developed during convalescence from scarlet fever, the hemiplegia was preceded during two days by hemiparesis, and accompanied for a year by complete aphasia. Finally, in these cases faradic contractility persisted in the paralyzed limbs (*Am. Journ. Obstet.*, May, 1874).

² Seeligmüller relates one case where hemiplegia, including the facial nerve, was observed in two days from the beginning of the fever.

Birdsall¹ has described one case of unilateral paralysis of the abdominal muscles.

Study of the precise combinations of the muscles paralyzed has recently acquired peculiar interest in connection with the localization in the spinal cord of the motor or trophic nuclei of their nerves.² Several facts have been ascertained: 1st, that, in notable contrast with progressive muscular atrophy, atrophic paralysis tends to involve definite groups of muscles; 2d, that this grouping is not effected in accordance with the proximity to each other of the muscles on the limb, but with their functional association. Remak affirms that Charles Bell had already called attention to the fact that in cases of local muscular paralysis of the extremities the paralysis does not spread by muscular continuity, but in accordance with the functional association of muscles. Thus, paralysis of the thumb is more often associated with that of the forearm than with paralysis of the other muscles of the hand. 3d. From such grouping may often be inferred a different localization of certain nerve-nuclei than would be supposed from the position of the muscles alone. 4th. That the fibres contained in a single nerve-trunk, but distributed to different muscles, probably separate from each other within the cord, to be there distributed to variously-situated nuclei.³

In the arm two mutually correlative cases are observed: (a) Immunity of the supinator longus during paralysis of the forearm muscles; (b) paralysis of the supinator in association with paralysis of the deltoid, biceps, and brachialis anticus. The latter constitutes Remak's upper-arm type of localization, and is exhibited in his first case.⁴

Ferrier has experimentally confirmed this muscular association by means of isolated irritation of the fourth cervical nerve, which threw into contraction the supinator longus, together with the deltoid, biceps, and brachialis internus. At the same time, in the experiment the flexors and extensors of the wrist were excited, while in the special form of paralysis noted they were exempt. This electrical method is a less precise mode of analysis than the pathological, for the double reason that (a) fibres whose nuclei are dissociated may pass together in the same root; (b) because the same muscles receive fibres from more than one root: thus the flexors and extensors of the wrist from the fifth as well as the fourth cervical. Thus when the nucleus of the latter was destroyed paralysis would be averted by means of the fibres coming from the fifth root.

The experiment and the pathological observation, however, concur in indicating that the fibres innervating the supinator longus, though passing to it in the path afforded by the radial nerve, afterward ascend in the cord to a ganglionic nucleus in close proximity to those of the upper-arm muscles specified—liable, therefore, to be affected with them. The purpose effected by such association is the supination of the arm.

It is excitation of the fourth root in Ferrier's experiment which gives

¹ *Journal of Nervous Diseases*.

² Ernst Remak, "Localis. der Atroph. lahmung," *Archiv f. Psych.*, ix., 1879; Ferrier, *Brain*, vol. iv. No. 3; also, *Proceedings Royal Society*, No. 212, p. 12.

³ The theory of course assumes the truth of the demonstration by which atrophic paralysis is rendered symptomatic of disease of the spinal cord, and the nutrition of a muscle dependent on the integrity of the muscles of origin of its nerves.

⁴ *Loc. cit.*; also, cases 1st and 2d by Ferrier, in which, however, other shoulder-muscles were involved.

results most closely corresponding to Remak's observations. Excitations of the fifth and sixth root reveal other combinations, which Ferrier has found realized in adult's spinal paralysis. Thus in his second case, in addition to the group of muscles already mentioned, the rhomboid, infraspinatus, and serratus magnus were paralyzed, the last muscle indicating complication with the fifth root. In the third and fourth cases muscles supplied from the sixth root were joined to those innervated by the fourth and fifth—namely, the pectoralis major and latissimus dorsi.

In this upper-arm type the muscles affected are supplied by three different nerve-stems—the axillary, musculo-cutaneous, and the radial. In the forearm type the most common variety consists in paralysis of the extensors of the wrist, thus exactly imitating lead palsy.¹ The supinator remains intact, the intrinsic muscles of the hand are sometimes intact, sometimes paralyzed. Sometimes, however, the extensors are relatively intact; the interossei are atrophied, and a clawed hand, resembling that characteristic of cervical hypertrophic pachymeningitis, is developed.²

The much greater frequency of extensor paralysis in the forearm type of anterior poliomyelitis indicates that the lesion of this disease begins about the middle of the cervical enlargement (see note).

The foregoing groupings have been made out almost entirely from cases of adult spinal paralysis or else of lead palsy. In the lower extremity it is much more difficult to establish such definite muscular association. Certain laws, however, can be made out: 1st. The liability to paralysis increases from the thigh toward the foot; thus, the muscles moving the thigh on the pelvis are the least liable to paralysis, then those moving the leg on the thigh, while the muscles moving the foot and leg and thigh are the most frequently paralyzed of any in the body. 2d. Of the upper thigh-muscles, the glutei are not infrequently paralyzed, the ilio-psoas hardly ever, the adductors rarely except in total paralysis. 3d. Of the muscles moving the leg on the thigh, the quadriceps extensor is very frequently paralyzed—the most often, indeed, after the foot-muscles: the sartorius is almost always exempt; the liability of the hamstring muscles corresponds to that of the thigh adductors. 4th. At the foot the tibialis anticus often suffers from isolated paralysis, sharing in this respect the fate of the deltoid in the upper extremity—a fact already noticed by Duchenne. On the other hand, (5th) the tibialis anticus often remains intact while the other muscles supplied by the perineal nerve, the perineus longus and brevis, are completely paralyzed.³

The remarkable contrast in the morbid susceptibility of the quadriceps on the one hand, and the sartorius on the other, suggests dissociations of their nuclei. Remak relates one interesting case (Obs. 13) where the

¹ It is on this fact, indeed, that Remak has been led to argue the spinal nature of saturnine paralysis ("Zur Pathogenie der Blei lähmung," *Archiv für Psych.*, Bd. vi., 1876).

² The march of this disease, together with that of tabes dorsalis, furnishes data for localizing the nervous nucleus for the wrist extensors. In both diseases the lesion is ascending: in tabes disturbance of sensibility occurs first in the distribution of the sensory fibres of the ulnar nerve; in cervical pachymeningitis the flexors and intrinsic muscles of the hand are first paralyzed. Hence it is to be inferred that the central nucleus for the latter muscles lies in the lower, that for the extensor muscles in the middle, segment of the cervical enlargement of the cord.

³ Thus Buzzard relates a case of paralysis involving the quadriceps extensor and peroneal muscles, while the anterior tibial were intact.

sartorius was paralyzed—coincidentally with the quadriceps, it is true, but also with partial paralysis of the ilio-psoas muscle, which is as rarely attacked as the sartorius itself. The two facts, taken together, would indicate that the nucleus of the sartorius lies high in the lumbar enlargement, in proximity to that of the ileo-psoas. The inference, continues Remak, is reinforced by functional considerations, since the sartorius, obliquely flexing the leg on the thigh, is generally in action at the moment that the psoas flexes the thigh on the pelvis.

Again: according to Remak the tibialis anticus is generally paralyzed together with the quadriceps extensor, although supplied by a different nerve.¹ And this should be expected from the necessity of exciting dorsal flexion of the foot by means of the tibialis anticus at the moment of extending the leg for the act of walking.²

Ferrier, from his experiments on the roots of the lumbar plexus, is inclined to doubt this association of the tibialis anticus with the quadriceps, and he adduces Buzzard's case, already quoted, to show coincident paralysis of the quadriceps and peroneal muscles. It is not improbable, however, that fibres associated together in nerve-roots may again diverge in the cord, and thus the discrepancy would be explained.

DIAGNOSIS OF SPECIAL PARALYSIS.—Paralysis of isolated muscles may sometimes be concealed by the vicarious action of their synergists: thus of the extensor communis for the tibialis anticus. Paralysis of both legs and feet may even be partly concealed by the energy of the thigh-muscles, which, using the paralyzed segments of the limbs as inert supports, succeeds in effecting locomotion.³ On the other hand, in limbs apparently abandoned to total paralysis persevering search will often discover some muscles or parts of muscles which respond to faradic electricity: these must be considered as susceptible of ultimate recovery.

The following table sums up some special diagnostic marks for the different paralyses⁴ afforded by the position of the limb and loss of movements:

- Upper Extremity. Deltoid. Absence of deformity, which is averted by weight of arm. Inability to raise arm. Sometimes subluxation. Frequent association with paralysis, biceps, brachialis anticus, and supinator longus.
- Lower Extremity. Ilio-psoas. Rare except with total paralysis. Associated with paralysis, sartorius. Loss of flexion of thigh. Limb extended (if glutæi intact).
- Glutæi. Thigh adducted. Outward rotation lost. Lordosis on standing. Frequent association with paralysis of extensors of back.
- Quadriceps extensor. Flexion and adducting of leg (if hamstrings intact). Loss of extension of leg. Frequent association with paralysis of tibialis anticus.
- Tibialis anticus. Often concealed if extensor communis intact. If both paralyzed, then fall of point of foot in equinus. Dragging point of foot on ground in walking. Big toe in dorsal flexion (if extensor pollicis intact). The tendons prominent. Hollow sole of foot (if perineus longus intact).
- Extensor communis. Nearly always associated with that of tibialis anticus. Toes in forced flexion.
- Peroneus longus. Sole of foot flattened. Point turned inward. Internal border elevated.

¹ Obs. 14, 15, 16, 17, from Remak's essay.

² At the moment that the foot is thus flexed, however, to allow the leg to be swung forward, the thigh and leg are both slightly flexed.

³ Thus in Cornil's famous case, *Soc. Biol.*, 1863.

⁴ See Duchenne, *loc. cit.*, and also Roth, *On Paralysis in Infancy*, London, 1869.

Sural muscles. Heel depressed. Foot in dorsal flexion (calcaneus). Sole hollowed if perineus longus intact; flattened if paralyzed. Point turned outward (calcaneo-valgus).

Extensors of back. Lordosis on standing. Projection backward of shoulders. Plumb-line falls behind sacrum (unilateral). Trunk curved to side. Trunk cannot be moved toward paralyzed side.

Abdominal muscles. Lordosis, without projection backward of shoulders.

After the paralysis the most remarkable symptom of anterior poliomyelitis is the rapid wasting of the paralyzed muscles. The atrophy begins within a week after the paralysis, and its progress is even more rapid than that following the section of a nerve. Sometimes all the flesh on a limb is shrivelled down to the bone; at other times the muscular atrophy is concealed by an abnormal development of fat, constituting a pseudo-hypertrophy. When all the muscles surrounding a joint are equally paralyzed and atrophied, no deformity develops,¹ unless, indeed, the segment of a limb is used by means of the non-paralyzed proximate segment. In this case deformities may be produced by the effect of weight quite irrespective of muscular action, or in directions opposed to what we should expect from that.

The weight of the limb or a portion of it, by stretching paralyzed muscles, often aggravates their atrophy. This is most likely to occur with the paralyzed deltoid when the arm is unsupported, and with the anterior tibial muscles when the foot is allowed to drop.

Muscular atrophy occurs in the spinal paralysis of adults as well as in children; but in the latter alone does the atrophy extend to the bones and cartilages, tendons, fascia, ligaments, and blood-vessels. The osseous projections to which the muscles are attached waste; so do the epiphyses.² The long bones are thinner and shorter, the foot is shorter, and the hand is shortened in paralysis of the upper extremity, even where this is limited to the upper arm, and the forearm is scarcely affected (Seeligmüller).

In exceptional cases the limb may become even elongated from passive extension of the ligaments of the articulation. The bones may become soft and flexible, and break if pressure be applied.³

Atrophy of the bones stands in no fixed relation to that of the muscles, now exceeding, now falling short of that in intensity. This naturally progresses more slowly; still, within seven or eight months there may be a centimeter of difference between two limbs.

In marked contrast with this profound trophic disturbance of the bones is the intact nutrition of the skin. The absence of decubitus is indeed an important diagnostic mark from ordinary myelitis. The subcutaneous fat, however, wastes so completely that the skin seems to be closely adherent to the subjacent tissues, and cannot be pinched up into folds.

The temperature of the skin always falls; the limb is perceptibly colder to the touch than its fellow, and is often bluish and cyanotic. Heine has observed that the temperature diminishes gradually from the centre to the periphery, and at the coldest point may sink to 14° R.⁴ Hammond relates a case where the local temperature was 75° in an

¹ Except talipes equinus.

² Seeligmüller, *Centralbl. f. Chirurg.*, No. 29, 1879.

³ Ch. Salomon, "Des Lésions osseuses et articulaires liées aux Maladies du Système nerveux," *Revue mensuelle*, No. 8, 1878.

⁴ *Loc. cit.*, p. 16. This is not a difference of 14 degrees between the sound and paralyzed limbs, as is erroneously quoted by Seeligmüller (*loc. cit.*, p. 67).

atmosphere of 72°. The author says that exact measurements of surface temperature should be taken with Lombard's differential calorimeter, especially when convalescence is expected, as then a rise of temperature, however slight, is of most favorable augury.

General factors contribute to the fall of temperature: diminished blood-supply from shrinkage of blood-vessels, or even atrophy of a certain number among these; loss of nerve-influence upon the oxidation processes; loss of muscular contractions, which should attract an afflux of blood. Among these factors the loss of nerve-supply is probably the most important, since the others exist in cerebral paralysis without causing the remarkable coldness characteristic of anterior poliomyelitis.

The atrophy of the blood-vessels is not always confined to the terminal twigs. The entire iliac artery, and even the lower part of the aorta, have been found markedly diminished in calibre.¹ This shrinkage is unaccompanied by any change in the walls of the blood-vessels: it is a simple arrest of development. It strikingly illustrates the dependence of the blood-vessels on the vascular demands of the tissues they are destined to supply.

The changes which take place in the electrical reactions of the paralyzed limbs rank in importance with their paralysis and their atrophy. They serve to establish the diagnosis, to decide, to a large extent, the prognosis, and to measure the degree of nervo-muscular degeneration.

It is well known that the early diminution, and even entire loss, of faradic contractility was first emphasized by Duchenne as pathognomonic of infantile spinal paralysis. Contractility is diminished in from three to five days after the occurrence of the paralysis, and by the end of a week is completely lost in those muscles in which the paralysis is to be permanent. The muscles which recover spontaneously during the period of early regression recover their faradic with their voluntary contractility. In others, persistently but less profoundly paralyzed and susceptible of cure, the faradic contractility remains simply diminished and in unequal degrees. Progress to recovery under treatment is usually marked by progressive increase in the faradic response; but sometimes the power of voluntary contraction is fully regained, while the faradic response is still permanently lessened. The loss of faradic contractility is more complete and permanent in muscles irretrievably paralyzed by anterior poliomyelitis than in any other disease. These laws have been generally accepted by late observers.²

In 1868, Salomon discovered that muscles in which faradic contractility had been completely lost were nevertheless capable of contracting under the stimulus of galvanism—that this contraction is exaggerated, and sometimes occurs at the opening as well as at the closing of the circuit.³ The author remarks that the persistence of galvanic reaction after the complete loss of faradic contractility is completely analogous to an observa-

¹ Charcot and Joffroy, *Archives de Phys.*, 1870, case by Séguin, *loc. cit.*, p. 9.

² Simon disputes their validity, and declares that the importance of electricity in the diagnosis of spinal paralysis may easily be exaggerated (*Union médicale*, 7, 28, p. 942, 1879).

³ *Jahrb. f. Kinderheilkunde*, N. F. i., 1868. According to Erb (*loc. cit.*, p. 984) and to Ross (*loc. cit.*, p. 111), Salomon was the first to make this observation. Séguin, however, attributes priority to Lobb (*Lond. Med. Times and Gaz.*, 1863), to Hammond (*New York Med. Journal*, 1865), and to J. Netten Radcliffe between 1863 and 1865. These dates precede that of the publication of Salomon's paper, but the latter seems to have been written without knowledge of earlier observations. (See also Onimus, *Soc. de Biol.*, 1878, who argues that muscle-termination of nerve is partly destroyed.)

tion of Brücke's on muscles poisoned by woorara,¹ where the intramuscular termination of the nerve is paralyzed. It is to be inferred, therefore, in both cases that the muscular contraction results from direct irritation of the muscle, and implies the entire loss of influence from the nerve.

Erb has greatly extended these observations, and shown that the galvanic reactions of paralyzed muscles indicate their structural degeneration, and are identical with those observed after section of a peripheric nerve. There are three characteristic peculiarities in the contractions thus obtained: 1st, they are slow, tonic, long drawn out; 2d, they are more painful than in normal muscles submitted to an equal amount of electricity; 3d, in complete degeneration the contraction obtained at anode closure equals or exceeds in intensity that excited by cathode closure [AnSZ = or > KSZ]. The excitability of the muscle to the galvanic current remains increased for several months, then gradually diminishes, and finally falls below normal. The qualitative alterations persist somewhat longer: finally, the muscle fails altogether to contract.

Spinal paralysis differs markedly from progressive muscular atrophy in the absence of constant correlation between the degree of paralysis or atrophy and of electrical changes.

The last positive symptom to be noted in the paralytic stage of infantile paralysis is the diminution and ultimate loss of reflex excitability. This is correlative in time and extent with the loss of faradic contractility. This seems to be an exception to the usual rule, which associates loss of tendon reflex with lesion of the posterior columns or nerve-roots. This is a proof that interruption of the reflex arc at any point suffices to abolish the tendon phenomena.²

Negative Symptoms.—The negative symptoms of atrophic paralysis are as important for the diagnosis and pathogeny as are the positive characters, which have now been sufficiently detailed. The absence of decubitus or other nutritive lesions of the skin has been already mentioned. The absence of anæsthesia, or, as a rule, of any marked degree of hyperæsthesia, is most important as indicating immunity of the sensory tracts in the cord. Some diffused hyperæsthesia is sometimes noted during the febrile stage: pain is by no means rare in adults. But in children this is altogether absent, or else slight and transitory. On the other hand, the complete preservation of sensibility constitutes, in children, a serious obstacle to electrical investigation.

After subsidence of the cerebral symptoms, if any, of the initial stage, the functions of the brain are always intact³ and the disposition of the children apt to be remarkably lively. The general health is often remarkable for its vigor. The worst, because the most neglected, cases are naturally most often seen among the poor: the ranks of professional beggars are largely recruited from among the victims of infantile paralysis.

¹ "Ueber den Einfluss der Stromes dauer auf die Elektrische Bewegung der Muskeln," *Sitzber. d. k. Akad. d. Wissensch. in Wien*, 1867, Bd. lxi., quoted by Salomon, *loc. cit.*, p. 388.

² Buzzard tested the tendon reflex in the zygomaticus major in a patient in whom the sensory branch of the fifth nerve had been stretched, and therefore, to a certain extent, insulted. The reflex response was decidedly lower than on the opposite side (*Lancet*, Nov. 27, 1880).

³ Practically, it may often be of importance for the physician to ascertain that an intellectual enfeeblement, or even idiocy, existing at the time of examination had preceded the onset of the paralysis by months or years.

The chronic stage is marked by the development of a new set of symptoms—contractions of certain muscles surrounding one or more joints and deformed positions of the limbs. These symptoms do not always appear. If all the muscles surrounding a joint are completely paralyzed and extensively atrophied, and if no weight is imposed on the limb by the action of a non-paralyzed upper segment, and if the paralyzed segment be so supported that its own weight does not approximate the insertion-points of muscles, and thus cause their passive retraction, then there is no deformity, but a dangling limb, a *membre de Polichinelle*.

Laborde states that contractions appeared at the earliest about two months after the paralysis. Seeligmüller, however, has seen *pes equinus* and *pes calcaneus* develop in four weeks. The date is partly, at least, determined by the time at which the children try to walk or otherwise to use the paralyzed limbs; and the deformities are very much more marked in the lower extremities, proportioned to the much greater weight which they are obliged to sustain.

All varieties of club-foot, and most frequently equino-varus, knock-knees, rigid flexions at the knee and hip, cyphosis, lordosis, and colossal scoliosis may develop as manifold consequences of atrophic paralysis. That subluxation of the humerus and the claw-hand may occur in the upper extremities has already been mentioned.

In Seeligmüller's 75 cases, 53, or 71 per cent., exhibited some kind of deformity. Among these, 43, or 56 per cent., were of the foot; 6 were cases of subluxated humeri; 5, easily-reducible luxation of the fingers.

The following table contains a summary of the deformities observed as a consequence of atrophic paralysis. They are distinguishable from congenital deformities dependent on altered relations of articular surfaces through defective development¹ by being easily reducible. This remark especially applies to paralytic club-foot:

| | |
|-----------|---|
| Foot. | { Equinus. Equino-varus (varus hardly ever alone). Calcaneus. Calcaneo-valgus. Valgus. |
| Knee. | { Genu-recurvation. Genu-incurvation. Permanent flexion. |
| Hip. | { Luxation. Permanent flexion. Permanent adduction. |
| Hand. | { Flexion fingers or wrist (rare). Extension of wrist. Claw-hand. |

¹ *Volkman's Handbuch*, Billroth und Pitha.

Mechanism of Deformities.—From what has been said on the cases in which deformities are absent it is evident that one at least of three conditions are required for their production: the paralysis must be unequally distributed in the muscles surrounding a joint; pressure must be exerted by the weight of the body or traction by the weight of the limb; effort must be made to utilize the maimed part of the limb by means of other parts, or even by the muscles of the trunk.

The share taken by these different factors in the production of deformities has been differently estimated by different observers. The French surgeon Delpech was the first to explain the phenomenon on the theory of muscular antagonism. The same theory has been most minutely elaborated by Duchenne.¹ According to it, the intact or less paralyzed muscles, in virtue of their tonus, constantly tend to draw the segment of the limb on which they act in a direction opposed to that in which it should be drawn by the paralyzed muscles. Since this action is unantagonized, its influence persists; the insertion-points of the contracting muscle being permanently approximated, the nutrition of the muscle is modified: it grows shorter (adapted atrophy). There results finally shortening and retraction of the muscles on one side of the joint, over-stretching of those on the other.

Duchenne used to illustrate this theory by means of a skeleton supplied with artificial muscles, whose successive section would cause the appearance of the corresponding deformity. Werner² first protested against this theory, and the protest has been further developed and a different theory built up through the efforts of Hueter³ and Volkmann.⁴ The latter observes that the muscles and ligaments surrounding a joint normally receive a large amount of the weight falling upon its articular surfaces. Removal of this elastic resistance exposes these surfaces to the full force of the pressure, and thence to almost certain danger of deformity—a danger, therefore, always incurred after paralysis of the muscles. Thus, the weight of the body, pressing, unresisted, on the arch of the foot, is able to displace the bones of the arch from their normal relations and completely flatten the arch.

A position of ease is that in which the movement of the joint has been pushed as far as possible until limited by the passive resistance of the ligaments or the conformation of the articular surfaces. The weight of the body must then be so placed that the line of gravity falls on the side of the open angle, while the limiting bands stretch across the base. Thus, a tired man sits with a curved back; the muscles which may extend the spinal column in a straight line are relaxed; the column falls forward until arrested by the anterior vertebral ligaments. Thus, in standing at ease the thigh presses against the leg, so as to form a wide angle open anteriorly. When the quadriceps extensor is paralyzed, this position is inevitable and exaggerated, since the force which might counteract it, contraction of the thigh extensor, has been removed.

Formerly, the rôle of muscles in this elastic resistance was under-estimated and that of ligaments exaggerated.

CRITICISM OF THE THEORY OF MUSCULAR ANTAGONISM.—Three considerations have been urged in objection to the theory of muscular

¹ *De l'Électrisation localisée*, 1861.

³ *Gelenkkrankheiten*.

² *Reform der Orthopædie*. 1845.

⁴ *Sammlung klin. Vort.*, No. 1.

antagonism: First, deformities may develop even in limbs totally paralyzed, provided these limbs be subjected to weight and pressure. *Pes equinus*, the most common form of paralytic club-foot, develops with total paralysis of the muscles of the leg where the child does not walk, but is carried on the arms of a nurse with its foot dangling. The part of the foot anterior to the ankle-joint being longer and heavier than that behind, the point falls; the *tendo Achillis* is passively shortened, and by nutritive adaptation to this position may become permanently retracted. Long persistence in this position accustoms the dorsal surface of the bones to a less degree of pressure than the plantar surface: as a consequence, the growth of the bone becomes more active above, while it is arrested below; the arch of the foot is increased until the sole is curved into a deep hollow; and the plantar aponeurosis is correspondingly shortened.

Volkman relates a case where this same deformity appeared without the least paralysis, but simply from prolonged passive extension of the feet in bed. The patient was an adult, and suffered from a severe typhoid with a double relapse. After recovering from the fever a year of orthopædic treatment was required to restore the feet to their normal position.

The second objection is the absence of any proof of such constant tonus in the muscles as may be sufficiently powerful to determine the position of a limb. Such tonus exists in the involuntary muscles, especially in those of the blood-vessels, but there is no evidence that it exists in the voluntary muscles. To this Seeligmüller has replied by admitting the objection to the theory as thus proposed, but substituting the more plausible influence of repeated contractions on the part of the non-paralyzed muscles. Each contraction draws the limb in a certain direction, and there it tends to remain, because there is nothing to antagonize the force which it has obeyed.

The third objection is that examination of individual cases not infrequently shows displacements in directions opposed to that which should be determined by muscular antagonism. Volkman has especially illustrated the latter assertion by the mechanism of genu-recurvatum. In paralysis of the quadriceps extensor of the tibia the weight of the body is exercised, not merely from above downward, but from without inward, falling, therefore, on the inner malleolus. It thus tends to press the anterior part of the foot outward,¹ and a valgus finally complicates the calcaneus. Seeligmüller, however, quotes two cases of *pes calcaneus* developed in children who had never walked: in one paralysis of the sural muscles had occurred at the age of four weeks, and the other case was observed at the age of fourteen weeks. Seeligmüller remarks that only early examination of the faradic contractility of a group of paralyzed muscles can decide whether any among them preponderate during a time sufficient to fix the limb in a vicious position. Thus in one case of *pes calcaneus* he found two years after the occurrence of the paralysis that some contractility still persisted in the dorsal flexors, but six months later this had quite disappeared. Had the examination then been made for the first time when all the muscles were equally paralyzed, it would have seemed impossible to explain the deformity by muscular antagonism.

¹ Sayre asserts that lateral rotation cannot take place at the ankle-joint, but at the medio-tarsal articulation. Hueter also refers *pes varus* and *pes valgus* to the talo-tarsal articulation.

RELATION OF WEIGHT AND MUSCULAR FORCES.—The influences of weight and of muscular action sometimes concur, sometimes are opposed to each other. Thus, the weight of the foot alone always tends to produce equino-varus; it acts therefore to intensify the action of the sural muscles when the anterior tibial are paralyzed, but to diminish the influence of paralysis of the gastrocnemius when the foot is being drawn into dorsal flexion. Hence one reason for the comparative rarity of pes calcaneus.

Paralytic deformities at the hip and knee are much rarer than those of the foot. At the hip this immunity is partly due to the relative rarity of paralysis in the muscles surrounding the joint—still more to the fact that the weight of the limb tends to correct excessive flexions. These are therefore more likely to occur in children allowed to remain in bed than in those who are encouraged to walk by means of suitable apparatus. The use of crutches, however, favors the development of deformity, because, since with paralysis of the thigh- or leg-muscles pes equinus nearly always exists, the thigh is unduly lengthened. To palliate this inconvenience the patient instinctively flexes the knee or hip, or both, and the position tends to become permanent.

When the flexion is rigid and extension becomes impossible, the gastrocnemii are relaxed until they lose their power of tension, and thence of fixing or raising the heel. Further, as by the flexion the limb is moved in front of the body, it is necessary to project the body forward again over the support. Hence a lordosis is developed, to be distinguished from that caused by paralysis of the vertebral extensors (*a*) by the rigid flexion of the thigh; (*b*) by the facility with which the patient can extend the back as soon as he is placed in a sitting position.

Although the quadriceps extensor is so frequently paralyzed, rigid flexion at the knee—such as on the theory of muscular antagonism might be expected from the action of the hamstring muscles—is very rare. As already observed, it occurs, if at all, in neglected children allowed to lie or sit with the leg partly flexed. In those who attempt to walk the leg is not flexed, but forced into hyper-extension by the following mechanism: The muscles inserted on the upper part of the thigh swing the leg forward like a passive support. Afterward the body bends forward over the support, and its weight, pressing from above downward and from before backward, and pressing the articular surfaces of the joint together, forces the head of the tibia backward until the movement is checked by the posterior ligaments. The deformity is the same whether the quadriceps or one or all the muscles surrounding a joint are paralyzed (Volkmann).

DISLOCATIONS.—Dangling limbs are, however, much more frequently the consequence of total paralysis, with extraordinary relaxation of the ligaments of the joint permitting dislocation. Reclus¹ has published several such cases. Verneuil has even suggested that congenital luxation of the hip-joint always depends on an intra-uterine spinal paralysis.²

In the upper extremities rigid contractions are much less frequent, even in proportion to the number of paralyses. Seeligmüller has seen five cases of reducible flexion of the fingers, and one of permanent extension of the wrist and fingers, associated with paralysis

¹ *Revue mensuelle de Méd. et de Chir.*, Mars, 1878.

² Quoted from Seeligmüller.

of all the flexors. In this case, if the arms were so suspended that the hand hung freely, its weight gradually overcame the action of the extensors and the fingers fell into flexion. Upon any attempt at exertion the hyperextension was reproduced.

DEFORMITIES OF THE TRUNK.—Scoliosis will be caused when, with unilateral paralysis of the extensors of the vertical column, the lower part of the trunk is drawn to the non-paralyzed side, and the upper half is bent over the paralyzed side in order to restore the balance. In bilateral paralysis of the extensors both shoulders are projected backward, so that a plumb-line dropped from between them falls behind the sacrum, and lordosis is developed, although the lumbar column is not projected forward. The same form of lordosis occurs when the glutæi are paralyzed. When, however, the abdominal muscles are paralyzed, the lumbar column is really projected forward, and then a plumb-line dropped from the shoulders passes over the sacrum.¹

PARALYSIS OF THE ABDOMINAL MUSCLES.—Unilateral paralysis of the extensors of the back is often difficult to detect in young children. Seeligmüller recommends that the child be laid across the mother's knees and told to move the trunk from one side to the other while the pelvis is held firm. If too young to obey the direction, the movement can be excited by pricking or by electric irritation. It will be seen that the trunk can be turned only to one side.

In these paralyzes of the trunk it is clear that the deformity does not develop under the influence of muscular antagonism alone, but only when the non-paralyzed muscles attempt to sustain the superincumbent weight of the body or a portion of it.

SUMMARY OF MECHANISMS OF THE DEFORMITIES.—We may indeed conclude, as stated at the beginning, that this complex etiology exists in almost all cases. When the limb is at rest in bed or the weight of the body is transferred to crutches, then repeated contraction of the flexus will suffice to bring the limb into a vicious position (contraction at knee- and hip-joint). When the foot or hand hangs unsupported, its weight is sufficient to cause deformity, even when all the muscles are paralyzed, and sometimes in opposition to the direction of intact muscles. Thus the weight which is passively borne by the limb, and the efforts of intact muscles to effect the function of the limb in spite of the paralysis, both concur in the production of the deformity.

ANATOMICAL LESIONS.—The theory of the anatomical basis of infantile paralysis constitutes one of the most interesting portions of its history. It is indeed one of the most instructive chapters of modern pathology from the rapidity with which in a short time precise knowledge has accumulated, and for the degree in which this has revolutionized previous ideas.

Autopsies.—Until 1863 only five autopsies had been made upon persons affected with infantile paralysis.² As the disease was never, of itself,

¹ Duchenne, *loc. cit.*, 1861.

² I believe the first list of modern autopsies was made by myself in a paper read before the New York County Medical Society, Dec. 22, 1873. The paper was not published until May, 1874, and in the mean time Seguin's lecture on "Infantile Paralysis" was published in the *N. Y. Med. Record*, Jan. 15, 1874, with a tabulated list of 25 autopsies, necessarily almost identical with my own—cases 9 and 10 are really identical. A case by Roth is included; 4 negative autopsies are omitted. In 1880, Seeligmüller, in his

fatal, opportunity for pathological investigation did not present itself, while attention was still vividly attracted to the paralysis. When this had become a chronic infirmity, and patients had succumbed to intercurrent disease, the opportunity must have occurred, but was not then utilized.

The first cases affording autopsies in which the spinal cord was thoroughly investigated, belonged, however, precisely to this class of extremely chronic lesions, which should be regarded as showing rather the results of the morbid process than that process itself. Omission to observe this distinction has been the occasion of several misinterpretations of the pathological appearances.

Premature Theories.—In the entire absence of evidence it is a little remarkable that such high authorities as Rilliet and Barthez,¹ West,² Vogel,³ Eulenburg,⁴ should have pronounced dogmatically that the disease was essential—i. e. unaccompanied by any structural lesion whatever; and that Bouchut,⁵ on the strength of most incomplete examination, should have built up a theory of myogenic paralysis. It is still more remarkable, after the published autopsies of Rinecker,⁶ Laborde,⁷ Cornil,⁸ Prévost,⁹ Charcot and Joffroy,¹⁰ Parrot and Joffroy,¹¹ Vulpian,¹² Roger and Damaschino,¹³ that Politzer in 1866,¹⁴ Brown in 1871,¹⁵ Barwell in 1872,¹⁶ Kétli,¹⁷ Adams in 1873,¹⁸ should still adhere to this doctrine. They are, however, entirely in the minority, and all recent monographs and works published with a view to presenting the state of science assume the spinal nature of infantile paralysis to be established beyond possibility of controversy.¹⁹

The following table contains a summary of the seven autopsies in which the spinal cord is said to have been examined with negative results. Of these, the only really important case is the third, in which a microscopic examination, made by so competent an histologist as Robin, was said to have discovered no lesion of the cord.

elaborate essay in *Gerhardt's Handbuch*, published a list of 32 cases, including the above, and adding to them the following: Case by Müller, 1871; 4 cases by Leyden, 1875 (*Arch. de Psych.*); 1 case by Raymond, 1874 (*Gaz. méd. de Paris*); 1 case by Demme, 1876 (*B. med. Bericht über das Jennerische Kinderspital zu Bern*); 1 case by Eisenlohr, 1876 (*Tageblatt des Hamburger Naturforscher Versammlung*); 1 case by Schultze, 1877 (*Virch. Arch.*, Bd. lviii.).

To this list we may now add 3 cases by Turner, Humphrey, Taylor, 1881 (*Path. Trans. London*); 2 cases by Dejerine, 1878 (*Progrès méd.*), giving a total of 37 cases with detailed histories and autopsies.

| 4 | 1873 | Elischer and Kötli. | | | | | | Negative. | <i>Treatise on Club-foot</i> , p. —. |
| 5 | 1873 | " | | | | | | " | <i>Jahrb. Kinderheilk.</i> , 1873. |
| 6 | 1873 | " | | | | | | " | <i>Ibid.</i> |

Heine, in the absence of autopsies, but arguing from clinical symptoms alone, already inferred the existence of a spinal lesion as cause of the paralysis, and believed that it consisted in congestion, or even in hemorrhagic exudation, capillary or massive, which should compress the cord and result in partial atrophy. The same opinion is advanced in 1844 by Brunnière,¹ also by Vogt,² in 1868 by Salomon³ and Radcliffe.⁴ The autopsies contained in the following table, in all of which vascular lesions are prominent, might be invoked in support of this view :

TABLE II.—AUTOPSIES SHOWING VASCULAR LESIONS OF CORD.

| No. | Year. | Name of Author and Patient. | Age at time of | | Nature of Symptoms. | Limbs Paralyzed. | Electric reaction. | Appearances at Autopsy. | Reference in Literature. |
|-----|-------|-----------------------------|----------------|----------|-------------------------------|------------------|--------------------|---|--------------------------|
| | | | Paralysis. | Autopsy. | | | | | |
| 7 | 1829 | Klein. | 5 | 5 | Persistent cerebral symptoms. | l. o. | ? | Congestion of pia around roots of left brachial plexus. | Quoted by Heine. |
| 8 | 1855 | Brund. | 1 | 5 | Meningitis? | r. u. | ? | Chronic spinal klepto-meningitis. | |
| 9 | | Hammond. | 4 yrs. stand. | | | l. u. | ? | Encysted clot in left ant. column, lower dorsal cord. | |

The first really modern autopsy, that made by Cornil in 1863, agrees with the two earliest on record in disclosing only an atrophy of the cord. Some of the other cases, contained in Table III., note in addition sclerosis of the lateral columns.

In all the remaining autopsies on record are noted atrophy of the anterior gray cornua and more or less extensive destruction of the ganglionic cells.

In a certain number of cases the atrophy seemed to be the unique lesion. But it never was confined to the ganglionic cells, but included the reticulum of gray fibres in which these were imbedded, and which

¹ *Krankheiten des Gehirns und Rückenmarkes.*

³ *Jahrb. f. Kinderheilk.*, 1865.

² *Lähmung der Kinder*, p. —.

⁴ *Reynolds's Syst. of Medicine.*

was replaced by a reticulum of connective tissue. These cases were all examined many years after the occurrence of the paralysis.

TABLE III.—AUTOPSIES SHOWING ATROPHY OR SCLEROSIS OF WHITE COLUMNS OR ROOTS.

| No. | Year. | Name of Author and Patient. | Age at time of | | Nature of Symptoms. | Limbs Paralyzed. | Electric reaction. | Appearance at Autopsy. | Reference in Literature. |

It will be useful to add another table, which will group together the cases in which the autopsies were made within two years after the occurrence of the paralysis. Of these, all but the two made by Laborde, in which the cornua are declared to be healthy and the lesion limited to the

white columns, show traces of destructive morbid processes in the gray substance of the cord, greatly predominating in the anterior cornua, but not absolutely limited to them, nor even to the part of the cord which corresponds to the paralyzed limb:

AUTOPSIES OF RELATIVELY RECENT CASES.—In cases relatively recent all macroscopic changes in the cord may be entirely wanting. There may be some degree of asymmetry in the surface of section, patches of white coloration in the anterior gray substance, or of gray or yellow color in the white columns; the anterior roots may be congested or even already atrophied.¹ On the other hand, there have several times been found foci of visible red softening, much more frequently at a point corresponding to the origin of the paralyzed nerves, but not absolutely confined to them, and sometimes existing at points where they have given rise to no symptoms whatever.²

Microscopic Lesions.—In striking contrast with this paucity of macroscopic lesions are the interesting structural changes revealed under the microscope. These lesions are usually comprised within circumscribed foci whose size may vary from a long diameter of 2 mm.³ to one of from 10 to 30 mm.⁴ Sometimes bilateral foci are found with monoplegic paralysis; thus one side or the other preponderates in the morbid process.

In recent cases (Damaschino's, at twenty-six days; Roger's, at two months; Turner's, at six weeks) patches of red softening existed at the portions of the cord containing the nuclei of origin of the paralyzed nerves. In Turner's case the focus contained hemorrhagic extravasation, and the traces of this were clearly perceptible in Roger's first case. The blood-vessels are dilated; their lymphatic sheaths infiltrated with leucocytes and with granular corpuscles; their walls are thickened, pigmented, or fatty.

¹ Roger's first case, No. 23 of Table V.

³ Case Roth, Tab. V.

² Case 1st of Roger, Tab. V.

⁴ Case Schulze, Tab. V.

Leucocytes are often disseminated through the diseased area, and in one case (Demme) were accumulated into a focus of pus. Besides the leucocytes, the foci are often infiltrated with large round granular cells that seem to be transformed neuroglia-cells (Leyden). In one case neuroglia nuclei were accumulated in a ring around the focus, seeming to indicate the beginning of encapsulation.

The most striking lesion, however, and the one which is common to the most recent as well as to old cases, is the deformation, atrophy, and final disappearance of the large ganglionic cells of the anterior cornua. The first change consists in granular pigmentation;¹ then the prolongations disappear, leaving the body of the cell shrunken and deformed; at last the whole cell disappears. Sometimes all the cells of an anterior horn have disappeared throughout the entire depth of the focus; quite as often, in certain sections at least, the atrophy is limited to certain groups, as the external,² or the external in one focus, the antero-lateral in another, situated on the opposite side of the cord.³

In a case rendered celebrated by Charcot it is stated that in many sections of the cord atrophy of ganglionic cells constituted the unique alteration, the tissue immediately surrounding the place whence they had disappeared being perfectly healthy. It is on this appearance that has been built up the theory of a primary idiopathic atrophy of the ganglionic cells as the characteristic lesion of infantile paralysis. But in other portions of the same cord Charcot himself describes destruction of the gray reticulum imbedding the cells; and this destruction is insisted upon in many other observations. In other words, there is a general disintegration of the gray nervous tissue of the anterior cornua which contain the focal lesion. The normal tissue is then replaced by a reticulum of conjunctive fibres, more or less dense according to the age of the case.

These focal lesions of the cord explain admirably, as will be seen, the permanent symptoms of the disease. But of great importance for understanding its initial period is the fact that structural changes—similar to, but less severe than, those just described—have been found diffused throughout the cord. In several cases hyperæmia, partial atrophy of ganglionic cells and nerve-fibres, infiltration with exudation corpuscles, in the anterior cornua and even central gray canal from the lumbar to the cervical region.⁴ In Damaschino's case, besides the focal lesions which corresponded to the paralyses of the right arm and left leg, were others corresponding to the left arm and right leg where no paralysis existed.

This case (1883) is also interesting in bringing out another lesion not usually noticed. This is the breaking up into balls of the myeline in the medullated tubes, both of the anterior intraspinal nerve-roots and of such fibres as traversed the anterior nerves. In balsam preparations these myeline drops are dissolved; but in osmic acid and glycerin preparations they appear as black balls all over the field. The lesion is identical with that already described by Dejerine (1875) in both nerves, roots, and white columns. The columns of Clarke have always been found intact.

¹ Case of Echeverria, Tab. V.

² Case by Schultze (this is a case of ancient lesion), Tab. V. (*Virch. Arch.*, Bd. lviii.).

³ Case by Taylor, Tab. IV. (*Path. Trans.*, London, 1879.)

⁴ See cases by Leyden, Roth, Schultze, Clarke, Damaschino.

In the recent cases no lesions of the white columns have been observed—a fact upon which reposes the doctrine that such lesions, when existing, are secondary to those of the cornua.

SECOND GROUP OF CASES.—The next group of cases contains 16, where the autopsy was made more than two years after the début of the paralysis.

TABLE VII.—AUTOPSIES SHOWING LESIONS OLDER THAN TWO YEARS.

| Case No. | Name of Author. | Date of Lesion. | Year of Publication. |

| 22 | Raymond. | 70 yrs. | 1875 |
| 16 | Prévost. | 76 yrs. | 1866 |

The date of these lesions varies from seven to seventy-six years. In two or three cases, where the autopsy was made on very old people, the early history of the disease was unknown, but the probable date of the paralysis was calculated.

In this group of cases patches of atrophy, semi-transparent and grayish in color, focal or diffused, are clearly perceptible to the naked eye. As a rule, the atrophy is unilateral, and sensibly affects the entire half of the cord. In some cases of paraplegia, however, there is a bilateral, symmetrical shrinkage of the entire lumbar cord, which has been reduced to the size of a quill.

The atrophy involves, first and most markedly, one or both anterior cornua; second, the anterior nerve-roots arising from them; third, the antero-lateral columns.

In both the latter localities the microscope will often find individual nerve-tubes wasted and deprived of their myeline. The atrophied patches are generally sclerosed as the seat of a proliferated neuroglia, coloring deeply with carmine. In Laborde's cases, published at the very beginning of what may be called the anatomical period, the atrophy and sclerosis were said to be limited to the antero-lateral columns and the nerve-roots, while the cornua remained intact. In all more recent observations, however, the lesion of the white columns and roots has been found strictly proportioned to that of the gray horns. The sclerosis extended into the latter, constituted by a reticulum of connective-tissue fibres, sometimes fine, sometimes so matted together as to form a dense felt-like substance, sometimes offering the ordinary aspect of sclerosis.

Amyloid corpuscles have been found infiltrated in great numbers

through both the gray and white substance in these old cases (case by Cornil),¹ seeming to replace the infiltration with exudation corpuscles observed in the more recent ones.² When the lesion is distinctly circumscribed the focus is often surrounded by a zone of embryonic cells, seeming to indicate a reactive proliferation on the periphery.³

As in the relatively fresh cases, the circumstance which has attracted the most attention is the atrophy of the ganglionic cells from the sclerosed patches of the anterior cornua. The completeness with which these have disappeared in any focus seems to be proportioned to the completeness of the paralysis in the corresponding limb. Partial atrophy or disappearance of spinal groups of cells from the cornua may sometimes be correlated with paralysis of special muscles.⁴

Study of the pathology of infantile paralysis is not completed when the above series of spinal lesions has been enumerated. Most various interpretations have been made of these lesions as they have been successively discovered. Thus, after the theory of congestion came the theory of primary sclerosis, built upon Laborde's two autopsies;⁵ then the theory of primary atrophy of ganglionic cells;⁶ then the theory of myelitis;⁷ finally, a theory of complex and variable lesion.⁸

It was Prévost who first ascribed a predominant importance to the atrophy of the ganglionic cells of the anterior cornua; but it was in the hands of Vulpian, Joffroy, and more especially Charcot and his pupils, that the theory was fully developed. Infantile paralysis was ranked in a newly-formed group of diseases, all characterized by atrophy of these same cells, and differing from each other principally in the acuteness of the process and in its complications.⁹ Seguin, in his original lecture in 1874, supported the same views, but in 1877 fully adopted that of myelitis. The objections to this theory are: 1st, that by it two diseases so different in their course, localization, electrical reactions, and form of paralysis as atrophic paralysis and progressive muscular atrophy are essentially identified on account of the identity of one lesion, the atrophy of the anterior ganglionic cells;¹⁰ 2d, the presence of other lesions or of traces of them peremptorily proves the pre-existence of a complex mor-

¹ *Loc. cit.*, *Soc. Biol.*, 1863.

² Seguin (*loc. cit.*) observes that the opinion is gaining ground which ascribes these to a transformation of the neuroglia corpuscles.

³ Case by Schultze, *loc. cit.*

⁴ Thus in Schultze's case, already quoted, the external group of cells had disappeared from the focus in one gray horn, and the extensors of the foot were alone paralyzed. This seems to confirm the opinion advanced by Spitzka, that this external group of motor-cells corresponds to the extensor, the internal groups to the flexor muscles.

⁹ Thus, acute anterior poliomyelitis, subacute anterior poliomyelitis, progressive muscular atrophy, amyotrophic lateral sclerosis, bulbar paralysis.

¹⁰ When this objection is accepted, Barlow's remark falls to the ground, that "the similarity of lesion found in two such different diseases as infantile paralysis and progressive muscular atrophy proves the failure of anatomical characters, taken alone, to serve as a basis of nosology" (*Brain*, April, 1879, p. 74).

bid process which involves the ganglionic cells, but is neither limited to them, nor, necessarily, originates in them.

This inference was drawn by Roger from the hemorrhagic softening, dilatation, and degeneration of blood-vessels, infiltrations with exudation-copuules, and hyperplasia of conjunctive nuclei present in his case. Similarly, Schultze, in a case examined nineteen years after the occurrence of the paralysis, found traces of an extensive myelitis in the diffusion of the lesions,¹ in the exquisite cellular infiltration, the proliferation of the neuroglia, and the atrophy of axis-cylinders of nerve-fibres together with the cells; and inferred an anterior myelitis, diffused in the long axis of the cord, but limited to the antero-posterior region. Schultze defines Charcot's theory to be an hypothesis of such an acute atrophy of ganglionic cells as leads to a rapid melting down of these bodies, whereby reactionary inflammation is excited in the surrounding tissue. This implies that the dying cells are able to act like a virulent substance on the imbedding tissue, and of this, declares Schultze, "Charcot has offered no proof."²

A third objection has been brought forward by Leyden, and is really an enlargement on the second. It is, that various lesions or morbid processes may underlie the same clinical history. In four autopsies of cases presenting all the clinical history of acute anterior poliomyelitis this author has found three different lesions. In one an extensive lepto-meningitis, together with irregular focal sclerosis of the white columns, evidently depended upon the latter, and in turn caused sclerosis of the anterior cornua with consequent destruction of their cells.³ In two other cases an anterior poliomyelitis was accompanied by diffused lesions of the central canal. Finally, in a fourth case the lesions were limited to the anterior cornua, as is most usual.

The theory of acute atrophy of ganglionic cells is not sensibly different from that of a parenchymatous myelitis.⁴ But all the objections which can be urged against the former theory apply to the latter also, with the exception that the hypothesis of inflammation suggests a cause for the otherwise inexplicable atrophy. Observation of the pathological appearances alone could not decide whether the irritation started in the parenchymatous or interstitial tissues. Reference to the etiology of the disease shows that of the two most frequent apparent causes, blood-poison-

¹ In this case, of paraplegia without lesion of the upper extremity, to which we have several times alluded, there was bilateral atrophy of the lumbar cord, atrophy of the right anterior nerve in the dorsal and lower cervical region, also in the cervical enlargement.

² It might be said that the fall of the fever as soon as the paralysis is declared and the motor cells presumably melted down should contradict the idea that their dying substance acts as an irritant upon surrounding tissues.

³ This case of Leyden's throws light on the two autopsies by Laborde with sclerosis of the white columns and intact cornua. It seems probable that a process originating in the cornua had then been arrested or had receded, while continuing its evolution in the white columns.

⁴ Hammond assumes such a form of myelitis in his classification of inflammations limited to the anterior part of the gray matter of the spinal cord:

1. Inflammation of motor and trophic nerve-cells: (a) Infantile spinal paralysis; (b) Spinal paralysis of adults; (c) Pseudo-hypertrophic spinal paralysis.

2. Inflammation of motor cells: (a) Glosso-labia-laryngeal paralysis.

3. Inflammation of trophic cells: (a) Progressive muscular atrophy; (b) Progressive facial atrophy (*Dis. Nerv. Syst.*, 6th ed., p. 464).

We think this classification open to several fundamental criticisms.

ing and traumatisms, the first would indicate that the inflammation started in the connective tissue supporting the blood-vessels; the second suggests that the irritation began in the spinal elements constituting the origin of the nerves.

Whatever be the starting-point, however, it is very evident that the morbid process soon involves all the tissues contained in the gray matter of the anterior horns, and constitutes, therefore, a real anterior poliomyelitis.

A question of much interest is the relation to this of the lesions of the anterior roots and of the white columns. Is the atrophy of nerve-tubes a passive consequence of their separation from the ganglionic cells, the sclerosis a secondary consequence of this? or is the sclerosis the cause of the atrophy, itself the result of an irritation propagated downward from the myelitic focus, according to the usual law for secondary degenerations in motor tracts? or, finally, is it a residuum of a leucomyelitis (or of the white substance), complicating by simple extension the inflammation of the gray substance?

Review of the autopsies recorded would indicate that the lesions in question are brought about sometimes in one, sometimes in another, of these ways—sometimes even, as in Leyden's case, by extension from a meningitis. That sclerosis of the white columns is most frequently a secondary degeneration is indicated by the frequency with which it appears below the lesion of the cornua, by the rarity with which it is found above, and also by the general proportion between its intensity and that of the disease of the gray matter.

We have devoted so much space to consideration of spinal-cord lesions, because they are by far the most constant and the most important; after these rank the structural alterations of the muscles, which received for a while such a preponderance of attention.

Hammond has studied the progress of these changes on the living subject by fragments of fibre successively removed with Duchenne's harpoon. In an incipient stage of degeneration the fibrillæ are found to be irregular and torn,¹ the transverse striæ dim; oil-globules are seen arranged according to the long axis of the fibre. In a more advanced stage the transverse striæ nearly disappear, the oil-globules are in large numbers, and fat-corpuscles are also abundant. Finally, the whole specimen is seen as a mass of air-globules. Six weeks later, however, these had in turn disappeared, and there remained a mass of connective tissue.

This series of changes, however, does not always take place, as Hammond himself recognizes. Laborde² first described a granular form of muscle atrophy, where the muscular substance gradually wastes away without ever becoming fatty, and leaving a transparent and hyaline sheath. The two forms of fatty and of simple atrophy can be distinguished by the naked eye. In the latter the muscle begins by being thinner or lighter and softer than usual, ultimately turning light brown. The fatty muscle becomes a homogeneous yellowish-white, diversified by occasional remnants of reddish fibres.

¹ Though, from the method of removal, this appearance cannot be considered as certainly pathological.

² *Loc. cit.*, p. 131.

Proliferation of the interstitial connective tissue may be combined with either simple or fatty atrophy. A combination of abundant sclerosis and abundant fatty infiltration may lead to a pseudo-hypertrophy of the muscles.

"There cannot be the slightest doubt," observes Erb, "that the lesions described constitute a degenerative atrophy similar to what may be caused by section or sense traumatism of a peripheric nerve."

The peripheric nerves have been much less thoroughly studied than the spinal cord. Leyden first directed special attention to the nerves. He found the sciatic altered in two cases,¹ in the first by an interstitial neuritis; in the second by partial atrophy. In 1880 the same writer, in an extensive article on poliomyelitis and neuritis,² greatly extends his views as earlier expressed. Not only does he claim the coexistence of neuritis with spinal-cord disease in atrophic paralysis, but thinks that many cases of this, and also of other forms of paralysis, "lately supposed to originate in the spinal cord, may really begin in any part of the motor apparatus," thence sometimes generalize throughout the whole apparatus, sometimes remain limited to the original portion affected. Thus, progressive muscular atrophy may sometimes begin in the nerves, sometimes in the muscles, and sometimes in the ganglionic cells of the cord; and this variety of origin explains the discrepancies of opinion which have been held upon the nature of this disease. Similarly, all forms of acute or chronic atrophic paralysis in either children or adults may begin in either the nerves or cord, thence become generalized to both, or remain limited to one part of the spinal motor system. Cases of atrophic paralysis which recover are probably not cases of poliomyelitis at all, but of multiple neuritis, rheumatic, traumatic, or infectious in nature. The regeneration of peripheric nerves is a well-demonstrated possibility, but not that of the cells of the cord. Lead-paralysis is usually confined to the nerves, but sometimes extends to the cord. In diphtheritic paralysis Buhl has found injection, thickening, and granular infiltration of nerves at the union of their anterior and posterior roots;³ and as long ago as 1876, Dejerine, in a case of atrophic paralysis in a syphilitic woman, found varicose swelling of the medullary sheath in the nerves of the paralyzed lower extremities, together with heaping up of the myeline into large drops, colored black in glycerin and osmic-acid preparations. Coincidentally, in the cord, at the origin of the same nerves, the number of motor-cells was diminished, and of those that remained the prolongations, and even the body, of the cell were atrophied.⁴

These views of Leyden's are extremely interesting, and should stimulate future research into the condition of nerves in all cases of atrophic paralysis. It is quite incorrect to say, as Archambault and Damaschino have recently done,⁵ that Leyden denies the existence of anterior poliomyelitis in such cases, especially in such as prove permanent. He only insists on the frequent coincidence of neuritis, on a varying point of departure for the morbid process, and on the probability that in cases of recovery this process has always remained peripheric.

¹ Cases 34 and 35 of Table V., quoted from *Arch. de Psychiatrie*, Bd. vi., 1876.

² *Zeitschrift für Klin. Med.*, 1880.

⁴ *Arch. de Phys.*, 1876.

³ *Zeitschrift für Biol.*, 1867.

⁵ *Le Union méd.*, 1883, 7, 35, case quoted in Table V. It is much to be regretted that Damaschino, who strongly controverts Leyden's views, did not examine the nerves in his own most interesting case.

The strongest objection to Leyden's theory is the absence in most recorded cases, either infantile or adult, of the usual signs of nerve inflammation, local pain, or tenderness. Autopsies of old cases are not able to differentiate an inflammation from an atrophic process in the nerves, followed by a secondary thickening of the endoneurium. This thickening was found in three cases examined by Edmonds in 1882, whose subjects had suffered from infantile paralysis in early life, and had had the paralyzed limb amputated at the age of fifteen or sixteen. Transverse sections were made from the internal popliteal nerves. The specimens showed some healthy nerve-fibres, presumed to be sensory; others much smaller, with the axis-cylinders wasted or degenerated; while strands of connective tissue traversed the nerve-bundles, resulting from hypertrophy of the endoneurium. The vessels showed inflammation of their coats, with proliferation of the endothelium.¹

The brain is usually normal, unless indeed the paralysis has affected children previously rendered idiotic by congenital atrophica cerebri. Sandie, however, examined one brain with an interesting positive result.² The brain was taken from a boy of fifteen paralyzed since the age of three in almost all his muscles, with even paresis of the muscles of the trunk and neck. The paralysis was more marked upon the right than on the left side. At the autopsy, in addition to atrophy of the muscles and of the motor nerves, with exquisite atrophy of the anterior columns and anterior cornua, was found a decided atrophy of the left central convolution, and, less marked, of the paracentral lobule. This was shown by comparative measurements with the opposite side of the same brain, and also with the corresponding convolution and lobule in two other brains. The child's intelligence had not been affected.

The arrest of development of the bones has been already mentioned, as well as that of their epiphyses and apophyses. The compact osseous tissue is atrophied: the medullary, on the contrary, abundantly developed and rich in fat.

PATHOGENY OF INFANTILE PARALYSIS.—In the pathological anatomy of infantile paralysis there are two principal facts to be correlated with its clinical phenomena—namely, the limitation of the myelitis to the anterior gray horns of the spinal cord; the destruction of the ganglionic nerve-cells in these gray horns. That the other lesions observed are subordinate to these is shown by their variableness as compared with the constancy of the anterior poliomyelitis. These lesions are, in the cord, the atrophy and sclerosis of the anterior nerve-roots and white columns; in the muscle, the fatty degeneration or simple atrophy of the fibre; in the nerve, breaking down, and finally atrophy of the myeline sheath, sometimes of the axis-cylinder; proliferation of the endoneurium.

Consequence of Limitation of Myelitis.—Limitation of the morbid process to a portion of the motor tract, the anterior cornua, and exclusion of the posterior horns and roots, readily explain the predominant positive symptom of motor paralysis, together with the absence of sensory disturbance. The absence of muscular rigidity, spasm, active contraction, and of exaggerated reflexes is similarly explained by the immunity from the morbid process of the posterior white columns and the portion of the

¹ *Trans. Path. Soc. London*, 1883.

² *Centralblatt f. d. Med. Wissenschaft.*, No. 15, 1875.

lateral columns immediately adjacent to them. The motor paralysis resulting from destruction of the anterior ganglionic cells of the cord is much more complete than that which depends on simple interruption of the motor tracts passing from the brain. The manner in which the motor tracts are connected by a succession of arching fibres with these cells already indicates that the latter are dépôts for the reinforcement of the motor impulses. We must believe, indeed, that the centrifugal impulses reaching the anterior cornua are not yet motor in character, but to become so must sustain a new elaboration in the ganglionic cells of this region. Evidently, the network of gray fibres connecting the arcuate strands of the antero-lateral columns with the cells become, in virtue of that fact alone, essential to the process. But it is also probable that the multiplied transmission of impressions, which lies perhaps at the basis of the process of their higher elaboration in ganglionic centres, is carried on in the larger network of gray fibres as well as in the smaller network contained in the ganglionic cells. Destruction of a portion of this network would therefore interfere with the elaboration of the motor impulse, in the same manner, though to a relatively less extent, as destruction of the ganglionic cells themselves.

Trophic Lesions.—The rapid wasting of the paralyzed muscles, with their degenerative electrical reactions, seems, however, to be an effect altogether peculiar to lesions of the ganglionic bodies.¹ According to Charcot, who has so especially formulated the laws of amyotrophic paralysis, all the ganglionic cells essential to the elaboration of motor impulses exercise a trophic influence upon muscles. The spinal cell, nerve-fibre, and muscle-fibre combine into a complex indissoluble unity or element. One part of this lesion of complex elements is necessarily followed by proportionate lesion of all its other parts.

According to Erb, however, who extends Samuel's doctrine of special trophic nerves, it is not the motor cells which influence the nutrition of the muscle-fibres with which they are connected, but special trophic cells lying among the others in the anterior cornua. This theory is principally based on the existence of muscular atrophies of central origin (progressive muscular atrophy, bulbar paralysis), unaccompanied for a long time by paralysis.² Hammond cites as a converse example the anterior poliomyelitis "where the peripheric disturbance is, in the first place, solely one of motility; this is paralysis without atrophy. After a time, which may be as much as six months or even more, the trophic changes begin."³

But surely this is an exaggerated emphasis on the exception, rather than the true inference from the rule of rapid wasting in anterior poliomyelitis—a rule so general as to have originated the title atrophic paralysis. Erb gives an ingenious scheme (Fig. 55) of the mental relations of motor and trophic cells with cerebral and spinal nerve-fibres. It will be seen that isolated lesions of one or the other trophic apparatus might occur without paralysis of motor tracts, while simultaneous lesion of the trophic

¹ The amyotrophic lateral sclerosis of Charcot exhibits in an exquisite manner the difference between paralysis without atrophy, caused by sclerosis of the antero-lateral columns, and paralysis with atrophy when the morbid process has extended to the anterior cornua.

² *Zeinssen's Handbuch.*

³ *Loc. cit.*, p. 429.

apparatus and of the ganglion-cells, or of the latter, involving the tracts coming from the trophic cells, would cause, as in anterior poliomyelitis,

motor paralysis, muscular atrophy, loss of the reflexes, degenerative reaction in nerves and muscles.

Duchenne and Joffroy¹ also argue the existence of special trophic nerve-cells. The absence² of the nutritive lesions of the skin and cellular tissue which are so conspicuous when the gray matter around the cen-

¹ "De l'Atrophie aigue et chronique des Cellules nerveuses," *Arch. de Phys.*, No. 4, 1870.

² Money, and also Gowers, have signalized a condition of the skin resembling myx-œdema (*Tr. Path. Soc. London*, 1884, and *Brit. Med. Journ.*, 1879).

tral canal or posterior to it is involved,¹ the dependence of the nutrition of the motor apparatus, nerves, muscles, bones on the integrity of the anterior horns, are facts which, taken together, seem to indicate that the maintenance of nutrition depends on the unbroken continuity of the motor or sensory apparatus from the periphery to the ultimate central element, rather than on any special central cells endowed with trophic functions.² Erb's hypothesis, as his own scheme moreover denotes, demands not only trophic cells distinct from motor cells, but separate trophic cells for the muscles, for the motor, and for the sensory nerves.

The peculiar grouping of nerve-centres within the cord that seems to be indicated by some of the groupings of infantile paralysis shows, as has been said, a probable divergence within the cord of nerve-fibres which run together in the same nerve-stem. The associations to be expected from the data of functional association and of clinical history are by no means fully decided. It is even a matter of dispute whether the tibialis anticus is functionally more associated with the flexors or with the extensors of the thigh, and whether its experimental irritation or clinical paralysis really coincides with that of the first or of the second group. This entire field of observation is new and promises fertile results.³

Relation between Limitation of Myelitis and Age.—From the relative frequency of anterior poliomyelitis in childhood, as compared with its much greater rarity in adult life, we must infer the existence of some special conditions in childhood which tend to limit the morbid process to such a portion of the cord. The theory of a primitive spontaneous atrophy of the motor cells would serve, indeed, to explain this limitation. The reasons already alleged for regarding the morbid process as a systematic myelitis decisively hinder the acceptance of such an explanation as it stands. On the assumption, however, that the myelitis is usually of functional origin, and starts, therefore, in the elements of the anterior cornua essentially involved in the motor functions, the morbid susceptibility of these elements may be ranked with the liability to disease of the entire locomotor system which is known to be so predominant in children. From pathological evidence, even without anatomical proof, we may reasonably infer an incompleteness of development in the anterior

¹ Mayer (Herman's *Handbuch Physiol.*) sums up the great mass of evidence now accumulated, which demonstrates the trophic influence of the central gray mass of the cord upon the tissue.

² Nepveu (*La France médicale*, 1879) mentions some cases of infantile paralysis complicated with trophic lesions of the skin. The facts, if accepted, could only indicate an extension of the myelitis to the central and posterior regions of the gray columns. The relations between non-atrophic paralysis caused by interruptions of the motor tracts and muscular atrophy dependent on lesion of the anterior cornua are exquisitely shown in a case reported by Sander. An adult suffered from chronic motor paralysis, gradually increasing, in the right arm, with paresis of the lower extremities. In the hand, arm, and shoulder the paralysis was followed by gradual atrophy and diminution of the faradic contractility; in the lower extremities no atrophy occurred. At the autopsy was found a gliomatous tumor seated in the anterior cornua, predominating on the right side, extending from the level of the sixth dorsal to that of the eighth cervical vertebra. The ganglion-cells were pigmented and compressed, not altogether destroyed. The lumbar cord was intact, and the non-atrophic paresis of the lower extremities evidently resulted from the interruption of the motor tract above.

³ It is from this field that has come a new argument for the spinal nature of lead-paralysis, from its peculiar grouping, and from analogy with that of anterior poliomyelitis of the upper extremities (Remak, "Ueber die Local. Atropa. Spinal Lahm.," *Archiv für Psych.*, Bd. ix.; also, Ferrier, *loc. cit.*).

cornua of the cord correlative with that well demonstrated in the bones and functionally inexperienced muscles. If the antero-posterior fibres which connect the anterior cornua with the central and posterior gray masses be also incomplete, the radiation of irritations, and consequent vascular irritation, would also be arrested within the boundaries of the original lesion. Thus a peculiarly circumscribed, instead of the common diffused, myelitis of adults.

Money¹ points out that for the gray matter of the cord, as of the brain, the centre or maximum force of the circulation is on the periphery, and the nutritive supply of the centre is thus easily cut off. Moreover, while the blood-vessels of the cervical and dorsal regions of the cord pass to it transversely, the vessels of the lumbar region are compelled to describe a somewhat prolonged vertical course before reaching their point of distribution. From these circumstances, even transitory congestions in the circulation of the cord are easily followed by irreparable injury of its delicate elements.

Finally, in all discussions on pathogeny must not be forgotten the doctrine of Leyden² that infantile paralysis, also progressive muscular atrophy, is a disease which may begin at the periphery and extend to the centres, as well as the reverse. It must also be remembered that, as yet, only very scanty evidence exists to support this, in itself, plausible theory.

COURSE OF INFANTILE PARALYSIS.—The most ordinary course of infantile paralysis is that already described as typical—namely, extremely rapid development to a maximum degree of intensity, then apparent convalescence, retrocession of paralysis, atrophy, and ultimate deformities in limbs in which paralysis persists.

Several variations from this typical course are observed. Complete recovery may take place, as in the so-called temporary paralysis of Kennedy³ and of Frey.⁴ These cases are very rare. But their possibility seriously complicates the estimate we may make of the efficacy of therapeutic measures.⁵

On the other hand, there may be a complete absence of regression; and this is observed sometimes in cases where the paralysis is originally limited; sometimes where it is extremely extensive, involving nearly all the muscles of the trunk or limbs;⁶ or muscles or limbs originally spared may become involved in a fresh attack. Laborde relates cases of this kind. In Roger's first case paraplegia occurred under the influence of scarlatina two months after paralysis of one arm.

The form of anterior poliomyelitis most frequent in adults is the subacute, and after that the chronic. Both are extremely rare in children, the latter excessively so. Seeligmüller and Seguin⁷ both admit the possibility of a chronic form in children, and the latter has kindly communicated to me one case from his private practice:

¹ *Loc. cit.*, *Path. Trans.*, 1884.

² See *loc. cit.*, ut supra.

³ *Dublin Quarterly Journal*, 1840.

⁴ *Berlin. Klin. Wochens.*, 1874. I have described one such temporary case in the article already quoted. These cases seem about as frequent in adults. (See Frey, *loc. cit.*; also case of Miles, etc. etc.)

⁵ As of the case of complete recovery, the only one the author had seen, related by Dally, *Journal de Thérap.*, 1880, 1, vii.

⁶ Thus in Eulenburg's case, quoted ut supra.

⁷ *Loc. cit.* (ed. 1877).

Miss N. D——, æt. 15, paresis in both legs, first at age of nine, increased at age of twelve, when weakness of vision first noted. At fourteen both feet in rigid pes equinus, and both tendons achilleis cut, without benefit. Hands became tremulous, without paresis. On examination at age of fifteen found moderate atrophy of muscles of both legs. Tendo Achillis united on both sides, and equinus persists. Voluntary movement exists, both in anterior tibial and in gastrocnemius muscles, but diminished in anterior tibial. Faradic contractility diminished in both sets of muscles; examination difficult from extreme sensibility of patient. In both hands interossei, muscles of thumb, and little finger show tremors and fibrillary contractions. Thenar eminences small, abductor pollicis nearly absent, not reacting to faradic current. Optic nerves slightly atrophied. Mind enfeebled, memory poor; articulation not affected. Five years later the motor paralysis and mental enfeeblement had still further progressed, but no exact notes exist of this period.

Erb¹ relates a case that he considers unique at the time in a girl of six. The paralysis began insidiously in the right foot in July; a fortnight later had extended to the left foot; complete motor paralysis existed in August, without any lesion of sensibility: after electrical treatment, then instituted, first return to motility to peroneal muscles in November; by January child able to walk again and electrical reactions nearly normal.²

COMPLICATION WITH PROGRESSIVE MUSCULAR ATROPHY.—Raymond³ and Seeligmüller describe some rare cases where progressive muscular atrophy declared itself in persons previously affected with infantile paralysis in other limbs. Both observers infer a gradual and chronic extension along the cord of the originally acute anterior poliomyelitis.⁴ Similar cases have much more recently (1884) been quoted by Ballet as tending to modify the prognosis which has usually been pronounced favorable quoad life and further spinal accidents. (See *infra*.)

PROGNOSIS.—The prognosis of atrophic paralysis, quoad vitam, is, as is well known, extremely good. The prospect of recovery from the paralysis is variable. It cannot be estimated either by the extent of the initial paralysis or by the severity of the fever or attendant nervous symptoms. The electrical reactions alone are of value in the prognosis, and their value is very great. Duchenne first formulated their law: "All the cases of infantile paralysis which I have seen where the faradic contractility was diminished but not lost, and which could be treated by faradic electricity within two years after the onset of the paralysis, have completely recovered."⁵ This encouraging statement must be read as applying rather to individual muscles than to cases as a whole. Few

¹ *Brain*, 1883.

² In the same number of *Brain*, A. Hughes Bennett quotes cases of so-called chronic paralysis in very young children which are evidently cases of general paresis from congenital cerebral atrophy. The children were defective in intelligence, could not sit up nor hold up the head; the electrical reactions were preserved. I have seen a great many such cases; they are indeed not at all uncommon. Much more so is Bennett's diagnosis.

³ *Gaz. méd.*, 1875, No. 17.

⁴ It seems to me that Seguin's case, above quoted, might be an example of such complication(?). But I have not seen the patient myself, and describe the case according to the views of the author.

⁵ *Loc. cit.*

complete recoveries of patients are claimed even by so enthusiastic an electrician as Duchenne; who nevertheless affirms his not unfrequent success in re-creating entire muscles out of a few fibres saved from degeneration.

The persistence of galvanic irritability in muscles which fail to contract to the faradic current has been shown by Erb to belong to the degenerative reactions. Hammond, however, without alluding to the qualitative changes in the galvanic contractions, sees in them the elements of a relatively favorable prognosis, even when faradic contractility is lost. Thus, out of 87 cases, in 39 of which the paralyzed muscles contracted to the galvanic but not the faradic current, 14 were entirely cured, 28 greatly improved, 30 slightly improved, 15 discontinued treatment very early.¹

Examination of fragments of living muscle obtained by Duchenne's harpoon, though useful, should not be allowed to exaggerate an unfavorable prognosis. Much fat may be found in such fragments when the muscle is as yet by no means completely degenerated and can be made to contract to one or the other current. Erb, however, admits that the results of treatment have not, in his hands, been brilliant; but adds that he has had no opportunity to treat any cases which were not of long standing.²

Volkman³ considers the paralysis entirely hopeless, and advises the concentration of all effort upon the prevention or palliation of deformities.

It seems probable that at the present moment sufficient data do not exist for formulating a fair prognosis; nor will they until a much larger number of cases than hitherto have been submitted to all the resources of a complex and persevering system of therapeutics from the earliest period of the disease.

SPECIAL PARALYSES.—Among the paralyses, some exercise a more unfavorable influence on locomotion than others. Thus, paralysis of the muscles of the trunk is more difficult to palliate, either by apparatus or by the efforts of the patient, than any paralysis of the limbs. Similarly, paralysis of the upper segments of a limb is more crippling than when confined to the lower. Partial paralysis of the muscles surrounding a joint is often (but not always) more liable to lead to deformity than total paralysis.

Influence of Neglect.—Apart from the influence of treatment in curing the paralysis, must be estimated in the prognosis the effect of care and watchfulness in limiting the disease and in averting many consequences, even of those which are incurable. The rescue of muscles only partially degenerated may often serve to compensate the inaction of those which are irretrievably ruined.

Ballet⁴ has recently called attention to the fact that in certain cases persons who had been attacked with an anterior poliomyelitis in childhood became predisposed to different forms of spinal disease. Four have been observed: (1) transitory congestion of the cord, causing paralysis of a day or two's duration; (2) an acute spinal paralysis of the form usually seen in adults; (3) subacute spinal paralysis; (4) progressive muscular atrophy. The author relates cases under each of these heads, and further quotes one

¹ *Loc. cit.*, p. 482.

³ *Loc. cit.*

² *Loc. cit.*

³ *Revue de Médecine*, 1884.

related by Dejerine in 1882.¹ The patient, a carpenter aged fifty-five and with an atrophic deformity of the foot, became suddenly paralyzed in the four limbs, trunk, and abdomen. The paralysis was complete in a month, was stationary for three months, then began to improve, and at the end of six months from the onset of the disease recovery was complete.

The observations of progressive muscular atrophy in persons bearing the stigmata of an infantile paralysis are quite numerous.²

The prognosis cannot be the same for cases where everything is done to avert malpositions and for those where all precautions are neglected. Thus, prolonged rest in bed favors pes equinus; the use of crutches necessitates flexion of the thigh and forced extension of the foot; locomotion without support tends to displace articulations by superincumbent weight, causing pes calcaneus, genu-recurvatum. Finally, compensatory deformities must be averted from sound parts, as scoliosis from shortening of the atrophied leg, equinus from passive shortening of the gastrocnemii through flexion of the leg, etc.

ETIOLOGY.—Concerning the etiology proper of infantile paralysis little definite is known. It is probable, as has been already noticed, that traumatism have a much more decided influence than is generally assigned to them. Leyden particularly insists on this influence, and on the facility with which a traumatism relatively severe for a young child may be overlooked, because it would not be recognized as such for an adult. It must be noticed, however, that children are much more liable to have the arms wrenched and pulled violently than the lower extremities; yet in a great majority of cases the lesion is situated in the lumbar cord.

It has been shown that the myelitis, though so limited transversely, is often far more diffused in the longitudinal axis of the cord than might be supposed from the permanent paralyses. This fact corresponds to the initial generalization of the motor disturbance. It seems possible that the traumatic irritation, starting from the central extremity of the insulted nerve, diffuses itself through the cord until it meets with its point of least resistance, and here excites a focal myelitis. That this point should most frequently be found in the lumbar cord would be explained by its relatively less elaborate development, corresponding to the imperfect growth and function of the lower extremities.

A second cause of anterior poliomyelitis is, almost certainly, the presence of some poison circulating in the blood. The frequent occurrence of the accident in the course of one of the exanthemata is one indication of this; other indications are found in such cases as that related by Simon, where three children in one family were suddenly attacked—two on one day, one, twenty-four hours later.³ The same author relates a case of motor paralysis in an adult, followed by atrophy of left lower extremity, and which occurred during a fit of indigestion caused by eating mussels.⁴ The acute ascending paralysis of Landry,

⁴ P. 357.

with its absence of visible lesion, has been said to strikingly resemble the effects of poison. Hydrophobia and tetanus are again examples of the predilection exhibited by certain poisons for the motor regions of the cord.

The evidence that infectious diseases may constitute the immediate (apparent) causal antecedent of acute poliomyelitis has led, not unnaturally, to the theory that all cases of acute infantile paralysis are due to a specific infecting agent, some as yet unknown member of the great class of pathogenic bacteria. It may be noticed, however, that the occurrence of the spinal accidents after the ordinary infectious diseases, as scarlatina and measles, should as well indicate that a specific agent proper to itself was at least not essential to its development.¹

The influence of exposure to cold, which seems to have been sometimes demonstrated, must probably be interpreted, as in the case of rheumatism and pneumonia, as effective by means of some poison generated in the organism when cutaneous secretion, exhalation, or circulation has been suddenly checked.

DIAGNOSIS.—The diagnosis of the acute anterior poliomyelitis of childhood is usually easy, but unexpected difficulties occasionally arise.

Typical cases are markedly different from typical cases of cerebral paralysis, but in exceptional cases these differences disappear. This is shown in the following table:

| SPINAL PARALYSIS. | CEREBRAL PARALYSIS. |
|--|--|
| Paraplegic or monoplegic (rule). | Hemiplegic, (rule). Monoplegic as residuum of hemiplegia or as consequence of solitary tubercle (exception). |
| Hemiplegic as residuum from paraplegia, or original and involving facial nerve (very exceptional). | |
| Intelligence free (rule). | Intelligence depressed (rule) |
| Intelligence depressed (when spinal paralysis has affected imbecile children). | Intelligence free (exception, especially with solitary tubercle). |
| Disposition lively. | Disposition apathetic or cross. |
| Initial convulsion unique; general symptoms of a few hours' duration (rule). | Convulsions repeated; pyrexia prolonged several days or weeks (rule). |
| Convulsion repeated during two to three weeks before paralysis; fever a month (rare exceptions). | |
| Sensibility intact (rule). | Sensibility intact after initial period. |
| Occasional hyperæsthesia (exception). | |
| Reflexes cutaneous, and tenderness lowered or lost (rule). | Reflexes intact. |
| Reflexes preserved when only single muscles in groups paralyzed. | |
| Associated movements of hand absent (Seeligmüller). | Associated movements frequently observed in hand. |
| No rigid contractions of upper extremity. | Extensive and rigid contractions of upper extremity very frequent. |
| Atrophy of paralyzed muscles and arrested development of limb, very marked. | Atrophy very slight. |
| Faradic contractility diminished or lost; degenerative galvanic reaction. | Electrical reactions normal. |

Rather singularly, the diagnosis from transverse myelitis is less liable to error than that from cerebral paralysis:

¹ Perhaps the occurrence of diphtheria in the course of scarlatina and typhoid should indicate a similar lack of real specificity in the morbid agent of the former disease.

ANTERIOR POLIOMYELITIS.

Fever brief or absent.
Sensibility intact.
Decubitus absent.
Reflexes lost.
Atrophy of muscles.

Electrical muscular contractility lost.

TRANSVERSE MYELITIS.

Persistent fever.
Hyperæsthesia, then anæsthesia.
Presence decubitus.
Reflexes increased.
Atrophy of muscles sometimes as intense.
Loss of electrical contractility, but not proportioned to sensory and motor disturbance; less rapidly completed.

The diagnosis from hæmatomyelitis is almost impossible, and practically useless. For if the hemorrhage be severe, the child dies at once, as in Clifford Albutt's case. If less severe, it excites a myelitis, and the history becomes identical with that of the disease we are considering; or if the clot beyond the anterior cornua, it is identified with a vulgar myelitis of traumatic origin.

Progressive muscular atrophy is extremely rare in childhood, but is occasionally seen under hereditary influence (Friedreich's disease). In adult cases confusion is not only easy to make, but often difficult to avoid, especially with the rare, chronic form of poliomyelitis. The basis of distinction is as follows:

ANTERIOR POLIOMYELITIS.

Onset sudden; maximum of paralysis at the beginning.
Faradic contractility lost almost at once.
Shortening of limbs and atrophy of limbs (in infantile cases).
Functionally associated muscles frequently associated in paralysis; hand rarely affected.

PROGRESSIVE MUSCULAR ATROPHY.

March very gradual; maximum of disease not attained for years.
Faradic contractility not lost until atrophy complete.
No arrest of development of limbs.
Capricious selection of muscles, but frequent wasting of these at eminences.

Paralysis from lesion of a peripheric nerve closely imitates anterior spinal paralysis.¹ It is distinguished by closely following the distribution of the injured nerve, and, usually, by concomitant lesions of the sensibility and of cutaneous nutrition.

The pseudo-paralysis sometimes observed in syphilitic children as a consequence of a gummatous infiltration of the bones at the junction of the epiphysis and diaphysis² might easily be mistaken for a spinal paralysis. But it is an affection peculiar to the new-born; the electrical reactions of the paralyzed muscles are intact; careful examination will show that the movements of the muscles are not impossible, but restrained by pain; often other syphilitic affections are present.

The diagnosis from diphtheritic paralysis is embarrassed, from the fact that true anterior poliomyelitis may develop in the course of diphtheria as of other infectious diseases. The paralysis of the soft palate, preservation of faradic reaction, absence of atrophy, and the usually rapid recovery must establish the differentiation.

In spinal paralysis there is loss of the reflexes,³ and also of faradic

¹ The importance of this fact has been shown in the section on Pathogeny. (See also quotations from Leyden and remarks on lesions of peripheric nerves.)

² Parrot, Wagner.

³ See Gowers's monograph on "Spinal-Cord Diseases" for an excellent summary of the spinal reflexes.

contractility, both of which are preserved in hysteria. In hysterical paralysis, also, there is no wasting of the affected muscles.

Various diseases of the bony skeleton or articulations may simulate spinal paralysis. Congenital club-foot, caused by unequal development of the bones and cuticular surfaces, is to be distinguished from the paralytic variety by the date of its appearance,¹ by the deformity of the tarsal bones, and by the extreme difficulty of reduction.

Caries of the calcaneum, leading the child to walk on the anterior part of the foot to avoid pressure on the heel, may leave after recovery such a retraction of the plantar fascia as to cause a degree of equinus and varus, with apparent paralysis of the peroneal muscles. I have seen one such case.

Congenital luxation of the hip may simulate paralysis; indeed, by Verneuil, it has been attributed to an intra-uterine spinal paralysis. There is, however, no change in the electrical reactions of the muscles surrounding the joint.

In coxitis, however, Newton Shaffer² has demonstrated a moderate diminution of faradic contractility in such muscles, and a corresponding degree of atrophy; and this fact might complicate the diagnosis of paralysis from arthritis of the hip-joint. Gibney³ has called attention to the facility with which this confusion may arise, and Sayre⁴ relates cases of infantile paralysis mistaken for coxitis.

In a case observed by myself, which had been previously diagnosed as coxitis, the mistake was all the more interesting as the paralysis which really existed seemed to have been caused by a meningitis rather than a primary myelitis of the cornua.⁵ It thus corresponded to the meningo-myelitic case related by Leyden.

Scoliosis, which may be caused by the relatively rare unilateral paralysis of some of the muscles of the trunk, may also be simulated by paralysis with shortening of one lower extremity. To compensate the

¹ Though in some cases paralysis of the muscles of the foot seems to take place during fetal life, and a club-foot result which is both congenital and paralytic.

² *Archives of Medicine.*

³ *Am. Journ. Med. Sci.*, Oct., 1878.

⁴ *Orthopædic Surgery.*

⁵ The details of this case are as follows: C. P.—, aged 11, ten months previous to consultation suffered from febrile attack, accompanied by retraction of head, severe pains diffused through body and intense at nape of neck; unconsciousness for thirty-six hours; vomiting; no convulsions. Case diagnosed as cerebro-spinal meningitis by attendant physician. Convalescence in a week, but with pain in lumbar region of back, predominating on right side, so aggravated by standing or walking that both acts impossible. Coincidentally, pain in right calf; exquisite tenderness to pressure even from stocking. No complaint in recumbent position. Child could not get from floor to bed, nor raise right leg from ground. As pain subsided walking became possible, but right leg dragged. Chronic twitchings on left side, face, arm, leg. These symptoms lasted ten or twelve weeks, but at end of nine weeks patient could walk up stairs. In ten months power of walking almost recovered, but there remained a certain amount of lordosis and oscillation of pelvis, which is jarred on the left side while the right leg is swung forward. Recumbent, all movements executed equally well on both sides and passive motion of the hip-joint perfectly free. Circumference of right thigh and leg diminished from one-half to one inch as compared with the left. Faradic contractility diminished on the right side in the gluteal muscles, vastus externus, and rectus, and in the gastrocnemii. The sacro-lumbalis muscle was, unfortunately, not examined, but from the lordosis was probably affected. The remaining muscles were intact. Pain on pressure persisted over right side of second, third, and fourth lumbar vertebrae. Diagnosis was made of a limited meningeal exudation, with compression of anterior part of cord or of a portion of the lumbar and of the sacral plexus.

shortening, the trunk is bent over on the paralyzed side; hence a lateral curvature, easily reducible, but easily leading into error.

It would seem easy to distinguish traumatic cases of subluxation of the humerus from those due to paralysis of the deltoid. Yet sometimes only the history will serve to establish, and that somewhat doubtfully, the diagnosis.¹

THERAPEUTICS.—The treatment of anterior poliomyelitis embraces two stages. In the first it is directed against inflammation of the spinal cord and the paralysis of the muscles; in the second period the spinal lesion has run its course and the paralysis is considered incurable. Treatment is then directed to the prevention or palliation of deformities or toward facilitating the functions of the limb in spite of them.

These two periods are not, however, rigidly separated from each other in chronological order. From the very outset it is important to take certain precautions to prevent deformities, and while palliating these with orthopædic apparatus it is important for years to continue treatment of the paralyzed muscles in the hope that at least a remnant of them may be saved. To abandon the case to the orthopædic instrument-maker, or to neglect the problem of dynamic mechanics while applying electricity and studying the progress of fatty degeneration, are errors greatly to be condemned.

The treatment of the initial stage is necessarily purely symptomatic for the fever and convulsions, since the diagnosis cannot be made out until these have subsided.

As soon as the diagnosis is clear, however, certain measures should be adopted to diminish the hyperæmia of the spinal cord. Dally² recommends the ventral decubitus; almost all modern authorities advise ice to the spine and ergot internally or subcutaneously. Thus, Althaus³ makes hypodermic injections of ergotin in doses of one-fourth of a grain for a child between one and two years old; one-third of a grain between three and five; and one half grain from five to ten; and these doses repeated once or twice daily. The only objection to this treatment is the degree of local irritation it can hardly fail to occasion. Hammond, who "affirms ergot to be of great service, the only medicine capable of cutting short the disease or of limiting its lesions," recommends the internal administration of the fluid extract—ten drops three times a day for infants of six months, half a drachm for children between one and two years.⁴

The belladonna treatment, at one time so warmly praised by Brown-Séquard, retains to-day few adherents.

Simon advises cutaneous revulsives to divert the circulation to the sur-

¹ A child of four was brought to me with a stiffness and rigidity of the shoulder-joint which could only very partially be overcome by passive motion, and not at all by voluntary effort. The mother stated that several months previously the child had, without apparent cause, become suddenly unable to move the arm. After two months' delay it was taken to a dispensary, and told that the arm was out of joint, and had it reset under ether. From this date the stiffness had gradually developed. The deltoid was atrophied, with marked diminution of the faradic contractility. Question: Were these signs merely symptomatic of an arthritis consequent on a dislocation, or was the latter the result of a spinal paralysis of the deltoid?

² *Journ. Thérap.*, t. viii., 1880.

³ *On Infantile Paralysis.*

⁴ I have elsewhere quoted one case of early recovery under the use of ice and ergot; or was this a case of temporary paralysis?

face; thus, hot-air baths, mustard powder sprinkled on cotton enveloping the limbs. Ross advises mercurial inunction along the spine, followed by iodine and blisters. At the same time, iodide of potassium should be given internally in large doses. The action of this drug upon inflammations of the nerve-centres seems, within certain limits, to be indisputable, but its mode of action is certainly very obscure. Where the lesion can be attributed to a meningo-myelitis,¹ the iodide may be expected to facilitate the absorption of the exudation. In these cases it should be continued for a long time.²

Electrical treatment may be begun by the end of the first week after the paralysis. At this stage Erb recommends central galvanization as an antiphlogistic remedy for the myelitis. For this purpose a large anode must be placed over the spine at the presumed seat of the lesion, while the cathode is applied over the abdomen. By a slight modification of the method the cathode is placed over the paralyzed muscles. The application is stable, and, according to Erb, should last from three to ten minutes; according to Bouchut, several hours daily. Erb's method is intended exclusively as a sedative to the local inflammation. When the cathode is placed on the muscles it is hoped that the descending current, replacing the lost nervous impulses, may avert the threatening degeneration of the muscle and nerve.

Faradization cannot modify the inflammatory lesions of the cord. As a means of averting degeneration in completely paralyzed muscles it is inferior to galvanism, and should not therefore be used in those muscles which refuse to contract under its stimulus. Its immense utility, however, is as a stimulus to muscles imperfectly paralyzed, but liable to degenerate from inaction and to be overborne by their antagonists. The excitation of contractions in such muscles is a powerful local gymnastic, helping to maintain nutrition by artificially-excited function.

For the same purpose, muscles inexcitable to the faradic current should be, when this is possible, made to contract by the interrupted galvanic current. After this treatment has been prolonged during several months, the faradic contractility often returns, and the current then should be changed (Seguin).

The value of electrical treatment has been very differently estimated. Erb remarks that "its results are not precisely brilliant." Roth, whose testimony perhaps is not above suspicion, since evidently prejudiced, insists that numerous cases fall into his hands which have submitted for months to electrical treatment without the slightest benefit. On the other hand, Duchenne, as is well known, has expressed almost unbounded confidence in the therapeutic efficacy of faradization, declaring that it was capable of "creating entire muscles out of a few fibres."

The sensitiveness of children to the electrical current, and their terror at its application, seriously interfere with its persistent use; as, if the patience of the physician is maintained, that of the parents is very likely to fail in the presence of the cries and resistance of the child.

It is very probable that some of the failures of electrical treatment are

¹ As in Leyden's first case, and my own.

² Binz explains the local action of iodine by an exudation of leucocytes which follows the dilatation of blood-vessels. These elements break down the exudation into which they are poured, and thus facilitate its absorption.

due to the attempt to rely upon it exclusively, instead of suitably combining both electrical methods with each other and with other remedial measures. With our present knowledge it is safe to assert the desirability of persistent electrical treatment during at least the first two years following the paralysis. The currents must never be too strong—the faradic, at least, never applied for longer than ten minutes at a time. The muscles should be relaxed by the position of the limbs (Sayre). If the muscles continue to waste, and especially if they become fatty, the electrical response will grow less and less, and finally cease altogether.¹ In the contrary case the galvanic contraction will become normal in quality, and the faradic contractility will return and increase, while the atrophy is arrested and the muscle regains its bulk and voluntary powers. Sometimes, as already stated, the latter is regained, while faradic contractility remains greatly diminished.²

A succedaneum to electricity that is highly prized by some authorities is strychnia, especially when subcutaneously administered. Pelione³ relates the cure of two cases in children of four and five years, after three and four years' duration of the paralysis, by strychnia—one-half milligramme daily. None should be given to children under six months, but over that age one-ninety-sixth of a grain may be given (Hammond). It should not be given subcutaneously more than two or three times a week (Seeligmüller).⁴

The incidental action of electricity in attracting blood to the paralyzed muscles may be sustained by several other methods.

Among these the external application of heat, either dry or in the form of hot douches, alternating with cold, is an adjuvant remedy of real importance. Beard has suggested tubing, malleable to the limbs, for the conduction of hot water. It is desirable to employ massage immediately after cessation of the hot applications.

On the value of massage and passive gymnastics opinion is even more variable than in regard to electricity. Roth, a specialist in orthopædics, places it at the head of all remedial measures, and denounces electricity in comparison. Many professional manipulators, ignorant of medical science, continually claim wonderful triumphs over regular physicians obtained by means of systematized massage. Volkmann, on the other hand, dismisses the pretensions of the Heilgymnastik with considerable contempt, declaring that faradization is the only method which can really secure exercise to paralyzed muscles.

The Swedish movement cure consists in passive movements imparted to a limb by the manipulator, at the same time that they are strenuously resisted by the patient. From the nature of this method, and its aim in stimulating the voluntary innervation of the muscles, it

¹ Passing through three stages: faradic contractility diminished, galvanic contraction increased; faradic response lost, galvanic degenerative; absence of contraction to either current.

² Sayre (*loc. cit.*) has noticed cases in which the muscle would contract several times under faradism, then refuse to do so for a day or two. This observation, if valid and not due to unequal working of the battery, is a most curious one.

³ *L'Union médicale*, 1883.

⁴ Duchenne relates a case of a paralysis general at the outset and remaining so for six months. It was then treated by strychnine for five or six months, and at the end of that time had become limited to the lower extremities (*Élect. local.*, ed. 1861, p. 278).

is admirably adapted to hysterical paralysis. Theoretically, it is difficult to perceive the applicability of this method in organic atrophic paralysis, especially in young children, whose voluntary efforts cannot be commanded. There are, however, several real indications for passive gymnastics in the treatment of infantile paralysis. Surface friction and deep massage have some influence in dilating the blood-vessels and causing an afflux of blood to the cold and wasting muscles. A probably more important effect may be produced upon the contraction caused by malposition and adapted atrophy of certain groups of muscles. It is these contractions which formerly constituted the special objection of the orthopædist, and were treated almost universally by tenotomy. They are in any case the proximate cause of deformities; and, generally existing on the side of the joint opposite to the most severely paralyzed muscles, they keep these over-stretched and prevent them from receiving the benefit of the electrical treatment. Muscles which will not contract to the faradic current while thus stretched will often begin at once to do so when the rigidity of their antagonists has been overcome.

Persevering stretching by the hands will often overcome this rigidity as completely, and even more permanently, than will the tenotomy-knife. It is in this part of the treatment that entirely ignorant and even charlatan manipulations do, not unfrequently, achieve remarkable results.¹

It is the retracted tendo Achillis and plantar fascia which most frequently require this manipulation. In the paralytic club-foot of young children all authorities agree in the value of repeated manipulations and restorations of the foot as nearly as possible to a position where it may be retained by simple bandaging. While turning the foot out it becomes perfectly white, but on releasing hold of it the circulation is restored, after which the manœuvre may be repeated (Sayre).

This principle of intermittent stretching by seizure of the segments of the limb above and below the joint applies to all forms of paralytic contraction. In the trunk the pelvis should be held by the mother, while the manipulator, seizing the thorax of the child between both hands, moves it gently but forcibly to and fro in the required direction. Great care is required in these manipulations—not merely to avoid exhausting the muscles, but even to avoid fracturing atrophied bones.

It may be laid down as a positive rule that tenotomy should never be performed in the contractions of spinal paralysis until the resources of manipulation have been exhausted. It is to be remembered that the rigidity depends on no active contraction of the muscle, but on its elastic retraction. The manœuvre of stretching does not appeal to the force of contractility, which may have been lost, but to the force of elasticity, which remains and can be made to act in a reverse direction. Finally, in the cases where the retracted muscles have not been originally paralyzed, but have lost the power of contracting during the process of shortening, this power may be restored if the muscle regain its normal length.

The operation of tenotomy, apparently a far more heroic measure, is often a less efficacious means of arriving at the results. Unless followed by the application of apparatus which permits motion in the joint, section of contracted tendons is only of brief utility.

¹ Of course many of those on record, and to some of which I have been a witness, relate to hysterical contractions, hysterical scoliosis, etc.

Though the edges of the cut tendon have been kept apart until the intervening space is filled by new tissue, union is finally effected by the latter, and retraction through elasticity is again imminent. Often, therefore, the deformity is repeated in spite of repeated operations; when it is not, the happy issue is due to the fact that, with increased freedom of locomotion immediately after the tenotomy, the patient has been enabled to bring the influence of weight to bear in such a manner as to fix the limb in a new and more convenient position. Thus, after section of the tendo Achillis for pes equinus, if the patient begins at once to walk on the paralyzed foot, the weight of the body, pressing down the heel, may keep the tendon stretched. So walking immediately after section of the hamstring muscles will have a tendency to produce genu-recurvatum by the same mechanism which produces it in total paralysis, and the original deformity will not recur.

Besides the tendo Achillis, the parts which may be occasionally submitted to tenotomy are the plantar fascia, the peroneal muscles, very rarely the anterior tibial and extensors, the hamstrings, the thigh adductors. Section of the external rotators of the thigh or of the tensors of the fascia lata could hardly ever be required, and among these operations Hueter¹ rejects that on the plantar aponeurosis as inadequate. The excavation in the foot it is designed to remedy depends upon alteration in the form of the tarsal bones, and can only be cured by means of forcible pressure exerted on their dorsal surface. Section of the peroneal muscles, often recommended by Sayre, is considered by Hueter to be superfluous after section of the tendon achilleis. Paralytic contraction of the hamstrings or of the hip flexors is rarely sufficiently severe to demand tenotomy.

From what has preceded it is evident that maintenance of locomotion is of great importance, in order to avoid the deformities which are threatened by prolonged repose. Locomotion, however, can only be safely permitted with the assistance of apparatus capable of restraining the movements liable to be produced by the weight of the body. The supporting instrument which restrains movement in certain directions must, however, facilitate it in others: immovable apparatus, such as is not infrequently applied after tenotomy, is always injurious.

In young children unable to walk, the development of pes equinus may often be prevented by drawing down the foot to a sole splint made of thin wood, gutta-percha, or felt, and fastening it with a flannel bandage. The point of the foot may be drawn up toward the tibia by a strip of diachylon plaster. If the equinus has already developed, a splint of gutta-percha or of felt (Sayre) may be modelled to the leg and foot while the latter is held forcibly in dorsal flexion. The splint is attached by means of strips of adhesive plaster. It should extend as far as the knee, and be suitably padded (Seeligmüller).

In children able to walk a sole splint of thin metal, to which the foot had been previously attached by a flannel band, should be inserted in a stout leather boot. On the outer side of this boot should run a metallic splint, jointed at the ankle and extending to a leather band surrounding the leg just below the knee. A broad leather band, attached to the outer edge of the sole anterior to the talo-tarsal articulation, also passes up on

¹ *Loc. cit.*, p. 416.

the outside of the foot, gradually narrowing until, opposite the ankle, it passes through a slit in the side of the shoe, to be attached to the leg-splint. This band tends to draw the point of the foot outward, and thus correct the varus (Volkman). Sayre¹ has improved on this shoe by dividing the sole at the medio-tarsal articulation, in which lateral deviation takes place, and uniting the anterior and posterior parts by a ball-and-socket joint, permitting movement in every direction.

The orthopædic boot for the treatment of calcaneo-valgus is constructed on the same principle. But the splint runs up the inner side of the leg, and the leather strap passing to it from the edge of the sole draws the point of the foot inward and raises its depressed inner border (Volkman). Essential to the treatment of this deformity, however, is the elevation of the heel. This is effected by means of a gutta-percha strap which is attached below to a spur projecting from the heel of the shoe, and above to a band encircling the leg. If, by rare exception, a paralytic calcaneus exists in a child unable to walk, a simple substitute may be found for the shoe in a board sole-splint projecting behind the heel, attached to the foot by a strip of adhesive plaster, which finally passes from the posterior extremity of the board up the back of the leg, and is there secured by a roller bandage.

The device of the gutta-percha elastic band to replace the gastrocnemius muscle illustrates a principle of wide application in orthopædic apparatus. The suggestion to replace paralyzed muscles by artificial ones was first made by Delacroix² in an apparatus designed for the hand. The suggestion was repeated by Gerdy;³ and in 1840, Rigal de Gaillac proposed to exchange the metallic springs hitherto used for India-rubber straps. Duchenne elaborated the suggestion in a remarkable manner,⁴ using delicate spiral springs as a substitute for the lost muscles, and taking the greatest pains to make the insertion-points of these to exactly correspond with the insertions of the natural muscles. This was effected by means of sheaths, imitating natural tendinous sheaths, sewed to a glove or gaiter in which the hand or foot was encased.

At the present day the prothetic apparatus the most employed is that contrived by Barwell.⁵ The principle is the same as Duchenne's, but the artificial muscles are made of India-rubber, to which a small metallic chain is adjusted, and they are attached to the limb by means of specially-devised bands of adhesive plaster and pieces of tin bearing loops for the insertion of the muscle. In this apparatus the artificial muscles do not attempt to imitate the situation of the natural muscles with the precision which Duchenne claimed for his. Barwell's own dressing for talipes valgus consists of two rubber muscles which pass from the inner border of the foot, one to the inner, the other to the anterior, part of a band which encircles the leg just below the knee. For talipes calcaneus another band is required behind the leg, passing to the heel, as in Volkman's apparatus, already mentioned. For talipes varus a rubber band

¹ *Loc cit.*, p. 88.

³ *Traité des Bandages*, 2d ed., Paris, 1837, quoted by Duchenne.

⁴ See chapter on "Prothetic Apparatus" in his treatise *De l'Électrisation localisée*.

⁵ A tolerably minute account of the Barwell dressing is given by Sayre, *loc. cit.*, p. 84.

should pass on the outside of the foot; for equinus, one or more from the anterior part of the leg to the sides of the anterior part of the foot.

Sayre endorses Barwell's dressing as entirely adequate for the treatment of any form of club-foot, but modifies it by substituting a ball-and-socket shoe for the adhesive plaster which should encircle the foot. The artificial muscles are then passed from the sides of the shoe to a padded leather girdle encircling the leg. A straight splint, jointed opposite the ankle, runs up from each side of the foot to this girdle, and from it two lateral upright bars, jointed at the ankle, pass to the heel of the shoe; and from below the joint passes forward on each side a horizontal bar reaching the point of origin of the artificial muscles and giving attachment to them.

In equinus it is necessary to bind the heel of the foot down firmly in the heel of the shoe; and this is accomplished by means of two chamois-leather flaps which are attached to the inside walls of the shoe and lace firmly across the foot.¹

Sayre places so much confidence in the power of this elastic tension to overcome contractions that he rarely resorts to tenotomy in the treatment of paralytic talipes. Hueter, however,² considers tenotomy much the speediest, and therefore the most desirable, way of removing contractions.³

Seeligmüller quotes with approval Böttger's method for the treatment of deformities, where the weight of the body is utilized to stretch the retracted tendons. Thus, for talipes equino-varus an over-reduction is effected under ether, and the foot forced into a position of moderate calcaneo-valgus. In this position it is retained by the immediate application of a plaster or silica bandage. After this has hardened the child should be encouraged to walk in the mould, with the addition of felt shoes having a slanting sole that is thickened like a wedge at the inner side of the foot and strapped on like a skate. Then, during the act of walking the body tends to constantly force down the heel and thus stretch the retracted tendo Achillis, while the bandage and felt sole (acting like a splint) prevent the inner side of the foot from slipping up.

For talipes valgus the method is analogous, but the foot is forced into an equino-varus position, so that the tendo Achillis is artificially shortened, and ultimately becomes a rigid band, capable, in spite of the sural paralysis, of sustaining the heel.

A cause of relapse in talipes not unfrequently overlooked is the presence of even slight contractions of the hip- and knee-joints. These by shortening the limb tend to the production of equinus, since the foot points itself in order to reach the ground. These contractions, whose rigidity is far inferior to that induced by chronic arthritis, may be overcome by forced extension under ether or gradually by manipulations, or by the weight-and-pulley apparatus, applied in the recumbent position, as in morbus

¹ "The aim of the dressing or instrument is simply to imitate the action of the surgeon's hand; accordingly, any apparatus combining elastic force is far superior to any fixed appliance; and, moreover, that is to be preferred which is the most readily removable. Shoes, therefore, are better than bandages or splints. A proper shoe must have joints opposite the ankle and the medio-tarsal articulation; it must permit the ready application of elastic power; and it must not so girdle the limb as to interfere with the circulation" (Sayre, *loc. cit.*, p. 91).

² *Loc. cit.*

³ *Loc. cit.*

coxarius. The obvious objection to the latter method is the confinement in bed which it necessitates in a child enjoying at the time perhaps robust general health.

The contraction once overcome, the limb must be placed in apparatus which shall both maintain suitable extension and assist in supporting the trunk during station and locomotion. The latter purpose is effected, as in apparatus for chronic joint diseases, by transferring the weight of the body to steel splints running up each side of the limb, the outer one as far as a girdle which encircles the hips; the inner to a band surrounding the upper part of the thigh. Thus is extended the support which in paralysis limited to the leg-muscles is given by the steel splints inserted in the side of the club-foot shoes.

In the simplest form of apparatus locomotion is expected to be accomplished by the action of muscles inserted above the seat of the paralysis. Thus, when the muscles passing over the ankle-joint are paralyzed, the foot is moved as a dead weight by means of the quadriceps extensor, popliteus, and hamstring muscles inserted at the upper extremity of the leg. If the quadriceps cruris is paralyzed, the rotators of the thigh, ilio-psoas, sartorius, and adductor muscles, passing from the pelvis to the thigh, and which are so frequently intact in atrophic paralysis, are enabled to move the limb if the weight of the body is borne by steel splints, if these be light and properly jointed at the hip, knees, and ankle.¹

But an important aid to locomotion may be obtained from the artificial muscles, whose elastic tension is of such value in overcoming contractions. The quadriceps extensor, the most frequently paralyzed, may be supplemented by an India-rubber band and chain passing down the front of the thigh from a point on the pelvic girdle corresponding to the anterior iliac spine to a point on a leg-band, imitating the tibial insertion of the quadriceps tendon. Analogous bands stretched on the posterior aspect of the thigh simulate the hamstring muscles. When the external rotators are paralyzed, the artificial muscle must stretch from the pelvic girdle to a band encircling the upper part of the thigh.

The action of these muscles, apart from their elastic tension of repose, is thus explained by Duchenne: When any effort is made to move a paralyzed limb, the intact antagonists to the paralyzed muscles contract; thus, the flexors of the leg. But this contraction, being constantly opposed by the elastic tension of the artificial quadriceps, is restrained and gradual, instead of being brusque, jerking, and excessive, as it otherwise would be. This is the first result obtained. In the second place, contraction of the antagonist having ceased, the artificial muscle which has been stretched returns upon itself in virtue of its elasticity, and restores the limb to the position of normal equilibrium.

For the act of walking, however, the artificial quadriceps would require to be made tense enough to resist flexion, and thus keep the limb in extension. An artificial anterior tibial muscle, however, would require to yield to the intact gastrocnemius while the heel was being raised from the floor; then its elastic force should be sufficient to retract the point of

¹ Or the joint of the knee may be kept locked while the patient walks, when extension of the limb is mainly required, during both the active and passive movements of locomotion, the necessary flexion being supplied at the hip and ankle. By means of a key the knee-joint can be flexed during the sitting positions.

the foot in dorsal flexion during the pendulum movement which passively swings the leg forward. The tension of the artificial muscle should therefore be so adjusted that it can only be overcome by the active contraction of the gastrocnemius, and at the moment of greatest tension, immediately after stretching, it should be able to quite overcome the gastrocnemius, then relatively¹ relaxed.

The anterior tibial, gastrocnemius, and many other of the artificial muscles devised by Duchenne are still in use in the modified form given to them by Barwell. On the other hand, the action of the long peroneus in pronating the foot, and which Duchenne imitated by an elaborate artificial tendon following the exact course of the natural one, is to-day generally supplemented by the jointed shoe and laced bandage.

In paralysis of all the muscles surrounding a joint, when the limb is placid and no retractions by adapted atrophy have taken place, the artificial muscles can only serve to oppose the malpositions which are threatened from mechanical influences.

In the upper extremities prothetic apparatus has been principally used for progressive muscular atrophy. Paralysis of the wrist extensors is perhaps the only case in which the artificial muscle is required in anterior poliomyelitis. A string may be necessary to support the arm in paralysis of the deltoid, to avert luxation of the humerus.

Duchenne's ingenuity did not shrink from the difficult task of supplementing the muscles of the trunk. This he did by inserting the elastic spirals in corsets in a direction following that of the muscles paralyzed. Thus, a unilateral paralysis of the sacro-lumbalis may be met by a spiral splint running up one side of the spine; below, to the lateral posterior portion of a pelvic girdle. In bilateral paralysis two springs are used to antagonize the action of the abdominal muscles.

In Barwell's apparatus for the trunk² India-rubber bands are again substituted for spiral springs. No attempt is made to imitate the direction of muscles, but the force is applied in any direction required to antagonize the pressure producing the deformity.³

It is always important to remember the rarity of scoliosis caused by spinal paralysis of the trunk-muscles, and the much greater frequency with which this deformity occurs as a consequence of the paralytic shortening of a leg. A high shoe, equalizing the length of the lower extremities, is then the simple and efficient remedy.

In cases of long standing, even when the scoliosis is due to this cause, certain muscles on the concave side of the curve may become so retracted and rigid as to require tenotomy. Before this operation it is necessary to put the rigid muscles on the stretch as much as possible; and this may be done, if necessary, by means of Sayre's hanging apparatus. After this operation the spine may be straightened out with ease—an important distinction from advanced habitual scoliosis, where the alteration in the shape of the vertebræ defeats all attempts at rectification. The position

¹ We say relatively, believing that the simultaneous contraction of antagonist muscles has been well established as a constant normal phenomenon.

² Especially designed for habitual scoliosis, but applicable also to the paralytic deformity.

³ Volkmann (*loc. cit.*, p. 778) thinks that the force of Barwell's India-rubber straps, whether for scoliosis or club-foot apparatus, is inadequate, and much inferior to metallic springs.

may be maintained by elastic straps or corsets and by removing the condition which has led to the deformity.

Seeligmüller criticises too unfavorably the entire system of elastic tension in the prophylaxis and treatment of paralytic deformities. He quotes Duchenne's admission, that in certain cases traction upon rigidly-retracted tissues becomes insupportably painful, and must be abandoned. It is in these cases that tenotomy becomes an indispensable preliminary to the use of apparatus. Sayre insists that the necessity for tenotomy is indicated when pressure on the rigid muscle is followed by instantaneous spasmodic contraction in the affected or neighboring muscles. He declares that such contractions indicate reflex irritations, show that the muscle has undergone structural change, and that any attempt to stretch or lengthen it would be followed by an excess of irritation and pain.

This explanation can hardly be accepted, since muscles, whether imperfectly or not at all paralyzed, which from position and adapted atrophy have become retracted, have necessarily undergone structural changes. The greater these changes, the greater the diminution of reflex excitability; and in any muscle completely paralyzed and degenerated this is entirely lost. If, however, the afferent nerves retain enough vitality, if the muscle be slightly paralyzed or altogether intact, then irritation of its tendon by stretching may serve to excite contractions in the belly of the muscle. The possibility of such spinal reflexes is demonstrated by the now familiar phenomenon of the tendon reflex in various spinal diseases.¹ The contractions must be painful from the impediments offered to the progress of the contracting nerve, and from the exaggeratedly vicious position into which they tend to force the limb. Under these circumstances prosthetic apparatus must be deferred until section of the tendons has been made.

¹ "Passive muscular tension excites tonic contraction in a muscle, and this action may, in abnormal conditions, be excessive, as in the myelitic contractions (so-called tendon reflexes). . . . The afferent nerves commence in the fibrous tissues of the muscle, and seem to be especially stimulated by extension" (Gowers, *On Epilepsy*, 1881, p. 97).

DISEASE OF ONE LATERAL HALF OF THE SPINAL CORD.

By H. D. SCHMIDT, M. D.

SYNONYMS.—Unilateral lesion of the spinal cord; Spinal hemiplegia and hemiparaplegia; Unilateral spinal paralysis.

INTRODUCTION.—This disease remained unnoticed until twenty years ago, when Brown-Séquard, observing that certain lesions of the spinal cord were accompanied by symptoms resembling those which he witnessed in animals after section of one lateral half of the cord, recognized it as a special affection. Although some of the accompanying phenomena of such a section had likewise been observed by Stilling, Budge, Eigenbrodt, Tuerk, Schiff, Von Bezold, and Van Kempen,¹ nevertheless this whole group of symptoms, as belonging to the same disease, was first clearly recognized and anatomically demonstrated by Brown-Séquard.² According to this physiologist, a section or a destruction of a small portion of a lateral half of the spinal cord in its cervical region gives rise to the following phenomena: namely, on the injured side is observed a paralysis of voluntary motion, of the muscular sense, and of the blood-vessels; the latter, manifesting itself by a greater supply of blood and a higher temperature of the parts, may continue to exist for some years. There is, furthermore, an increased sensibility of the trunk and extremity to touch, prick, heat, cold, electricity, etc., owing to vaso-motor paralysis, though in some cases a slight anæsthesia may exist in a limited zone above the hyperæsthetic part, and also in certain parts of the arm, breast, and neck. Besides these symptoms, vaso-motor paralysis of the corresponding side of the face and of the eye, manifested by an elevated temperature and sensibility, partial closure of the eyelid, contracted pupil, slight contraction of some of the muscles of the face, etc., may also be present. On the opposite side of the injury an anæsthesia of all kinds of sensation, excepting the muscular sense, is observed in both extremities; there is also an absence of motor paralysis. The anæsthesia on this side is owing to the decussation of the sensory nerves in the spinal cord.

If the hemisection of the cord is made in the dorsal region, the functional disturbances are limited to that part of the body below the point

¹ Eckhard, "Physiologie des Nervensystems," in *Handbuch der Physiologie*, edited by L. Hermann, 2d part of vol. ii. p. 165.

² "On Spinal Hemiplegia," *Lancet*, Nov. 7, 21, and Dec. 12, 26, 1868, reported in *Virchow and Hirsch's Jahresbericht* for the year 1868, vol. ii. p. 37.

of division, and a hemiparaplegia, or paralysis of the corresponding lower extremity, will be the result.

From these facts it will be readily understood that a lesion occurring in any portion of one lateral half of the spinal cord of man must be followed by some or all of the above-mentioned symptoms, and that the phenomena produced by physiological experiments on animals constitute, in reality, the pathological basis of unilateral spinal paralysis in man. They will be more clearly understood by calling to mind the course of the musculo-motor, vaso-motor, and sensitive tracts in the spinal cord. Thus, the musculo-motor tracts, after having descended to the *crura cerebri*, cross one another in the pyramids of the medulla oblongata and adjoining upper portion of the spinal cord, forming the so-called decussation of the pyramids; they then descend through the spinal cord to supply the muscles of the same side of the body.¹ A section of one lateral half of the cord therefore causes motor paralysis on the same side. The vaso-motor tracts remain uncrossed, and pass, each, through one lateral half of the cord to supply the vessels on the same side; some regions of the body are stated to make an exception to this rule. According to Brown-Séquard, the sensitive tracts conducting the different kinds of sensation, with the exception of the muscular sense, on the contrary, cross over to the opposite half of the spinal cord soon after their entrance into it, and thence pursue their further course to the brain. A section of one lateral half of the cord, therefore, will be followed by a loss of sensation of touch, pain, heat, tickling, etc. on the other side of the body.

The symptoms above mentioned must of course vary according to the extent, the intensity, and the particular nature of the lesion, as well as the height at which it is located in the spinal cord.

DEFINITION.—The chief characters of unilateral spinal disease are motor paralysis, hemiplegia, or hemiparaplegia, paralysis of the muscular sense and of the blood-vessels on the side of the lesion, and paralysis of sensation with preservation of the muscular sense on the other side of the body. These symptoms may vary, and be accompanied by other phenomena according to the particular seat, extent, and depth of the lesion.

SYMPTOMS.—According to the nature of the lesion, the symptoms of unilateral disease of the spinal cord may be developed suddenly, as, for instance, when caused by traumatic injuries; or in a gradual and slow manner, when they may be preceded by premonitory symptoms, such as vertigo, pain on the side of the lesion, etc. The most prominent clinical phenomena, as before mentioned, are motor paralysis on the side of the lesion, and anæsthesia on the opposite side of the body. The motor paralysis on the side of the lesion may, according to the seat of the latter, manifest itself in either the form of a hemiplegia or hemiparaplegia, and even extend in a light form to the opposite side of the body. In typical cases, however, in which the injury or disease is strictly confined to one lateral half of the cord, the motor power on the other side

¹ Though, in the majority of cases, a complete decussation of the motor tracts probably takes place in the pyramids, the researches of Flechsig have shown (*Die Leitungsbahnen im Gehirn und Rückenmark des Menschen*, p. 273) that there are a number of others in which the decussation is not complete, but where a part of these tracts passes to the spinal marrow uncrossed on the inner surface of the anterior white columns.

of the body remains entirely undisturbed. At the same time, the muscular sense on the injured side is paralyzed or considerably diminished, and in some cases (Fieber, Lanzoni, Allessandrini) the electro-muscular excitability also has been found lowered, while in others it has remained normal. There is furthermore observed, on the side of the lesion, a vaso-motor paralysis, manifesting itself by a greater supply of blood to, and a higher temperature of, the paralyzed trunk and limbs, giving rise to an increase of sensibility (hyperæsthesia) of touch, prick, heat, cold, electricity, etc. in these parts. If the seat of the lesion is sufficiently high up in the cord, this paralysis extends, moreover, to the corresponding side of the face and eye, where it also causes an elevation of temperature, increase of sensibility, partial closure of the eyelid, contracted pupil, slight contraction of some of the muscles of the face, etc. In a number of cases at the boundary of the hyperæsthetic region a narrow anæsthetic zone is observed to exist on the breast, neck, or arm. This anæsthesia is owing to the division, at the level of the section, of some nerves of sensation on their way to the other half of the spinal cord. An increase of the reflex irritability of the tendons has in some cases (Erb, Schulz, Revillons) been observed, while in one case (Glaeser) the reflex was found to be absent. Swelling and œdema of the paralyzed limbs have also been met with (Glaeser), and in one case (Allessandrini) even swelling and pain in all the joints of the injured side were observed before death, while masses of coagulated blood in these joints, particularly in the knee, were revealed by the autopsy. The inflammatory affection of the knee-joint of the paralyzed leg has, moreover, been observed by Viguès, Joffroy, and Solomon.¹ Frequently, atrophy of the paralyzed muscles takes place, especially in chronic cases. In one case (Fieber) even atrophy of the upper extremity of the uninjured side of the body was observed.

The most prominent symptoms observed on the side of the body opposite to the seat of the lesion are anæsthesia of every kind of sensation, preservation of the muscular sense, and absence of motor paralysis. Reflex action and electro-muscular contractility generally remain normal, though in one case (Fieber) the latter was found increased. Although the anæsthesia of the skin generally comprises every kind of sensation, three cases were observed (Fieber) in which the sensation of heat remained unimpaired, while the electro-cutaneous sensibility appeared to be lost. As a general rule, there is no vaso-motor paralysis on the uninjured side, though in some cases (Erb, Allessandrini) an elevation of temperature has been observed.

Besides the above symptoms, some others, less characteristic in nature, are now and then observed in individual cases. They are painful sensations on one or the other side, or even simultaneously on both sides of the body, and also a feeling of constriction at the level of the lesion (Erb). Disturbances of the functions of the bowels or bladder are also met with, though in other cases they are absent.

PATHOLOGICAL ANATOMY.—The pathological changes taking place in the spinal cord of patients affected with unilateral spinal paralysis must vary in different cases according to the particular nature of the lesion giving rise to the characteristic symptoms. In those cases reported to

¹ Erb, "Diseases of the Spinal Cord, etc.," *Cyclopædia of the Practice of Medicine*, edited by H. v. Ziemssen, Amer. ed.

have terminated by a gradual disappearance of the symptoms with or without therapeutic interference it is very probable that the exciting cause was a hyperæmia or a myelitis of a small portion of one lateral half of the spinal cord, sufficiently high in degree to impair the conducting power of the nerve-fibres passing through it. In some cases the myelitis may lead to a degeneration of the nerve-fibres, or even extend to the other half of the cord, and by calling forth additional symptoms render the case more complicated. In syphilitic cases the disease depends upon syphilitic deposits or neoplasms in the affected portion of the spinal cord; these cases, however, generally yield to treatment. In the same manner may circumscribed sclerosis give rise to the disease. Another cause may be found in the compression of the cord caused by meningeal tumors or by the fractured portions of some of the vertebræ. Chronic disease of the vertebral bones themselves (Pott's disease) may also, by encroaching upon the spinal cord, become an exciting cause.

The most typical cases, however, are those depending upon traumatic injuries, by which one lateral half of the spinal cord is forcibly divided. These lesions resemble in nature the division of the cord in the physiological experiments on animals, and are most frequently caused by a stab from a knife penetrating to the cord through the intervertebral spaces.

DIAGNOSIS.—In those cases in which the symptoms of unilateral spinal paralysis appear soon after an external injury to the spine, it becomes obvious that the latter is the exciting cause. In cases of a more chronic character, in which the symptoms appear gradually, the nature of the exciting cause can only be correctly determined by the observation of certain collateral symptoms characteristic of such causes as might give rise to the symptoms of the disease in question. As regards the diagnostic symptoms of unilateral spinal paralysis themselves, they are sufficiently characteristic to be easily distinguished from those of other forms of hemiplegia or hemiparaplegia. Thus, cerebral hemiplegia may be distinguished from the disease under discussion by the sensory disturbances being either absent or on the same side as the paralysis; furthermore, by the one-sided paralysis of the face and of the tongue and by the affection of various cranial nerves. The hemiplegic form of spasmodic spinal paralysis is distinguished by the absence of sensory disturbance, etc. Lastly, hemiplegia depending upon lesion of one side of the cauda equina is distinguished from unilateral spinal disease by the paralysis and anæsthesia being confined to the same side, and by generally affecting certain nervous districts of the lower extremities.

PROGNOSIS.—In unilateral spinal lesions the prognosis depends obviously on the particular nature and intensity of the exciting cause. On the whole, there are quite a number of cases reported, even of traumatic origin, which have terminated favorably.

TREATMENT.—The treatment of unilateral spinal paralysis depends, like the prognosis, upon the nature of the exciting cause. The principles upon which it is to be pursued of course are the same as those upon which the treatment of the various lesions causing the disease—such as hyperæmia, myelitis, sclerosis, wound of the spinal cord, etc.—is based.

PROGRESSIVE LABIO-GLOSSO-LARYNGEAL PARALYSIS.

By H. D. SCHMIDT, M. D.

SYNONYMS.—Chronic progressive bulbar paralysis; Progressive muscular paralysis of the tongue, soft palate, and lips.

HISTORY.—Although the particular group of symptoms constituting this disease must have been met with and known to the older medical observers, they were nevertheless first recognized as a special variety of paralysis in 1841 by Trousseau,¹ who named the affection labio-glossolaryngeal paralysis. But as the memorandum prepared by this distinguished physician at the time when, in consultation with a medical colleague, he had observed the particular symptoms of this affection, unfortunately remained unpublished, twenty years more elapsed before the first accurate and detailed description of the symptoms and progressive nature of this disease under the name of progressive muscular paralysis of the tongue, soft palate, and lips was rendered by Duchenne. The writings of this author directed at once the attention of other medical men to this disease, and since that time a large number of cases have been reported and discussed,² while the microscopical examination accompanying the autopsies of many of them finally revealed that the seat of the lesion giving rise to the phenomena of this disease was to be sought in the nervous nuclei of the medulla oblongata. Hence at the present time the pathology of this disease is thoroughly understood.

DEFINITION.—That form of labio-glossolaryngeal paralysis to be treated in the following pages is characterized by a progressive paralysis and atrophy of the muscles of the tongue, lips, palate, pharynx, and larynx, interfering in a greater or lesser degree with the articulation of words and sounds and with the functions of mastication and deglutition—affecting, furthermore, in the later stages of the disease, the voice and the function of respiration. The paralysis is caused by a progressive degeneration and atrophy of the ganglion-cells of those nerve-centres in the medulla oblongata from which the muscles of the above-named organs receive their supply of nervous energy, though in most cases the pathological process extends to, or even beyond, the roots of those nerves

¹ *Clinique médicale de l'Hôtel Dieu de Paris*, vol. ii. p. 334.

² A very considerable number of cases of this disease, and discussions thereon, will be found reported in *Virchow and Hirsch's Jahresbericht über die Leistungen und Fortschritte der Gesamten Medizin*, for the years 1866–80, vol. ii., section “Krankheiten des Nervensystems.”

which originate in these centres and terminate in the respective muscles. In many cases the pathological process extends to the spinal marrow, and there causes paralysis and atrophy of the muscles of the trunk, and, generally, of the upper extremities. Almost in every case the disease, as its name indicates, slowly progresses until it terminates in death.

There are, however, a number of cases observed which, though exhibiting the same or similar symptoms, do not, in reality, depend upon a progressive degeneration and atrophy of the centres and nerve-roots of the medulla, but, on the contrary, owe their symptoms to other causes; as, for instance, to tumors, hemorrhages, syphilitic neoplasms, etc., which, either by pressing upon the medulla from without, or, if situated within, by deranging in various manners the individual nervous elements of that part, may give rise to some or even all of the symptoms of true labio-glosso-laryngeal paralysis. These symptoms, however, according to the character of the lesion, may, after remaining stationary for some time, retrograde, and even disappear, as has been observed in syphilitic cases; or they may progress, and finally end in death. In order to distinguish these cases from the chronic or progressive bulbar paralysis some authors have attached the term *retrogressive* to this form of the disease.

SYMPTOMS.—As the degeneration of the nerve-centres in the medulla oblongata, upon which the disease depends, does not proceed in a regular fixed order, the order in which the clinical symptoms successively appear also varies in different cases. In the majority of cases, however, the symptoms appear gradually, manifesting themselves generally in the form of a greater or lesser impediment in the articulation of certain sounds or letters depending upon the movements of the tongue, such as *e, i, k, l, s,* and *c*, while at the same time a difficulty of mastication and deglutition may be experienced by the patient, due to the progressive development of the paralysis, which deprives the tongue of its lateral and forward movements. To this cause also, at this period, the apparently increased secretion of saliva, running from the corners of the mouth, must be attributed. With intelligent patients these symptoms are rendered less prominent by the special effort which they make to pronounce slowly for the purpose of hiding the deficiency in their speech. But as the disease advances the difficulty of articulation increases on account of the paralysis extending to the orbicularis oris, thus affecting the mobility of the lips and interfering with the pronunciation of the labial sounds *p, b, f, m,* and *w*. With the loss of power of articulation the patient's speech becomes gradually reduced to monosyllables, or even, finally, to incomprehensible and inarticulated grunts, by which he expresses his wants to his friends. In consequence of the paralysis of the lips the patient becomes unable to whistle or blow or to perform any movement depending upon these organs, while at the same time, through the disturbance created in the co-ordination of the facial muscles by the paralysis of the orbicularis oris, the mouth becomes transversely elongated and drawn downward by the action of the remaining unparalyzed muscles upon its angles. With the mouth partially open and the lower lip hanging down, the face of the patient has a peculiar sad and painful expression, while the voice assumes a nasal sound on account of the paralysis of the palate.

After a while the difficulty of deglutition, caused by the inability of the

tongue to properly assist in the formation of the bolus of food and its propulsion into the pharynx, increases on account of the paralysis extending to the muscles of the pharynx. The failure of these muscles in the performance of their special function of grasping the food and carrying it to the œsophagus obliges the patient to push it down the pharynx with his fingers. In some cases the difficulty of swallowing rests with solids, in others with fluids. The defective deglutition furthermore gives rise to spells of coughing and suffocation by portions of food getting between the epiglottis and larynx, while the paralyzed muscles of the palate allow the fluids to pass through the nose and enter the posterior nares.

As the case slowly proceeds the symptoms grow worse. The paralysis of the orbicularis oris reaches a point when this muscle is no more able to close the oral cavity; the mouth of the patient therefore remains open. The tongue, having now entirely lost its lateral, forward, or upward movements, rests motionless upon the floor of the mouth, evincing no other signs of life but occasional slight muscular twitchings. In some cases a diminution of the sense of taste, and also of that of touch in the tongue, pharynx, and larynx, has been observed. Atrophy of the tongue and lips now sets in, and the function of speech is almost entirely lost. The only letter which the patient is still able to pronounce is *a* (broad); all other sounds are indistinct and can hardly be understood. The paralysis of the tongue and other muscles of deglutition gives rise, furthermore, to an accumulation of the now excessively secreted saliva, which, being retained in the oral cavity, assumes the form of a viscid mucous liquid dripping from the mouth, extending, in the form of strings or ribbons, between the surfaces of the lips. Finally, when, through the progressive paralysis of the orbicularis oris, the patient can no more close the lips, the flow of saliva from the mouth becomes continuous; he is then seen engaged in the constant use of his handkerchief for removing the secretion.

In the latter stages of the disease the pathological process extends to the centres of respiration, paralyzing not only the muscles of respiration, but diminishing at the same time the contractile power of the lungs. A great difficulty of breathing—consisting not only in the want of depth of the inspirations, but, moreover, in a feebleness of expiration (manifested by weak, powerless coughing)—then ensues, and the patient is no further able to blow his nose or clear his bronchial tubes from the accumulating mucus. The paralysis of the muscles of the larynx, also occurring at this stage, not only increases the difficulties of deglutition, but most seriously affects the voice of the patient by decreasing the innervation of the vocal cords; the voice then becomes hoarse and weak, to be finally entirely lost.

The decrease in the innervation of the heart—which, lastly, also occurs—gives rise to irregularities in the action of this organ, followed by irregularity of the pulse, attacks of syncope, feelings of extreme weakness, and fears of death; whilst simultaneously the insufficient performance of the respiratory function renders the breathing of the patient weaker and weaker. Feelings of great oppression in the chest then arise, and the patient may die during one of the now frequent attacks of dyspnoea and suffocation.

No fever or pain is observed during the course of this disease; sensation

remains unaffected and the mind is perfectly clear. It is owing to these circumstances that frequently the patient walks about and attends to the duties of life, until shortly before death he becomes confined to bed by the great weakness caused by the want of nutrition. The appetite also remains good, but, unfortunately, in consequence of the difficulties attending the act of deglutition, the patient cannot satisfy the demands of his stomach. In the latter stages of the disease, therefore, when feeding can only be accomplished by the aid of the stomach-tube, every attempt to relieve the terrible gnawings and pains of hunger ends in a failure. With starvation staring in his face, the unhappy victim of the disease finally sinks into a state of extreme inanition, which, if life is not suddenly extinguished by an attack of suffocation, slowly leads to final dissolution.

The symptoms above described are those generally observed in uncomplicated cases of labio-glossolaryngeal paralysis. There are, however, a number of cases reported in which the degenerative process has passed from the medulla oblongata to the spinal cord, and given rise to paralysis of the muscles of the neck, especially of the trapezius, and to those of the shoulders, and even to those of the upper extremities. Atrophy of the interosseus muscles of the hand, with those of the ball of the thumb, is not unfrequently observed. In other cases the disease has been found associated with progressive muscular atrophy, and in others, again, with paralysis of the lower extremities, accompanied by contractures and depending upon amyotrophic lateral sclerosis.

Labio-glossolaryngeal paralysis is, as before mentioned, slow but progressive in its course, the duration of which is from one to three, or even five, years. It always terminates in death within the limits of this time, either from suffocation, inanition, paralysis of the heart, or some other intercurrent disease.

PATHOLOGICAL ANATOMY.—The macroscopical and microscopical examinations made during the last fifteen years of the cerebro-spinal axis in quite a number of cases of progressive labio-glossolaryngeal paralysis show that this disease depends upon a degeneration of the nervous elements of the nuclei or nerve-centres in the medulla oblongata, involving also the roots of the nerves arising from the latter, and supplying with nervous energy the muscles of the different organs paralyzed in this disease. The exact nature of this degeneration—that is, whether it represents the sequel of a previously existing myelitis or originates in a so-called parenchymatous inflammation—appears to be as yet not definitely settled, though a number of pathologists entertain the view that it is preceded by a chronic myelitis. This view appears to be corroborated by the fact that frequently portions of the medulla oblongata and cervical portion of the spinal cord are found in a state of sclerosis. The uncertainty in the determination of the exact nature of the pathological process here concerned chiefly depends upon the diverse conditions in which the blood-vessels of the medulla are found. For while, in some cases, perhaps the majority, they have been found empty and in a normal condition, they have in others been met with congested with blood—a condition pointing to a chronic inflammatory process. In other cases, again, their walls have been found thickened or undergoing fatty degeneration.

At any rate, whether inflammatory or not, the now numerous microscopical examinations have revealed that the main features of the pro-

cess are a degeneration and atrophy, not only of the ganglion-cells of the respective nervous nuclei with their plexuses, but also of the fibres of the roots of the peripheral nerves arising from these centres; frequently the degeneration extends to some distance upon the nerves themselves. The microscopical changes in the ganglion-cells consist of an increase of yellow pigment, a gradual disappearance of their nuclei, terminating in an atrophy of the ganglionic bodies themselves, the pathological process leaving, finally, nothing but irregularly-shaped masses of pigment in the places of these bodies. The degeneration of the nerve-fibres appears to consist, as elsewhere, in a swelling of the axis-cylinder, accompanied by atrophy of the medullary sheath—a condition which finally leads to the complete destruction of these elements of the nerve-fibres, so that, at last, the whole nerve is only represented by the connective tissue of its neurolemma. Besides these changes, certain pathological products, such as conglomerations of fatty granules or globules, amylaceous bodies, etc., are also found in the degenerated nerve-centres and nerve-fibres.

Although in different cases the route which the degenerative process pursues is not the same, a certain general order, in which the nerves and nerve-centres are successively affected, and corresponding to the clinical symptoms, appears, nevertheless, to exist. It is thus that the nucleus of the hypoglossus has been observed to degenerate before the other nerve-centres. The nuclei of the spinal accessory and pneumogastric nerves, and also that part of the facial nucleus from which the inferior division of the facial nerve arises, appear to be affected next. The glosso-pharyngeal nucleus appears not to be affected in all cases, and still less frequently the nuclei and roots of the abducens, auditory, and trifacial nerves. The fibres forming the anterior pyramids have frequently been found degenerated throughout the medulla oblongata and pons; sclerosis also has been met with in this locality. In many cases, as has been remarked before, the pathological process descends into the spinal cord. Here, as in the medulla oblongata, the degeneration is principally confined to the motor centres located in the anterior horns, while the posterior horns, together with the lateral and posterior white columns, remain free from disease. The degree of degeneration taking place in the fibres of the respectively paralyzed muscles also corresponds to that of the elements of the nerve-centres from which they are supplied. The microscopical changes observed in the muscular fibres consist in a decrease of their diameter, accompanied by an increase in the number of their nuclei, as well as in the quantity of the connective tissue surrounding the primary bundles; some authors have observed amyloid degeneration of the muscular fibres.

ETIOLOGY.—The causes which give rise to the pathological process above described are but little known. Nevertheless, in a number of cases the disease has been traced back to taking cold, to physical as well as cerebral over-exertion, mental excitement, sorrow caused by misfortunes, poverty of nutrition, excessive use of tobacco, etc. In some cases the disease commences in the spinal cord in the form of progressive muscular atrophy or amyotrophic lateral sclerosis, and gradually extends to the medulla oblongata; in many other cases no particular cause can be found. The disease is rarely if ever met with in persons under twenty years of age, but is confined to adult life and old age. It occurs in

both high and low walks of life, attacking more frequently men than women.

DIAGNOSIS.—The symptoms of progressive labio-glosso-laryngeal paralysis are so characteristic in themselves as to exclude any mistake in the formation of a diagnosis. There are, nevertheless, some pathological conditions, such as hemorrhages in the medulla oblongata or thrombosis and embolism of the arteries supplying the latter with blood, which may give rise to the same or very similar phenomena, and thus render a correct diagnosis difficult. In such cases it must be remembered that the cause of true labio-glosso-laryngeal paralysis, depending upon degeneration and atrophy of the nervous nuclei along the floor of the fourth ventricle, is very gradual, while the symptoms produced by the causes before mentioned generally make their appearance in a more acute and sudden manner. The latter also, if not remaining stationary for some time, have rather a tendency to improvement, wanting, therefore, the progressive character of the former.

Tumors at the base of the brain also, by pressing upon the roots of the cerebral nerves or upon the medulla oblongata itself, may produce similar symptoms, which, on account of their comparatively slow and gradual development, may prove more difficult to distinguish from those characterizing genuine, progressive labio-glosso-laryngeal paralysis. Errors of diagnosis, however, may here be avoided by taking into consideration the special symptoms which generally accompany the presence of tumors of the brain, such as vertigo, headache, vomiting or even hemiplegia, and local paralysis. The sensory nerves also may become affected by the pressure of the tumor upon them. Thus, pressure upon the trifacial nerve may give rise to neuralgic pains, feelings of tingling and numbness, or even anæsthesia; while pressure upon the optic nerves or their tracts, or upon the olfactory and lingual nerves, will be followed by derangements of vision, smell, and taste. The symptoms produced by the pressure of a tumor at the base of the brain, moreover, are not strictly progressive, but may for some time appear, and disappear again before becoming permanent.

Facial diplegia, in which the expression of the face somewhat resembles that of a patient affected with labio-glosso-laryngeal paralysis, is distinguished from the latter disease by the paralysis affecting both divisions of the facial nerve, while the tongue remains free and deglutition is undisturbed.

There are still other affections of the cerebro-spinal axis, such as paralysis of the insane, disseminated sclerosis, etc., which in their course present some or perhaps all of the symptoms characterizing labio-glosso-laryngeal paralysis; these may be distinguished from the latter disease by taking their own special symptoms into consideration.

TREATMENT.—Although almost all cases of progressive labio-glosso-laryngeal paralysis terminate fatally, some cases have been reported by several observers in which a temporary improvement in the symptoms of the disease, or even a total cure, had been obtained by treatment. Of course such favorable results can only be obtained in the initial or earlier stages of the disease. Thus, Kussmaul recommends in the initial stage, when pains in the head and neck are present, wet cupping of the nape of the neck in strong persons, also the use of the shower-bath, while

nitrate of silver may be given internally. The application of galvanism in an alternate direction he also recommends—first, through the neck, and later on through the whole spinal column—and at the same time currents in an alternating direction from the neck and hypoglossus nerve to the tongue. Dowse reported a case of bulbar paralysis which he cured by the application of the constant current upon the paralyzed parts, subcutaneous injections of atropine and strychnine, with the internal administration of cod-liver oil, quinine, and phosphorus. He attaches great importance to the careful feeding of the patient through a tube passed through the nose, and to the strict application of the galvanic current; for excessive salivation he recommends atropine. Erb recommends to regulate the diet and the habits of life of the patient in such a manner as to avoid every irritation of the nervous system; furthermore, to generally stimulate the nutrition in order to produce a tonic effect upon the nervous system. For this purpose he principally relies upon a cautious hydropathic treatment, to be continued for a long time and with great regularity. The greatest importance, however, he attaches to electricity, considering the best method of galvanism as follows: "Galvanize with stable application transversely through the mastoid processes and longitudinally through the skull, the so-called galvanism of the cervical sympathetic (anode on the nuchus, and cathode at the angle of the lower jaw), and then induce movements of deglutition (twelve to twenty at each sitting); besides this, apply, according to circumstances, direct galvanic or faradic currents to the tongue, lips, and palate." The electric treatment must be continued for some time, with from four to seven sittings a week. Of the medicines taken internally, Erb recommends nitrate of silver, iodide of potassium, iodide of iron, chloride of gold and sodium, ergotin, belladonna, and preparation of iron and quinine.

DISEASES OF THE PERIPHERAL NERVES.

By FRANCIS T. MILES, M. D.

THE nervous system of the higher animals is the apparatus by which stimuli coming from the external world or originating in the interior of their own bodies are perceived (its sensitive functions), or cause muscular contraction (its motor functions), or, lastly, cause molecular changes in tissues (its trophic functions).

Besides this power which the nervous system possesses of receiving impressions originating outside of itself and actively replying to them, it appears also to possess the power of originating within itself changes the result of which are sensations, movements, and trophic alterations. In other words, it can act automatically.

The apparatus for the performance of these various functions consists of the end-organs, the nervous centres, and the nerves.

The end-organs are peripheral mechanisms for the reception of impressions. The structure and mode of action of some of them, as the eye and the ear, are pretty well understood, while others, as those connected with the sense of touch, temperature, etc., are but imperfectly known. It is probable that there are also peripheral mechanisms which facilitate the delivery of the impulses coming from the nerve-centres to the organs, tissues, muscles, glands, etc.

The nervous centres are made up of nerve-cells variously connected with each other. They are immediately concerned in receiving impressions conveyed to them by the nerves and transforming them into sensations, or transmitting them to other organs, causing reflex actions, or in originating sensations and impulses.

The nerves are organs which, connected at one extremity with the end-organs and at the other with the nervous centres, convey peripheral impressions to the centres, and impulses and influences from the centres to the various organs of the body.

As it is with diseases of the peripheral nerves that we are now concerned, let us begin by looking more closely into their structure and functions.

The nerves appear to the naked eye as white strands of variable size, which a close inspection shows to be made up of threads or fibrils (best seen when the cut end of a nerve is examined) bound together by fine connective tissue and scantily supplied with blood-vessels. A microscopic examination shows that each of the fibrils visible to the naked eye is made up of a great number of fibres. These are the medullated nerve-

fibres, and they extend unbroken between the nerve-centres, with the cells of which they are connected, to the various organs and tissues, with which they also enter into organic union.

If we examine the structure of a medullated nerve-fibre, we find it to consist of a central thread called the central axis or axis-cylinder, in which close microscopic investigation shows a longitudinal striation, indicating that it is made up of fibrillæ. Surrounding the central axis like a sheath is the white substance of Schwann, composed of an oleo-albuminous substance, myeline, to which the nerves owe their white appearance. According to some observers, the white substance of Schwann is pervaded by a meshwork of fibres. Surrounding the white substance of Schwann is the sheath of Schwann, a structureless membrane having at intervals upon its inner surface nuclei, around which is a small amount of protoplasm.

At intervals along the course of the nerve-fibres are seen constrictions which involve the sheath and white substance of Schwann, but which do not affect the central axis, which passes unbroken the points of constriction. These are the nodes of Ranvier. Each space on the fibre beneath the nodes of Ranvier contains one of the nuclei of the sheath of Schwann, and probably, together with the white substance of Schwann, represents a cellular element. Diseased conditions sometimes respect the limits of these cellular elements.

The central axis is the true conducting part of the nerve-fibre, and it is probable that each of the fibrillæ of which it is composed has a separate peripheral termination and possesses the power of isolated conduction. The white substance of Schwann and the sheath of Schwann protect the central axis and seem to be connected with its nutrition.

The fibres in a nerve are bound together by loose connective tissue, the endoneurium, into the primitive bundles, which are again united by the perineurium, a membrane of laminated connective tissue, into more definite funiculi seen by the naked eye, the secondary bundles.

The secondary bundles are tied together by connective tissue, in which are found fat-cells and in which run the fine blood-vessels supplying the nerves. This connective tissue has been named the epineurium, and its condensed outer layers constitute the sheath of the nerve. It is important to observe that the connective tissue of the nerves is permeated by lymphatics which penetrate to the nerve-fibres, so that these are brought in contact with, and as it were, bathed in, the lymph.

Each nerve-fibre runs an isolated course from end to end, without anastomosing with other fibres, and near its peripheral termination it usually divides into two or more branches.

The fibres of the peripheral nerves depend for their integrity and nutrition upon their connection with central organs. The large multipolar cells of the anterior horns of gray matter of the spinal cord preside over the nutrition of the motor fibres; the ganglia on the posterior roots of the spinal nerves over the nutrition of the sensitive fibres.

If a nerve be severed from its connection with these centres of nutrition, it in a short while undergoes degenerative changes which result in complete destruction of its fibres.

The nerve-fibres when in a state of functional activity conduct impressions along their length to the end-organs or to the nerve-centres with

which they are in connection. This property of the fibres we call their conductivity. Each fibre conducts impressions in an isolated manner, not communicating them to other fibres with which it may be in contact. The rapidity of this conduction in human nerve-fibres is estimated at 33.9 meters (about 38 yds.) per second. This rate may be diminished by cold or by the anelectrotonic condition which is induced in the nerve by the passage through it of an electric current.

The nerve-fibres are irritable; that is, the application to them of stimuli excites their functional activity, and the impression made by the stimulus is transmitted to their extremities.¹

The natural or physiological stimuli of the nerves act upon their extremities. Either they act through the peripheral mechanisms, giving rise to impressions which are conducted centripetally to the cells of the nerve-centres and there cause sensations or reflex actions, or they act upon the nerve-centres, giving rise to impulses which are conducted centrifugally and cause the various phenomena of contraction of muscles, inhibition of contraction, secretion, etc. Besides the physiological, there are other stimuli which excite the functional activity of nerve-fibres when applied at any point along their course.

Mechanical stimuli, blows, concussions, pressure, traction, etc., excite the nerves, causing sensations when applied to sensitive nerves, or contraction of muscles when applied to motor nerves. When mechanical stimuli are pushed farther, the irritability of the nerves may be destroyed. The gradual application of mechanical stimuli may destroy the irritability of nerve-fibres without any exhibition of excitation, as in paralysis from pressure. In nerve-stretching it is probable that many of the results depend upon the mechanical stimulation of the nerve-fibres by the traction. With a certain amount of force used the irritability of the nerve may be increased; carried farther, both the irritability and the conductivity may be diminished, and finally destroyed. As the centripetal fibres are soonest affected in the stretching, we can see how this proceeding is most beneficial in neuralgias, where a potent factor, if not the cause of the disease, is an abnormal excitability of the nerve-fibres. It is to be observed, nevertheless, that in cases of continued pressure upon mixed nerves the motor fibres are the first to suffer loss of their conductivity.

Sudden alterations of temperature act as stimuli to nerves. Heat increases their irritability, but its prolonged application diminishes it. Cold in general diminishes the nervous irritability, and may be carried to the point of completely destroying it temporarily.²

Many substances of widely-different chemical constitution, as acids, alkalies, salts, alcohol, chloroform, strychnine, etc., act as stimuli when applied directly to the nerves, apparently by causing in them rapid molecular changes. Also may be enumerated as chemical stimuli to the nerves substances found naturally in the body, as bile, bile salts, urea. The rapid withdrawal of water from nerve-tissue first increases, and then diminishes, its irritability. The imbibition of water decreases nervous irritability.

¹ The nerve-fibres in man do not appear to attain their full irritability until the fifth or tenth month after birth (Soltman).

² But at a certain age in freezing the ulnar nerve Mitchell found its irritability notably increased.

An electric current of less duration than the 0.0015 of a second does not stimulate the nerve-fibres. It would appear that more time is required for the electric current to excite in nerve-tissue the state of electrotonus which is necessary to the exhibition of its functional activity. The electric current stimulates a nerve most powerfully at the moments of entrance into and exit from the nerve, and the more abruptly this takes place the greater the stimulation. Thus the weak interrupted currents of the faradic or induced electricity owe their powerfully stimulating effects to the abruptness of their generation and entrance into and exit from the nerves. At the moment of the entrance of the electric current into the nerve—that is, upon closing the circuit—the stimulating effect is at the negative pole or cathode; when the current is broken—*i. e.* leaves the nerve—the stimulating effect is at the positive pole or anode. A current of electricity very gradually introduced into or withdrawn from a nerve does not stimulate it. But if while a current is passing through a nerve its density or strength be increased or diminished with some degree of rapidity, the nerve is stimulated, and the degree of stimulation is in proportion to the suddenness and amount of change in the density or strength of the current. Although with moderate currents the stimulation of the nerve takes place only upon their entrance and exit, or upon variations of their density, nevertheless, with a very strong current the stimulation continues during the passage of the current through the nerve. This is shown by the pain elicited in sensitive nerves, and the tetanic contraction of the muscles to which motor nerves are distributed.

An important factor in electrical stimulation is the direction of the current through the nerve. A current passed through a nerve at right angles with its length does not stimulate it. Currents passing through a nerve stimulate in proportion to the obliquity of their direction, the most stimulating being those passing along the length of the nerve. Motor nerves are more readily stimulated by the electric current the nearer it is applied to their central connection. Experiments on the lower animals would seem to indicate that the motor fibres in a nerve-trunk do not all show the same degree of irritability when stimulated by the electric current.

The irritability of the nerve-fibres may be modified or destroyed in various ways. Separation of nerves from their nutritive centres causes at first an increase of their irritability, which is succeeded by a diminution and total loss, these effects taking place more rapidly in the portions nearer the nerve-centres. It is important to observe that an increase of irritability preceding its diminution is generally observed in connection with the impaired nutrition of nerves, and is the first phase of their exhaustion.

Prolonged and excessive activity or disuse of nerves causes diminution of their irritability, which may go to the extent that neither rest in the one case nor stimulation in the other can restore it. If a galvanic current is passed through a nerve in its length, the irritability of the fibres is increased in the region of catelectrotonus—*viz.* in the part near the cathode—and diminished in the region of anelectrotonus—*viz.* in the part near the anode. Certain substances, as veratria, first increase and then destroy the irritability of the nerves; others, as woorara, rapidly destroy it.

The fibres of the peripheral nerves are divided into two classes: first, those which conduct impressions or stimuli to the nerve-centres, the afferent or centripetal fibres; and, secondly, those which conduct impulses from the centres to peripheral organs, the efferent or centrifugal fibres. Belonging to the first class are (1) sensitive fibres, whose stimulation sets up changes in the nerve-centres which give rise to a sensation; (2) excitomotor fibres, whose stimulation sets up in the nerve-centres changes by which impulses are sent along certain of the centrifugal fibres to peripheral end-organs, causing muscular contraction, secretion, etc. Belonging to the second class are (1) motor fibres, through which impulses are sent from the nerve-centres to muscles, causing their contraction; (2) secretory fibres, through which impulses from nerve-centres stimulate glands to secretion; (3) trophic fibres, through which are conveyed influences from the centres, affecting the nutritive changes in the tissues; (4) inhibitory fibres, through which central influences diminish or arrest muscular contraction or glandular activity. No microscopic or other examination reveals any distinction between these various fibres.

Every nerve-fibre has the power of conducting both centripetally and centrifugally, but the organs with which they are connected at their extremities permit the exhibition of their conductivity only in one direction. Thus, if a nerve-fibre in connection with a muscle at one end and a motor nerve-cell at the other be stimulated, although the stimulus is conducted to both ends of the fibre, the effect of the stimulus can only be exhibited at the end in connection with the muscle, causing the muscle to contract. Or if a fibre in connection with a peripheral organ of touch be stimulated, we can only recognize the effects of such stimulation by changes in the nerve-cells at its central end which give rise to a sensation.

When we consider the extensive distribution and exposed position of the peripheral nerves, their liability to mechanical injury and to the vicissitudes of heat and cold, we cannot but anticipate that they will be the frequent seat of lesions and morbid disturbances. It may be that not a few of their diseased conditions have escaped observation from a too exclusive looking to the central nervous system as the starting-point of morbid nervous symptoms. This occurs the more readily as many of the symptoms of disease of the peripheral nerves, as paralysis of muscles, anæsthesia, hyperæsthesia, etc., may equally result from morbid conditions of the brain or spinal cord, and not unfrequently the peripheral and central systems are conjointly affected in a way which leaves it doubtful in which the disease began or whether both systems were simultaneously affected.

The elucidation of such cases involves some of the most difficult problems in diagnosis, and requires not only a thorough acquaintance with the normal functions of the peripheral nerves, but also the knowledge of how those functions are modified and distorted in disease.

The symptoms arising from injuries and diseases of the peripheral nerves are referable to a loss, exaggeration, or perversion of their functions, and we often see several of these results combined in a single disease or as the result of an injury.

The fibres may lose their conductivity or have it impaired, causing feebleness or loss of motion (paralysis), or diminution or loss of sensation (anæ-

thesia). Or there may be induced a condition of over-excitability, giving rise to spasm of muscles and sensations of pain upon the slightest excitation, not only from external agents, but from the subtlest stimulation of molecular changes within themselves (*hyperæsthesia*). Or diseased conditions may induce a state of irritation of the nerve-fibres, which shows itself in apparently spontaneous muscular contraction or in sensations abnormal in their character, and not corresponding to those ordinarily elicited by the particular excitation applied, as formication or tingling from simple contact, etc. (*paræsthesiæ*), or in morbid alterations of nutrition in the tissues to which the fibres are distributed (*trophic changes*).

If we could recognize the causes of all these varied symptoms and discover the histological changes invariably connected with them, it would enable us to separate and classify the diseases of the peripheral nerves, and give us a sound basis for accurate observation and rational therapeutics. But, although the progress of investigation is continually toward the discovery of an anatomical lesion for every functional aberration, we are still so far from a complete pathological anatomy of the peripheral nerves that of many of their diseases we know nothing but their clinical history. We are therefore compelled in treating of the diseases of the peripheral nerves to hold still to their classification into anatomical and functional, as being most useful and convenient, remembering, however, that the two classes merge into each other, so that a rigid line cannot be drawn between them, and that such a classification can only be considered as provisional, and for the purpose of more clearly presenting symptoms which we group together, not as entities, but as pictures of diseased conditions which may thus be more readily observed and studied.

It is well to begin the study of the diseases of the peripheral nerves by a consideration of nerve-injuries, because in such cases we are enabled to connect the symptoms which present themselves with known anatomical alterations, and thus obtain important data for the elucidation of those cases of disease in which, although their symptomatology is similar, their pathological anatomy is imperfectly or not at all known.

Injuries of the Peripheral Nerves.

If the continuity of the fibres of a mixed nerve be destroyed at some point in its course by cutting, bruising, pressure, traction, the application of cold, the invasion of neighboring disease, etc., there will be an immediate loss of the functions dependent on the nerve in the parts to which it is distributed. The muscles which are supplied by its motor fibres are paralyzed; they no longer respond by contraction to the impulse of the will. No reflex movements can be excited in them either from the skin or the tendons. They lose their tonicity, which they derive from the spinal cord, and are relaxed, soft, and flabby. As the interrupted sensory fibres can no longer convey impressions to the brain, we might naturally look for an *anæsthesia*, a paralysis of sensation, in the parts to which they are distributed, as complete as is the loss of function in the muscles. Such, however, is not the fact. Long ago cases were observed in which, although sensitive nerves were divided, the region of their distribution retained more or less sensation, or seemed to recover it so

quickly that an explanation was sought in a supposed rapid reunion of the cut fibres. Recent investigations, moreover, show that in a large number of cases where there is complete interruption of continuity in a mixed nerve the region to which its sensitive fibres are distributed retains, or rapidly regains, a certain amount of sensation, and that absolute anæsthesia is confined to a comparatively small area, while around this area there is a zone in which the sensations of pain, touch, and heat are retained, though in a degree far below the normal condition; in short, that there is not an accurate correspondence between the area of anæsthesia consequent upon cutting a sensitive nerve and the recognized anatomical distribution of its fibres. We find the explanation of this partly in the abnormal distribution of nerves, but principally in the fact of the frequent anastomoses of sensitive nerves, especially toward their peripheral distribution, thus securing for the parts to which the cut nerve is distributed a limited supply of sensitive fibres from neighboring nerves which have joined the trunk below the point of section. This seems proved not only by direct anatomical investigation, but also from the fact that the peripheral portion of the divided nerve may be sensitive upon pressure, and that the microscope shows normal fibres in it after a time has elapsed sufficiently long to allow all the divided fibres to degenerate, in accordance with the Wallerian law. Some of the sensation apparently retained in parts the sensitive nerve of which has been divided may be due to the excitation of the nerves in the adjacent uninjured parts, caused by the vibration or jar propagated to them by the mechanical means used to test sensation, as tapping, rubbing, stroking, etc.¹ It is to be observed that this retained sensation after the division of nerves exists in different degrees in different regions of the body; thus it is greatest in the hands, least in the face.

As the vaso-motor and trophic nerve-fibres run in the trunks of the cerebro-spinal nerves, destructive lesions of these trunks cut off the influence of the centres with which those fibres are connected, and hence they are followed by changes in the circulation, calorification, and nutrition of the parts to which they are distributed. Thus, the loss of the vaso-motor influence is at first shown in the dilation of the vessels and the unvarying warmth and² congestion of the part.³ This gives way in time to coldness, due to sluggish circulation and diminished nutritive activity. Marked trophic changes occur in the paralyzed muscles. They atrophy, their fibres becoming smaller and losing the striations, while the interstitial areolar tissues proliferates, and finally contracts cicatricially. The skin is sometimes affected in its nutrition, becoming rough and scaly. Other trophic changes of the skin resembling those produced by irritation of a nerve are very rarely seen, and they may probably be referred to irritation of fibres with which the part is supplied from neighboring trunks.

¹ Létitiant, *Traité des Sections nerveuses*.

² A remarkable exception is seen, however, in the effect of gradual pressure experimentally applied to nerve-trunks until there is complete interruption of sensation and motion, in which case the temperature invariably falls.

³ In a case of gunshot wound that came under the writer's care in 1862, the leg and foot, which were paralyzed from lesion of the popliteal nerve, remained warm and natural in color during repeated malarial chills, which caused coldness and pallor of the rest of the body.

Anatomical Changes in the Divided Nerve and Muscles.—The peripheral portion of a divided nerve separated from its nutritive centres degenerates and loses its characteristic appearance, looking to the naked eye like a grayish cord, and being shrunk to one-fourth of its natural size. The changes which take place in the degeneration of the nerve-fibres, and which proceed from the point of lesion toward the periphery, are, first, an alteration of the white substance of Schwann, which breaks into fragments, these melting into drops of myeline, and finally becoming reduced to a granular mass. The central axis at a later period likewise breaks up, and is lost in the granular contents of the sheath of Schwann. Meanwhile, absorption of the *débris* of the fibres goes on, until, finally, there remains but the empty and collapsed sheath of Schwann with its nuclei, the whole presenting a fibrous appearance. When this has taken place the degenerated motor nerve-fibres can no longer be excited, and no stimulation applied to them can cause the muscles to contract. At the same time, the muscles atrophy and undergo degenerative changes in their tissue. The fibres become smaller and their transverse striæ indistinct, with the appearance of fatty degeneration, and finally there is proliferation of the interstitial cellular tissue. They do not, however, lose their contractility, and upon a mechanical stimulus being applied directly to them they contract in a degree that is even exaggerated, but with a slowness that is abnormal. If, now, we apply the stimulus of electricity to the muscles themselves, we encounter phenomena of the greatest interest and importance. The application of the faradic current, however strong, elicits no contraction; there is loss of faradic excitability. But if the galvanic current be applied the muscles contract, and that, too, in reply to a current too weak to excite healthy muscles to action; there is increased galvanic excitability. The kind of contraction thus induced is peculiar, differing from that ordinarily seen in muscles. Instead of its being short, and immediately followed by relaxation, as when we make or break the galvanic current in healthy muscles, it is sluggish, long-drawn out, and almost peristaltic in appearance. This is characteristic of degenerated muscles, and is the degenerative reaction. But there is also a change in the manner in which the degenerated muscles reply to the two poles of the galvanic current. Instead of the strongest contraction being elicited, as in the normal condition, by the application of the negative pole to the muscle (C. C. C., cathode closing contraction), an equally strong or stronger is obtained by the application of the positive pole (A. C. C., anode closing contraction), while the contraction normally caused on opening the circuit by removal of the positive pole (A. O. C., anode opening contraction) becomes weaker and weaker, until it is at last exceeded by the contraction upon opening the current by the removal of the negative pole (C. O. C., cathode opening contractions). In short, the formula for the reply of the healthy muscles to galvanic excitation is reversed; there is a qualitative galvanic change in the paralyzed and degenerated muscles.

If no regeneration of the nerve takes place, the reaction of the muscles to the galvanic current is finally lost, and they exhibit those rigid contractions which probably result from a sclerotic condition of the intramuscular areolar tissue.

After complete destruction of the fibres of a nerve at some point of its

course, even when a considerable length of it is involved, and after the consequent degeneration of the peripheral portion has taken place, we have, with lapse of time, restoration of its function, consequent upon its regeneration and the re-establishment of its continuity. The histological changes by which the degenerated fibres are restored and the divided ends reunited have not been made out with such certainty as to preclude difference of opinion as to the details. But the process in general seems to be a proliferation of the nuclei in the sheath of Schwann, with increase of the protoplasm which surrounds them, filling the sheath of Schwann with the material from which the new fibre originates. In this mass within the sheath is formed first the central axis of the new fibre, which is later surrounded by the white substance of Schwann. With the regeneration of the nerve-fibres the functions of the nerve return, but in the order of sensation first, and afterward the power of transmitting the volitional impulse to the muscles. Even after regeneration has so far advanced that the muscles may be made to contract by an exercise of the will, the newly-formed fibres fail to respond to other stimuli; thus, the faradic current applied to the nerve does not cause the muscles to contract; the stimulation is not transmitted along the imperfectly restored fibres.

It may be here remarked that after regeneration has restored the functions of a divided nerve the muscles to which it is distributed may still exhibit for a time the degenerative reaction in consequence of unrepaired changes in themselves. In the end we may look for complete restoration in both nerve and muscles.

The time required for the regeneration and reunion of a divided nerve depends somewhat upon the manner in which the destruction has been caused. Thus, a nerve which has been divided by a clean cut, and where the cut ends remain in apposition or close proximity, unites much more readily than one in which bruising, tearing, or pressure has destroyed an appreciable length of its fibres or the divided ends have been thrust apart.

In complete division of a nerve we must not look for regeneration and restoration of its functions, even in favorable circumstances, before the lapse of several months, although cases have been recorded where the process has been much more rapid.

Injuries of mixed nerves, with incomplete destruction of the fibres, give rise to many and varied symptoms, some of which are the direct result of the injury—many others of subsequent changes of an inflammatory character (neuritis) in the nerves or in the parts to which they are distributed. Pain is one of the most prominent symptoms immediately resulting from nerve-injury, although as a rule it soon subsides. There is sometimes merely numbness or tingling, or there may be no disturbance of sensation at the moment of injury. Rarely is spasm of muscles an immediate effect. Generally, motion is at first very much impaired, but if the injury is not grave enough to cause a lasting paralysis, the muscles may rapidly regain their activity. In observing the effects of injuries of mixed nerves one remarkable fact strikes us: it is the very much greater liability of the motor fibres to suffer loss or impairment of function. Thus, it is common to see sensation but little or only transiently affected by injuries which cause marked paralysis of muscles.

So in the progress of recovery the sensory disturbances usually disappear long before restoration of the motor function ; indeed, sensation may be entirely restored while the muscular paralysis remains permanent. Direct experimental lesions of the mixed nerve-trunks of animals give the same result.¹ For this immunity of the sensitive nerve-fibres no explanation can be given other than an assumed difference in their inherent endowments.

According to the amount of damage the nerve has sustained will there remain after the immediate effects of the injury have passed off more or less of the symptoms already described as due to loss of conductivity in the fibres—viz. paralysis of motion, and anæsthesia. Sometimes the impairment of conductivity in the sensitive fibres shows itself by an appreciable time required for the reception of impressions transmitted through them, giving rise to the remarkable phenomenon of delayed sensation. Degeneration of the nerve peripherally from the point of lesion, and consequently of the muscles, will likewise take place in a greater or less degree, according to the amount of the injury and the subsequent morbid changes, and give rise to the degenerative reaction which has been already described. We will not, however, always encounter the degenerative reaction in the typical form which presents itself after the complete division of nerves. Many variations from it have been observed ; as, for instance, Erb's middle form of degenerative reaction, in which the nerve does not lose the power of replying to the faradic or galvanic current, but the muscles show both the loss of the faradic with increased galvanic excitability, with also the qualitative change in regard to the poles of the galvanic current. Such irregularities may be explained by the supposition of an unequal condition of degeneration in the nerve and the muscles. A rare modification has been recorded which has once come under the writer's observation, in which the muscles reply with the sluggish contraction characteristic of the degenerative reaction to the application of the faradic current.

A highly important class of symptoms arise later in injuries of nerves, due not so much to a loss as to an exaggeration or perversion of their functions : they are the result of molecular changes in the nerves, giving rise to the condition called irritation. Irritation of motor nerves shows itself in muscular spasm, or contractions of a tonic or clonic character, or in tremor. If the sensitive fibres are irritated by an injury or the subsequent changes in the nerve resulting from it, we may have hyperæsthesia of the skin, in which, although the sense of touch may be blunted, the common sensation is exaggerated, it may be, to such a degree that the slightest contact with the affected part gives rise to pain or to an indescribable sensation of uneasiness almost emotional in its character—something of the nature of the sensation of the teeth being on edge. There may be hyperæsthesia of the muscles, shown by a sensitiveness upon deep pressure, in which the skin has no part. Pain, spontaneous in its character, is a very constant result of nerve-irritation, whether caused by gross mechanical interference or by the subtler processes of inflammation in the nerve-tissue. It is generally felt in the distribution of the branches of the nerve peripheral to the point of lesion, although it is occasionally located at the seat of the injury. Neuralgias are a common result of the irritation of nerves from injuries.

¹ Luderitz, *Zeitschrift für klin. Med.*, 1881.

Causalgia, a burning pain, differing from neuralgia, and sometimes of extreme severity, is very frequent after injuries of nerves, especially in parts where the skin has undergone certain trophic changes (glossy skin). A number of abnormal sensations (paræsthesiæ) result from the irritation of sensitive fibres, and are common after nerve injuries. Among these we may mention a sensation of heat (not the burning pain of causalgia) in the region of the distribution of the nerve, which does not coincide with the actual temperature of the part; it occurs not unfrequently after injury to a nerve-trunk, and may be of value in diagnosis.

The effect of irritative lesions of mixed nerves upon nutrition is very marked, and sometimes gives rise to grave complications and disastrous results. Any or all of the tissues of the part to which the injured nerve is distributed may be the seat of morbid nutritive changes.

In the skin we may have herpetic or eczematous eruptions or ulcerations. It may become atrophied, thin, shining, and, as it were, stretched tightly over the parts it covers, its low nutrition showing itself in the readiness with which it ulcerates from trifling injuries. This condition, called glossy skin, usually appears about the hands or feet, and is very frequently associated with causalgia. The hair may drop off, or, as has been occasionally seen, be increased in amount and coarsened, and the nails become thickened, crumpled, and distorted.

The subcutaneous cellulo-adipose tissue sometimes becomes œdematous, sometimes atrophies, and rarely has been known to become hypertrophied. The bones and joints, finally, may, under the influence of nerve-irritation, undergo nutritive changes, terminating in various deformities.

With regard to the trophic changes, as well as to the pain and paræsthesiæ resulting from nerve-injury, we must bear in mind that they may be attributed not only to the direct irritation of trophic and sensitive fibres in the injured nerve, but also, in part, to influences reflected from abnormally excited nutritive centres in the spinal cord, and to the spread of the sensitive irritation conveyed to the brain by the injured fibres to neighboring sensitive centres, thus multiplying and exaggerating the effect, causing, as it were, sensitive echoes and reverberations. Indeed, the variety of the symptoms resulting from apparently similar nerve lesions would seem to point to the introduction of other factors in their causation than the simple injuries of the nerve-fibres themselves.

DIAGNOSIS OF NERVE INJURIES.—Although in the great majority of cases the circumstances attending nerve injuries render their diagnosis a matter of little difficulty, it is yet important to keep in mind those symptoms which distinguish them from lesions or diseases of the brain and spinal cord, inasmuch as in cases of multiple lesion, injuries to the spinal column, or where the history of the case is imperfect, it may be difficult to determine to which part of the nervous system, peripheral or central, some of the gravest resulting troubles are due. Paralysis, spasm, anæsthesia, atrophy, etc. may be of central or spinal as well as peripheral origin, and an intelligent prognosis and rational treatment alike demand that we should distinguish between them. Moreover, many diseased conditions of the peripheral nerves of whose pathology we are ignorant, and in which localizing symptoms—*i. e.* those indicating the exact point at which the nerve is implicated—are wanting, can only be distinguished as peripheral affections by the occurrence of symptoms which we recog-

nize as identical with those arising from injuries of nerves, in which definite histological changes are known to occur. Indeed, cases of disease of the nervous system are not infrequent in which a careful study of their symptomatology leads to a difference of opinion in the minds of the best observers as to whether their seat is central or peripheral. We will notice here some of the prominent symptoms resulting from nerve injuries which may be useful in distinguishing peripheral from central lesions, although in many cases it is only by the careful consideration of all symptoms and the impartial weighing of all attending circumstances that a probable conclusion can be arrived at.

The rapid loss of muscular tone and the early atrophy of the muscles is a mark of paralysis from nerve-injury which distinguishes it from cerebral paralysis, even when the latter occupies circumscribed areas, as is sometimes the case in cortical brain lesion. In spinal paralysis also the muscles retain their tone and volume (the latter being slightly diminished by disuse), except in extensive destruction of gray matter, when all tonicity is lost, and in lesions of the anterior horns of gray matter (poliomyelitis), when there is loss of muscular tone and marked atrophy. The first of these spinal affections may be distinguished by the profound anæsthesia and by the paralysis being bilateral—by the implication of bladder and rectum and the tendency to the formation of bed-sores; such symptoms being only possible from nerve-injury when the cauda equina is involved. In poliomyelitis the complete integrity of sensation—which is almost always interfered with at some period after nerve-injury—and the history of previous constitutional disturbance will aid us in recognizing the diseased condition. While the reflexes are wanting in peripheral, they are, as a rule, retained, and often exaggerated, in cerebral and spinal paralysis; the exceptions being in the two lesions of the cord above mentioned, in which the reflex arc is of course destroyed by the implication of the gray matter. Loss or alteration of sensation, where it occurs from nerve-injury, generally shows itself in the distribution of the nerve, while the sensitive disturbances from disease or injury of the brain or spinal cord are less strictly confined to special nerve territories. The trophic disturbances arising from nerve-irritation are distinctively characteristic of nerve-injury.

But it is in the behavior of the nerves and muscles to electricity that we find some of the strongest points on which to base a diagnosis of nerve-injury, and, although not always conclusive as to the seat of lesion, it enables us to reduce within very narrow limits the field for discrimination. The degenerative reaction which we have seen takes place in muscles the continuity of whose nerves have been destroyed, or in which degenerative changes have taken place in consequence of injury to their nerves, is never found in muscles paralyzed from the brain. In spinal paralysis resulting from transverse myelitis the electrical excitability of the nerves and muscles may be increased or diminished, but there is no degenerative reaction. In progressive muscular atrophy a careful electrical examination may discover the degenerative reaction in the affected muscles; but it is too obscure, and there are besides too many characteristic symptoms in that disease, to allow of a practical difficulty in diagnosis from its presence. In poliomyelitis anterior (infantile paralysis and the kindred affection in the adult) we have, it is true, the quantitative,

qualitative changes of degenerative reaction, such as are seen after nerve-injury, and in such cases its presence is not conclusive of peripheral lesion. Here we may be assisted by remembering that while in poliomyelitis sensation is intact, in nerve-injury it is almost always affected in a greater or less degree, although it may have been recognizable but for a short time. In lead paralysis we also have the degenerative reaction, but whether the seat of lesion in that affection is central or peripheral is an undecided question.

TREATMENT OF NERVE-INJURIES.—The therapeutics of nerve-injuries belong largely to surgery. When there is complete division of a nerve the ends should be united by suture at the time of injury. When this has not been done, and after the lapse of time no return of function is observed, the ends of the nerve should be sought for, refreshed with the knife, and brought together by suture. There is the more hope that such a procedure will be successful as we know that after a time the fibres of the peripheral portion of the nerve may be regenerated, even when there has been no reunion, and thus be in a condition to render the operation successful. It is a matter for consideration whether in injuries in which a certain portion of the nerve, not too great in extent, has been crushed or otherwise obviously destroyed, it would not be best to excise the destroyed portion and bring the ends together. Whether the use of electricity, the galvanic current, hastens the regeneration and restitution of the injured nerves cannot be affirmed with certainty, although in practice this has seemed to us to be the case, and the known catalytic action of the current gives us a possible explanation of such beneficial effects. But, however this may be, it is certain that with the first symptoms of returning function in the nerves and muscles the use of electricity obviously accelerates the improvement. And, again, in the treatment of the results of nerve-injury, such as paralysis, anæsthesia, pain, it is in the careful and very patient use of the electric currents, both faradic and galvanic, that most confidence is to be placed; the galvanic being generally most applicable and giving the better results. The symptoms of nerve-irritation are amongst those most difficult to treat successfully. Counter-irritation, heat, cold, electricity, may all be tried in vain, and as a last resource against pain, ulceration, and perverted nutrition we may be obliged to resort to nerve-stretching, or neurotomy. Under the head of Neuritis much must be said of treatment applicable to the inflammation, acute and chronic, resulting from nerve-injuries.

INFLAMMATION OF NERVES.

Neuritis.

ALTHOUGH inflammation of the nerves has been for a long time a recognized disease, its frequency and the extent and importance of its results have been appreciated only within a comparatively short time. The observations upon neuritis were formerly almost exclusively confined

to acute cases, the results of traumatic lesions or the invasion of neighboring disease, while the more obscure forms occurring from cold, toxic substances in the circulation, constitutional disease, etc., or those apparently of spontaneous origin, escaped attention, or were classed according to their symptoms simply as neurosis, functional disease of the nerves, or affections of the spinal cord. Hence the classic picture of neuritis is made to resemble exclusively the acute inflammation of other tissues, and tends to blind as to the subtler but not less important morbid processes in the nerves which at present we must classify as inflammation, though wanting, it may be, in some of the striking features seen in connection with inflammatory processes elsewhere. In short, we must not look for heat, redness, pain, and swelling as absolutely necessary to a neuritis.

Entering into the structure of the peripheral nerves we have the true nervous constituent, the fibres, and the non-nervous constituent, the peri- and endoneurium, in which are found the blood-vessels and lymph-channels. Though intimately combined, these tissues, absolutely distinct structurally and functionally, may be separately invaded by disease; and although it may not be practicable nor essential in every case to decide if we have to do with a parenchymatous or interstitial (peri-) neuritis, it is necessary to keep in mind how much the picture of disease may be modified according as one or the other of the constituents of the nerve are separately or predominantly involved. Thus, a different group of symptoms will be seen when the vascular peri- and endoneurium is the seat of inflammation from that which appears when the non-vascular nerve-fibres are themselves primarily attacked and succumb to the inflammatory process with simple degeneration of their tissue. Furthermore, it is not too speculative to consider that the different kinds of nerve-fibres may be liable separately or in different degrees to morbid conditions, so that when mixed nerves are the seat of neuritis, motor, sensitive, or trophic symptoms may have a different prominence in different cases in proportion as one or other kind of fibres is most affected.

ETIOLOGY.—Traumatic and mechanical injuries of nerves are the most common and best understood causes of neuritis. Not only may it be occasioned by wounds, blows, compression, and other insults to the nerves themselves, but jolting and concussion of the body, and even sudden and severe muscular exertion, have been recorded as giving rise to it. We readily understand how neuritis is caused by the nerves becoming involved in an inflammation extending to them from adjacent parts, although the nerves in many instances show a remarkable resistance to surrounding disease. Less easily understood but undoubted causes of neuritis are to be found in the influence of cold, especially when the body is subjected to it after violent exertion. Although the causal connection is unexplained, we find neuritis a frequent sequel of acute diseases, as typhoid fever, diphtheria, smallpox, etc. In the course of many chronic constitutional affections, as syphilis, gout, elephantiasis græcorum, we encounter neuritis so frequently as to make us look for its cause in these diseases. Finally, neuritis may develop apparently spontaneously in one or many nerves.

MORBID ANATOMY.—The macroscopic appearance of nerves affected by neuritis is very varied, according as the disease is more interstitial or parenchymatous, acute or chronic. Sometimes the nerve is swollen, red,

or livid, the blood-vessels distended, with here and there points of hemorrhage, the glistening white of the fibres being changed to a dull gray. Sometimes the nerves are reduced to gray shrunken cords. When the perineurium has been the principal seat of the inflammation we may have swellings at intervals along the course of the nerve (neuritis nodosa, perineuritis nodosa acuta) or, as in chronic neuritis, the trunk of the nerve may be hard and thickened from proliferation of the connective tissue, sclerosis of the nerve. The nerve does not always present the appearance of continuous inflammation, but the evidence of neuritis may be seen at points along its course which are separated by sound tissue. These points of predilection are usually exposed positions of the nerve or near joints. Often the nerve appears to the naked eye normal, and the characteristic changes of neuritis are only revealed by the microscope. The microscopical changes in neuritis may extend to all of the constituents of the nerve, and present the ordinary picture of acute inflammation, hyperæmia, exudation, accumulation of white corpuscles in the tissues, and even the formation of pus, the nerve-fibres exhibiting in various degrees the destruction of the white substance of Schwann and the axis-cylinder. Or, as in chronic neuritis, the alterations may consist in the more gradual proliferation of the peri- and endoneurium, which, contracting, renders the nerve dense and hard and destroys the nerve-fibres by compression. In acute as well as in chronic neuritis the perineurium may be exclusively affected, the fibres remaining normal (Curschman and Eisenlohr). The nerve-fibres themselves may be the primary and almost exclusive seat of the neuritis, exhibiting more or less complete destruction of all their constituent parts, except the sheath of Schwann, without hyperæmia and with little or no alteration of the interstitial tissue. Sometimes the fibres are affected at intervals, the degeneration occupying a segment between two of Ranvier's nodes, leaving the fibre above and below normal (*névrite segmentaire peri-axile*, Gombault). All of these lesions of the nerve-fibres may be recovered from by a process of regeneration, the fibres showing a remarkable tendency to recover their normal structure and function.

SYMPTOMS OF NEURITIS.—When a mixed nerve is the seat of an acute neuritis, with hyperæmia of its blood-vessels, it becomes swollen by inflammatory exudation, and can be felt as a hard cord amongst the surrounding tissues. It is not only highly sensitive to direct pressure, but muscular exertion, or even passive movement of the part, excites pain. Spontaneous pain is one of the most prominent symptoms, and is sometimes so severe and continuous as to destroy the self-control of the patient, and demand the employment of every agent we possess for benumbing sensibility and quieting the excited system. At first there may be hyperæsthesia of the skin in the region of the distribution of the nerve, but a much more constant and significant symptom is cutaneous anæsthesia, which generally makes its appearance early in the course of the disease. The degree and extent of the anæsthesia varies very much in different cases, but is seldom total, except over small areas, even when the inflammation has seriously damaged the nerve-fibres. This is explained by the sensibility supplied to the part by neighboring nerves, as already described in treating of traumatic nerve-injuries. Very characteristic of acute neuritis are various abnormal sensations (*paræsthesiæ*) which are

developed in a greater or less degree during the progress of the disease, and are described by the patients as numbness, tingling, pins and needles, burning, etc. In a case of acute neuritis of the ulnar nerve seen by the writer the patient was much annoyed by a persistent sensation of coldness in the little and ring fingers, which caused him to keep them heavily wrapped up even in the warm weather of summer. When motor symptoms make their appearance they begin with paresis of the muscles, which may increase rapidly to paralysis. As this is the result of destructive changes, more or less complete, in the motor nerve-fibres, we will have, as would be expected, accompanying the paralysis the symptoms already detailed in the consideration of nerve-injuries with destruction of continuity—namely, absence of muscular tone, loss of skin and tendon reflexes, increased mechanical excitability, atrophy of muscles, and the different forms of degenerative reaction, with loss of faradic contractility. When spasm or tremor has been observed in acute neuritis of mixed nerves, it is a matter of doubt whether it is not to be explained by reflex action of the cord excited by irritated centripetal fibres. Various trophic symptoms may show themselves, as herpes zoster or acute œdema. Erythematous streaks and patches are sometimes observed upon the skin along the course of the inflamed nerve-trunks. In chronic neuritis, into which acute neuritis generally subsides or which arises spontaneously, the symptoms above described are very much modified; indeed, cases occur which exist for a long time almost without symptoms. While the affected nerve may be hard and thickened by proliferation of its connective tissue, pain, spontaneous or elicited by pressure, is not of the aggravated character present in acute neuritis, and may be quite a subordinate symptom. It has more of a rheumatic character, is less distinctly localized, more paroxysmal, and has a greater tendency to radiate to other nerves. It is probable that many ill-defined, so-called rheumatic pains which are so frequently complained of are the result of obscure chronic neuritis. Anæsthesia and various paræsthesiæ are often more prominent symptoms than pain. Sometimes there is a hyperæsthetic condition of the skin, in which touching or stroking the affected part causes a peculiarly disagreeable nervous thrill, from which the patient shrinks, but which, however, is not described as pain.

The motor symptoms in chronic neuritis of mixed nerves often remain for a remarkably long time in abeyance or may be altogether wanting. They may appear as tremor, spasm, or contraction, these, however, being probably reflex phenomena. Most commonly there is paresis, which may deepen into paralysis with atrophy of muscles and degenerative reaction. The trophic changes dependent on chronic neuritis are frequently very prominent and important. The skin sometimes becomes rough and scaly, sometimes atrophied, smooth, and shining (glossy skin). Œdema of the subcutaneous cellular tissue is often seen, for example, on the dorsum of the hand, where it may be very marked. The hair of the affected part shows sometimes increased growth, sometimes it falls off. The nails may become thickened, ridged, and distorted. Deformity of joints with enlargement of the ends of the bones is not infrequently met with as the result of chronic neuritis. In short, we may meet with all of those trophic changes which have been described as arising from nerve-irritation, and which occur in chronic neuritis as the result of compression of

nerve-fibres by the contraction of the proliferated connective tissue in the nerve-trunk.

The symptom-complex varies greatly in neuritis, so that there is hardly a symptom which may not be greatly modified or even wanting in some cases—a fact, which, as we have already said, may be explained by the morbid process fixing itself exclusively or in different degrees upon one or other of the component parts of the nerve-trunk, or, it may be, upon fibres of different functional endowment. Thus pain, usually one of the most prominent symptoms of neuritis, may be quite subordinate, or even absent, in cases of neuritis acute in invasion and progress. In a case of neuritis of the ulnar nerve seen by the writer, beginning suddenly with numbness and paresis, and rapidly developing paralysis, atrophy of muscles, loss of faradic contractility, with degenerative reaction, there was no pain during the disease, which ended in recovery.¹ On the other hand, in mixed nerves the sensitive fibres may be long affected, giving rise to pain and various paræsthesiæ before the motor fibres are implicated, or these last may escape altogether.

The swollen condition of the nerve, so characteristic in many cases of neuritis where the perineurium is the seat of a hyperemia, is wanting in cases where the stress of the attack is upon the nerve-fibres themselves. Again, the trophic changes induced in the tissues by a neuritis may predominate greatly over the sensitive or motor alterations. Thus, in the majority of cases in which herpes zoster occurs it is without pain or paræsthesia. Indeed, in chronic neuritis the symptoms show such variations in different cases that it is difficult to give a general picture of the disease sufficiently comprehensive and at the same time distinctive. The prognosis in acute neuritis is generally favorable, although it must depend in a great measure upon the persistence of the cause producing it. Thus, if it has been excited by the inflammation of neighboring organs it cannot be expected to disappear while these continue in their diseased condition. In other cases the symptoms may subside with comparative rapidity; and so great is the capacity of the nerve-fibres for regeneration that recovery may be complete and nothing remain to indicate the previous inflammation. The nerve, however, that has once suffered from neuritis shows for a long time a tendency to take on an inflammatory action from slight exciting causes. If there has resulted an atrophy of muscles, we must expect some time to elapse before they recover their functional activity and normal electric reaction.

Acute neuritis most frequently passes into the chronic form, and it may then drag on indefinitely, stubbornly resisting treatment and giving rise to permanent derangement of sensibility, loss of muscular power, or perverted nutrition. Neuritis shows a tendency to spread along the affected nerve centripetally, sometimes reaching the spinal cord, and, as it has appeared in some cases, even the brain, causing tetanus or epilepsy.

Reflex paralyses, which at one time were believed to be the not infrequent result of nerve-irritation and inflammation, affecting from a distance the functions of the spinal cord, have been shown to be the effect of an extension of the lesion of the inflamed nerve to the cord, causing organic disease. Instances of the extension of a neuritis to distant nerves, as those of an opposite extremity, without the implication of the spinal

¹ "Two Cases of Neuritis of the Ulnar Nerve," *Maryland Medical Journal*, Sept., 1881.

cord (neuritis sympathica), are most probably cases of multiple neuritis, to be considered farther on.

The DIAGNOSIS of cases of traumatic neuritis can scarcely present a difficulty. Acute neuritis with spontaneous pain, swelling, and tenderness of the nerve, presents distinctive features hardly to be confounded with any other affection, although thrombosis of certain veins, as the saphenous, may present some of its symptoms. To distinguish chronic neuritis or the cases wanting those obvious symptoms just indicated (many cases of sciatica) from neuralgia is a more difficult task. The following distinctive points may be noted: In neuritis the persistent and continuous character of the pain helps us to distinguish it from the more paroxysmal exacerbations of neuralgia, and its tendency, often seen, to spread centripetally spontaneously or when pressure is made on the nerve, may be also considered as characteristic of neuritis. Cutaneous anaesthesia, paresis, and atrophy of muscles are distinctive in any case of a neuritis rather than a neuralgia. Herpes zoster and other trophic changes speak strongly for a neuritis.

In the TREATMENT of neuritis the first indication is to get rid, as far as possible, of such conditions as may cause or keep up the inflammation, as, for instance, the proper treatment of wounds, the removal of foreign bodies, the adjustment of fractures, the reduction of dislocations, the extirpation of tumors, etc. Absolute repose of the affected part in the position of greatest relaxation and rest is to be scrupulously enforced. In acute neuritis local abstraction of blood by leeches and cups in the beginning of the affection is of the greatest advantage and should be freely employed. The application of heat along the course of the inflamed nerve has appeared to us preferable to the use of ice, although this also may be employed with excellent effect. The agonizing pain must be relieved by narcotics, and the hypodermic injection of morphia is the most efficient mode of exhibition. Salicylic acid or salicylate of sodium in large doses contributes to control the pain. Iodide of potassium in large doses appears to act beneficially, even in cases with no syphilitic complications. In subacute or chronic neuritis local bloodletting is not as imperatively demanded as in the acute form, although it is sometimes useful. Here counter-irritation in its various forms and degrees, even to the actual cautery, is to be recommended. An excellent counter-irritation is produced by the application of the faradic current with the metallic brush. It appears from general experience that the counter-irritation has the best effect when applied at a little distance from the inflamed nerve, and not directly over its course. In the galvanic current we possess one of the very best means not only for relieving the symptoms of chronic neuritis, but for modifying the morbid processes in the nerve and bringing about a restoration to the healthy condition. Its application is best made by placing the anode or positive pole as near as possible to the seat of the disease, while the cathode or negative pole is fixed upon an indifferent spot at a convenient distance. The positive pole may be held stationary or slowly stroked along the nerve. Finally, in protracted cases nerve-stretching may be resorted to with great benefit. It probably owes its good effects to the breaking up of minute adhesions which have formed between the sheath of the nerve and the surrounding tissues, and which act as sources of irritation.

Multiple Neuritis, Multiple Degenerative Neuritis, Polyneuritis.

Cases of this important form of neuritis have been observed and recorded since 1864, but the resemblance of its symptoms to those of certain diseases of the central nervous system (poliomyelitis, Landry's paralysis, etc.) has prevented its general recognition, and it is only within the last few years that its distinctive pathological lesions have been demonstrated and its diagnosis made with considerable certainty. We can hardly overrate the importance of this in view of the great difference in gravity of prognosis between it and other diseases with which it may be confounded.

Multiple neuritis consists in a simultaneous or more or less rapidly succeeding inflammation of several or many usually bilaterally situated nerves, with a greatly preponderating, almost exclusive, lesion of the motor fibres. Commonly the disease attacks the lower extremities and progresses upward, although occasionally it has been seen to begin in the arms. It does not confine itself to the nerves of the extremities and trunk, but often involves the phrenics, causing paralysis of the diaphragm, and frequently invades one or more of the cranial nerves, notably the vagus, thus giving rise to the rapid heart-beat so often seen in the disease. In the cases of multiple neuritis observed the muscles of deglutition have never been paralyzed. The sphincter ani and bladder have likewise escaped. All degrees of acuteness are observed in the course it runs, from the cases terminating rapidly in death to those in which the disease extends over months, slowly involving nerve after nerve, until nearly all of the muscles of the body are paralyzed, when death may result or a more or less complete recovery take place. The invasion of the disease is in most cases sudden, even when its subsequent course is chronic, and is often marked by decided constitutional disturbance, as rigors, fever, delirium, albuminuria, etc. Disturbances of sensation are prominent among the initial symptoms, and are of great importance for the diagnosis of the disease. Severe, spontaneous, paroxysmal pain of a shooting, tearing character has ushered in most of the cases on record, remitting, however, during their progress. Pain is not always present, nevertheless, and cases not infrequently occur which run a painless course. In some cases which have come under the writer's notice spontaneous pain did not occur until some days after the disease was fully declared by other symptoms. More constantly present, and more characteristic of multiple neuritis, are the disturbances of sensation which show themselves in subjective feelings of numbness, tingling, pins and needles, coldness, burning, and other paræsthesiæ, which appear at its outset and continue to be present more or less during its course. Anæsthesia, not of a high degree nor at all coextensive with the paralysis of the muscles—sometimes, indeed, confined to very circumscribed areas—may be said to exist always in multiple neuritis—a fact of great diagnostic value. Hyperæsthesia of the skin is frequently seen. Hyperalgesia and analgesia are sometimes observed. Hyperæsthesia of the muscles is a very marked symptom in almost every case, and shows itself not only upon direct pressure being made, but also in the pain elicited by passive movements of the parts affected. Pressure upon nerve-trunks does not cause pain as

invariably as might have been expected from the location of the disease. Delayed sensation has been frequently observed.

Paresis of muscles, often commencing suddenly, is early seen in multiple neuritis, and increases until there is more or less complete paralysis, the most important feature of the disease. The paralyzed muscles present the flabby condition characteristic of muscles deprived of the tonic influence of the spinal cord. Atrophy, which is not commensurate, however, with the paralysis, soon begins, and may go on to an extreme degree. As the paralysis develops the tendon reflexes are lost, and there may be diminution or loss of the skin reflexes also. The paralyzed muscles lose their faradic contractility, and exhibit diminution of electric excitability to the galvanic current, and, finally, the various forms of degenerative reaction. It is remarkable that neither the impairment of sensation nor the paralysis is, as a rule, strictly confined to the areas of distribution of particular nerves, but is diffused over regions of the body. Thus in the limbs the motor and sensory symptoms are most marked at their extremities, gradually diminishing toward the trunk. In some cases multiple neuritis appears to have occasioned the inco-ordinate movements of locomotor ataxy. In the progress of the disease a rigidity and contracted condition of muscles may be developed, occasioning a fixed flexion of some of the joints. Profuse sweating, œdema of the hands and feet, trophic changes in the skin, mark at times the implication of trophic and vaso-motor nerves. Bed-sores do not occur.

The pathological changes in pure cases of multiple neuritis are found in the nerve-trunks, mainly toward their peripheral terminations, and in their muscular branches, the evidences of disease diminishing toward the larger trunks, the nerve-roots being unaffected and the spinal cord showing no lesions. Sometimes the affected nerves present, even to the naked eye, unmistakable proof of acute inflammation. They are reddened by hyperæmia, swollen by exudation, and small extravasations of blood may be seen among their fibres. The microscope shows congestion of the blood-vessels, exudation of the white corpuscles, even to the formation of pus, alteration of the endo- and perineurium; in short, all the evidence of an interstitial inflammation, the nerve-fibres being comparatively little altered, and suffering, as it were, at second hand. In most of the cases, however, the nerves macroscopically present little or nothing giving indication of disease. The microscopic changes, however, are extensive, and pertain almost exclusively to the nerve-fibres themselves. These are altered and degenerated, giving an appearance almost precisely the same as already described in treating of the changes occurring in nerves separated by injury from the centres—Wallerian degeneration.¹ There is no hyperæmia, thickening, or change in the endoneurium. So great are these differences in the microscopic appearance of the nerves in different cases of multiple neuritis that objection has been raised to classing the two varieties together, and it has been argued that we cannot with right designate the cases in which hyperæmia and other evidence of

¹ Gombault's observations (*Arch. de Névrologie*, 1880) would seem to show that there is a difference in the lesion of the fibres in neuritis from that in simple Wallerian degeneration, inasmuch as that in the former the first alteration is seen about the nodes of Ranvier, and occurs at points separated from each other by healthy fibre, and also in the more tardy destruction of the axis-cylinder.

a general inflammation are absent as neuritis. It has been, however, argued—apparently, to the writer, with better reason—that the same morbid influence which at one time affects the blood-vessels, causing their congestion and the passage through their walls of the white corpuscles and the exudation of inflammation, may at another time, by a direct and isolated influence upon the nerve-fibres, cause their degeneration; in other words, that there may be a parenchymatous neuritis, which shall affect only the nerve-fibres. The vastly disproportionate implication of the motor fibres would point to the fact of a selective infection in multiple neuritis of certain fibres, as there is a selective infection in poliomyelitis of the motor cells of the anterior horns of the spinal gray matter.

ETIOLOGY.—Much in the symptomatology of multiple neuritis, especially of its invasion, strongly urges us to the conclusion that it is a constitutional disease caused by an unknown morbid influence, the stress of which falls upon the nervous system. This view receives strong support from the history of the Japanese kak-ke or Indian beriberi, a disease at times epidemic in those countries, and which has the undoubted symptoms and the characteristic pathological alterations of multiple neuritis. After many acute infectious diseases neuritis of individual nerves is not uncommon, but the distinctive characteristics of multiple neuritis have, so far, been observed almost exclusively after diphtheria, to which it is not infrequently a sequel. It has been observed as the result at least occurring in intimate connection with polyarthritis, and the frequency with which it has occurred in the phthisical is remarkable. There have been not a few cases of multiple neuritis recorded as having been produced by chronic alcohol-poisoning. A well-marked case has come under the writer's observation in which the immediate cause was acute poisoning by arsenious acid, a very large amount having been taken at one dose by mistake. The poison of syphilis has been regarded as standing in a causal relation to multiple neuritis. For the rest, the exciting causes (probably acting in connection with a peculiar condition of the system) have appeared to be exposure to cold, great muscular exertion, direct mechanical injury to the nerves, as the rough jolting of a wagon, or the inflammation of a nerve which has in some unknown way extended to others.

The **DIAGNOSIS** of multiple neuritis in certain cases presents great difficulty, from the close resemblance of its symptoms to those of poliomyelitis. The prominent symptoms in the muscular system—viz. paralysis, atrophy, the degenerative reaction—are the same in both. It may be remarked, however, that in multiple neuritis the paralysis is more generally diffused over the muscles of the affected limbs, while in poliomyelitis it is more confined to the areas of distribution of particular nerve-branches. Pain is common to the beginning of both diseases, but it generally passes off more quickly and completely in poliomyelitis. The persistent hyperæsthesia of the muscles is wanting in poliomyelitis. But it is in the diminution and alteration of sensation that we have the surest means of distinguishing between the two affections. This symptom seldom or never fails to show itself in multiple neuritis, although its area may be circumscribed and it may be slight in degree, while it certainly makes no part of the symptomatology

of poliomyelitis. It has been asserted that the implication of the cranial nerves so often seen in multiple neuritis never occurs in poliomyelitis. When we consider the intimate connection of the anterior horns of the spinal gray matter with the motor nerve-fibres, it appears highly probable that the same morbid influence may invade both simultaneously or in quick succession, thus producing a complex of symptoms rendering a diagnosis very difficult, and probably giving rise to some confusion in the recorded symptoms of multiple neuritis. From Landry's paralysis multiple neuritis is to be distinguished by the impairment of sensibility, the loss of faradic contractility, and absence of the tendon reflex; from progressive muscular atrophy, by the loss of sensibility and the much more obvious degenerative reaction.

The PROGNOSIS of multiple neuritis is in the great majority of cases not grave, so far as life is concerned, even when there is extensive paralysis. Death may occur early in the acute form of the disease or it may take place at the end of chronic cases. When the disease proves fatal, it is from paralysis of the diaphragm and the other muscles of respiration. Where the paralysis and atrophy have been great, showing profound alteration of the nerves, a long time is required for recovery, and more or less paralysis, contracture, or defective sensibility may permanently remain.

The TREATMENT consists, at the outset, in rest and position, the local abstraction of blood (in cases where the nerve-trunk is swollen and tender), and the administration of such drugs as we suppose act favorably upon the inflammation of the nerves. Salicylic acid or salicylate of sodium seem to act beneficially in relieving the severe pains in the outset of the disease. Iodide of potassium, gradually increased until large doses are taken, has, in the experience of the writer, seemed to beneficially modify the course of multiple neuritis. The necessary relief of pain is best obtained by hypodermic injections of morphia, supplemented by heat applied to the affected nerves. To these means may be added rubbing with chloroform and applying to the painful parts cloths dipped in a 5 per cent. solution of carbolic acid. After the acute stage has been passed and in chronic cases, just as soon as we have reason to suppose that the degenerative process in the nerves has come to a standstill, we possess in the use of electricity the means of hastening the regeneration of the nerve-fibres, strengthening the paralyzed muscles, and restoring the sensation. The galvanic current is to be preferred, and it is to be applied to the crippled nerves and muscles—sometimes stable for its electrolytic action, sometimes interrupted to obtain its exciting and stimulating effect. The excitement to nerves and muscles by the use of the faradic current has also its uses in hastening recovery. Protracted treatment and much patience are required to overcome contractions and restore the nerves and muscles, and the effects of the disease may be seen for a long time in the weakness and diminished electric reaction of the muscles.

Anæsthesia of Peripheral Origin.

A prominent and important symptom of the lesion of peripheral nerves is the diminution and loss of cutaneous sensibility. Besides the anæsthe-

sia caused by the affections of the fibres themselves, which has been touched upon in the preceding pages, it may be produced by morbid states of the peripheral end-organs or cutaneous terminations of the nerves. Cold applied to a nerve-trunk may produce alterations which for days after cause numbness and paræsthesia in the surface to which it is distributed, and the application of cold to the surface of the body, as we know from common observation, causes blunting of the cutaneous sensations, especially that of touch. In this way, from exposure to the atmosphere at low temperatures, to cold winds, or by the immersion of the body in cold water, the end-organs of the nerves in the skin are morbidly affected, and anæsthesia results, the so-called rheumatic anæsthesia. Many substances, as acids, notably carbolic acid, alkalies, narcotics, etc., act upon the cutaneous end-organs in a way to destroy their capacity for receiving or transmitting impressions and produce a more or less persistent anæsthesia of the skin. In the anæsthesia so often observed in the hands and forearms of washerwomen we have an example of the action probably of several of these causes, as the frequent plunging of the hands into cold water and the action upon the skin of alkalies and alkaline soaps. The diminution or interruption of the circulation through the skin, as in ischæmia from spasm of the minute arteries due to an affection of the vaso-motor nerves, is also a cause of cutaneous anæsthesia. In *lepra anæsthetica* (*Spedalskhed*) the cutaneous anæsthesia is dependent upon a neuritis of the minute branches in the skin. The local anæsthesia met with so often in syphilis, though its pathology is doubtful, is not improbably sometimes caused by an affection of the peripheral nerves (neuritis?) and their end-organs. After many acute diseases, diphtheria, typhoid fever, etc., we have cutaneous anæsthesia in connection with muscular paralysis, the cause of both being a neuritis. The patient is made aware of the loss of sensation by some interference with his usual sensations and movements. If he puts a glass to his lips, the sensation is as if a bit were broken out of the rim; his accustomed manipulations are awkward, because of the want of distinct appreciation of the objects he holds; he fumbles in buttoning his clothes or he stumbles unless looking to his steps. An examination, nevertheless, almost always reveals that the anæsthesia is greater than would have been supposed from the subjective feelings of the patient; indeed, cases occur in which he is not aware of an existing defect of sensation. But a careful examination is not only required to determine the extent, but by it alone can we arrive at a knowledge of the quality of the anæsthesia—viz. whether there is a loss of all of the different kinds of sensation, whether they are affected in an unequal degree, or whether some have entirely escaped. Thus we must test for the acuteness of the simple sense of touch by comparing the sensations elicited by the contact of small surfaces of unequal size, as the point and head of a pin or pencil, observing the appreciation by touch of the patient for different substances, as woollen, silk, linen, cloth, or comparing the sensation of the anæsthetic part with the same part on the opposite healthy side of the body. The sense of locality and space may be examined by placing at the same instant upon the skin of the patient, his eyes being closed, two points (the anæsthesiometer or the points of a compass), and observing his capacity for appreciating the impression as double. As there is an enormous difference of acuteness of the space-

sense in the skin of different parts of the body (see textbooks of physiology)—ranging from the tip of the tongue, where the touch of two points separated 1.2 mm. gives a double sensation, to the thigh, where the points must be separated 77 mm. to be felt as two—we must be careful to consider in making the examination the normal space-perception of the region. Care must be taken not to repeat the test too often, as a rapid education of the surface to a more delicate appreciation of the impressions is the result. In certain abnormal conditions from spinal disease we have a condition of polyæsthesia in which the impression of one point is felt as two or more. The sense by which we appreciate the pressure of objects must be tested by placing upon the surface to be examined, in succession, objects of different weight, care being taken to have the area which touches the skin and the temperature the same in each. The parts to be tested must be firmly supported, and all muscular contraction on the part of the patient prevented. The temperature sense is examined by the application of hot and cold water or bodies of different temperature. We sometimes meet with a perversion of this sense in which the application of a cold surface to the skin gives the sensation of warmth, and the contrary. In testing the sense of temperature and the sense of pressure it is not the absolute capacity of appreciating on the part of the patient that we investigate, but the power of discriminating between different degrees of temperature or pressure. The sense of pain must likewise be tested, since morbid conditions occur in which it may be caused more readily than is normal by exciting the cutaneous nerves, and that, too, in parts which have in a great measure or quite lost the sense of touch; or, on the other hand, touch may be retained, while irritation of the skin can excite no feeling of pain (analgesia). We have in the faradic current an excellent means of testing the cutaneous sensibility, inasmuch as it excites the skin over the various parts of the body about equally, and it can be employed in very gradually increasing or decreasing strength. Its effects on the affected part must be compared with those produced on the healthy surface of other parts of the patient's body or on healthy individuals.

Frequently accompanying cutaneous anæsthesia, but constituting no part of it, are various paræsthesiæ, as formication, pins and needles, burning, etc. Pain, sometimes of great intensity, is not infrequently connected with it (anæsthesia dolorosa). The paræsthesiæ and pain are the result of irritation in some portion of the conducting tracts, and, together with the trophic changes so often seen in connection with nerve-injuries, they have been already considered under that head.

It is a very important point to make the diagnosis between central and peripheral anæsthesia, but it is often a matter of great difficulty, and sometimes not to be made at all. The history of the case must be carefully considered, and an examination made for symptoms of brain or spinal disease, the existence of nerve lesions, or if there is a history of toxic influences, etc. In peripheral anæsthesia the reflexes which may be normally excited from the affected surface are wanting, in contradistinction to anæsthesia of central origin, in which they are most generally retained or even increased. Concomitant trophic changes speak strongly for a peripheral origin, as do also paralysis and atrophy of muscles.

Loss of some of the forms of sensation, with retention of others—*i. e.* partial paralysis of sensation—indicate a central origin.

The TREATMENT of peripheral anæsthesia must look, in the first place, to removal, if possible, of its cause, and the treatment of diseased conditions, if any exist, of the nerve-trunks, as neuritis, mechanical injuries, etc. Local applications of a stimulating character may be advantageously used upon the anæsthetic parts. By far the most effective stimulant to the diseased nerves is the faradic or galvanic current, and it should be used in the way that will produce the greatest amount of excitation in the cutaneous end-organs. This is best done by applying the faradic current to the dry skin with the metallic brush, or by allowing the cathode of the galvanic current to rest upon it for some time.

The PROGNOSIS in peripheral anæsthesia is in the main favorable, but it must, of course, depend much on the gravity of the lesion causing it, as mechanical injury, pressure, neuritis, cold, etc. Rheumatic anæsthesia, the result of exposure to cold, is in general readily recovered from. Vaso-motor anæsthesia yields in most cases without difficulty to treatment. Washerwoman's anæsthesia and allied cases are intractable, and often resist the patient and well-conducted application of remedies.

As a concrete picture of peripheral anæsthesia we will give a description of anæsthesia of the fifth nerve—the rather that in its consideration we meet with some of the most interesting and important complications occurring in connection with paralysis of sensitive nerves. The fifth nerve may have either of its three branches separately affected, giving rise to anæsthesia limited to the distribution of that branch, or all of its fibres may be simultaneously involved, giving rise to complete anæsthesia of the nerve. In the latter case the lesion of the nerve in all likelihood exists at some point of its course between the apparent origin from the pons and the ganglion of Gasser, which rests upon the apex of the petrous portion of the temporal bone. Beyond this point the nerve divides into its three branches. Amongst the causes of trigeminal anæsthesia are injuries, tumors, syphilitic thickening of the dura mater, neuritis, etc., affecting the nerve within the cranial cavity. In complete anæsthesia of the fifth nerve the parts implicated are the skin of the forehead to the vertex, the nose, the lips, and chin up to the median line, the cheek and temporal region, including the anterior portion of the ear, the conjunctiva, the mucous membrane of the nose, the mucous membrane of the mouth, and partly of the fauces of the same side. The tongue is deprived not only of common sensation on the affected side in its anterior two-thirds, but the sense of taste is also lost over the same region, by reason that the fibres of the chorda tympani, the nerve of taste for this region of the tongue, are derived from the fifth nerve. If the whole thickness of the nerve-trunk is involved, including the small motor root, there is, in connection with the anæsthesia, paralysis of the muscles of mastication on the side affected, which may be distinguished by the want of hardening of the masseter when the jaws are forcibly brought together, and by the thrusting of the chin over to the paralyzed side when the mouth is widely opened, caused by the want of action of the external pterygoid muscle, which allows the condyle on the paralyzed side to remain in the glenoid fossa, while the condyle of the opposite side is pulled forward upon the articular eminence by the sound

pterygoid. The face is of a dusky or livid color, and cooler than natural. Ulcers of a stubborn character in the mucous membrane of the cheek may be caused by the patient unconsciously biting the insensitive parts. An inflammation of the conjunctiva is frequently set up, which may extend to the cornea, causing ulceration, perforation, panophthalmitis, and destruction of the eye (ophthalmia neuro-paralytica). This has been regarded by some as caused by trophic changes in the tissues, the direct result of irritation or destruction of trophic fibres connected with the ganglion of Gasser. Experiments made upon animals, however, seem to show that the inflammation of the eye depends upon the irritation caused by the intrusion of foreign bodies, which, owing to the loss of sensation, are not appreciated, and which from loss of reflex action are not removed by winking nor washed away by an increased lachrymal secretion, as in the healthy eye. It may be that although the latter is the true explanation of the origin of the inflammation, nevertheless the tissues may have lost their normal power of resistance to its invasion by reason of nutritive changes consequent upon the lesion of trophic fibres running in the trunk of the nerve. The reflexes ordinarily induced by irritation of the parts in their normal state are lost. Irritation of the conjunctiva causes no winking of the lids nor secretion of tears, and titillation of the nostrils no movements of the muscles of the face nor mucous or lachrymal secretion. The movements of the face are less lively on the affected side, not on account of paralysis of the muscles, but from the loss of that constant play of reflex activity in them which takes place in the normal condition. The loss of the reflexes distinguishes peripheral trigeminal anæsthesia from that of cerebral origin, in which they may still be excited by irritating the anæsthetic surfaces. In trigeminal anæsthesia, which sometimes occurs from the effect of cold upon the surface of the face, the mucous surfaces are not affected.

The SYMPTOMS and DIAGNOSIS of peripheral paralysis having been already given under the heads of Injuries of Nerves and Neuritis, a consideration of the distribution of any motor nerve will enable us to anticipate the distinguishing features of the paralysis dependent upon it. With each the picture will be modified according to the position of the muscles paralyzed and the motor functions destroyed. It now remains to give the symptoms, diagnosis, and treatment of the paralysis of an individual motor nerve, which may serve as an example and paradigm, in the consideration of which points of interest and instruction may be touched upon applicable to all other cases.

Peripheral Paralysis of the Facial Nerve (Bell's Paralysis).

Of all the peripheral paralyses, probably that of the seventh is the one we are most frequently called upon to treat and the symptoms of which are the most complex and interesting. The frequency of its paralysis is due to the length and peculiarity of its course, enclosed as it is in a bony canal which permits no increase of its volume without compression, the run of its terminal branches through parts liable to inflammation and disease (parotid gland), and their final distribution to parts exposed to all vicissitudes of heat and cold and in constant danger of mechanical injury.

The complexity and interest of the symptoms of its paralysis depend in a great measure upon the intimate connections it forms at different points of its course with the fibres of other nerves of entirely different functions (acoustic and fifth).

The seventh nerve is liable not only to intercranial compression from tumors, inflammation of the meninges, syphilitic processes, etc., but its long course through the petrous portion of the temporal bone renders it liable to injury from fracture or caries, and its close proximity to the middle ear causes it often to suffer from the diseased conditions of the bony walls or mucous lining membrane of that chamber, its paralysis being not infrequently the result of simple aural catarrh. After the exit of the nerve from the stylo-mastoid foramen it is imbedded in the parotid gland, and sometimes suffers from compression produced by an inflammation or abscess in that organ or by enlarged lymphatic glands in the neighborhood. Surgical operations, so often demanded for disease of the bones or soft parts of the face, may necessitate the lesion of its trunk or branches. The exposed position of this nerve is sometimes the occasion of its injury at the very outset of the life of the individual, when the application of the forceps to the head has been resorted to in delivery. But the most frequent cause of facial paralysis appears to be the exposure of one side of the face directly to cold—as sleeping in a draught of air, sitting at the open window of a railroad coach, etc. Here the causal connection appears evident from the rapidity with which the paralysis usually follows, although cases occur in which an interval of hours or days elapses after the exposure before the paralysis declares itself. Although this is usually designated rheumatic paralysis, there is nothing to connect it with that disease, nor are rheumatics more liable to it than others. Under such circumstances the paralysis is probably brought about by the occurrence of a neuritis of the nerve-trunk, which is compressed by the hyperemia, and it may be by an inflammatory exudation against the bony walls surrounding it, until not only does it lose the power of conduction, but its fibres undergo the degenerative process. In some cases the neuritis thus excited by exposure to cold attacks the nerve after it has issued from the bony canal, and then the resulting injury to the fibres is much less grave. Although in some cases there are prodromal symptoms, as stiffness or pain in the face, generally the paralysis occurs suddenly, very often being first observed upon awaking. The patient may be first made aware of the paralysis by an inability to drink without the fluid dribbling from the affected side of the mouth or by the overflow of tears from the eye of the same side. When the paralysis is recent and the face in complete repose, there may be little or no deformity to mark the condition of the muscles. When, however, the patient speaks or the slightest emotional or reflex movements of the face are excited, as laughing, frowning, etc., it becomes obvious from the bizarre grimace caused by a one-sided contraction. After the paralysis has existed for some time the contrast of the two sides of the face is marked. The paralyzed side is characterized by a vacancy of expression to which the staring, unwinking eye contributes. From loss of the tonicity of the muscles the angle of the mouth droops, and the expressive furrows and lines about the brow, below the eye, and beside the nose are smoothed out and obliterated. Speech is affected, inasmuch as the paralysis of the

lip interferes with the pronunciation of the labials, and all attempts to purse up the mouth, as in whistling, is abortive. The eye not only remains open, the lids motionless, but there is partial eversion of the lower lid (lagophthalmos), and the tears, no longer directed to the punctum (paralysis of Horner's muscle), flow over the cheek. The natural impulse to reflex winking caused by evaporation from the conjunctiva or by the contact of particles of dust is answered by a rolling of the eyeball upward to wipe the cornea beneath the momentarily relaxed and drooping upper lid. Excited respiration causes no movement of the ala of the nose on the affected side, but in deep inspiration, in contrast to the normal elevation of the ala, it is flattened down by the suction of the intrushing current of air. In masticating, the cheek bulges out from want of power in the paralyzed buccinator to press the food inward against the opposing movements of the tongue. In persons who have the rather unusual power of voluntarily moving the ear we may detect the paralysis of the muscles concerned in those movements—a useful point in diagnosis. Moreover, on the sound side of the face the features have not entirely the natural appearance. The angle of the mouth is drawn upward and the naso-labial line more deeply impressed than natural. This results not from excessive contraction, but from the muscles remaining in the position they have taken during contraction, the antagonistic tonic traction from the opposite side, which would have restored them to their normal position, being wanting. This may be in a measure remedied by mechanical appliances which will keep up an elastic pull from the paralyzed side, or by restoring the muscles after contraction to position with the hand. The tongue rests symmetrically in the floor of the mouth, and is thrust out straight, although in appearance it is pushed toward the side paralyzed—a deceptive appearance produced by the asymmetrical position of the mouth. In some cases there is partial paralysis of the velum palati, the half arch on the affected side hanging lowest, and if we cause the patient to make the sound of *ah* the opposite side of the palate is alone drawn upward. The uvula may also participate in the paralysis, but the explanation of its position, sometimes directed away from, sometimes toward, the side of the paralysis, cannot be given. In proportion to the amount of the paralysis of the soft palate will be the prominence of the symptoms caused by it, such as difficulty in deglutition, a nasal tone in speaking, and the escape of fluids through the nostril in swallowing. The sense of hearing is often affected coincidently with facial paralysis. Thus by reason of their close juxtaposition the same cause may in common affect the acoustic and the facial, causing imperfect hearing, subjective noises, etc. The hearing is frequently affected by diseased conditions of the middle ear, which also cause a facial paralysis. Still another defect of hearing, however, is caused by the paralysis of the facial nerve itself. The stapedius muscle, supplied by a branch of the facial, is the antagonist of the tensor tympani, and when it is paralyzed the over-tense tympanic membrane vibrates more readily to sound-waves, and a condition of uncomfortably exaggerated sensitiveness to sounds is the result (hyperacusis). The rarely-occurring symptom of dryness of the mouth on the side of the paralysis receives its explanation in the well-known fact of the presence of secretory fibres for the salivary gland in the chorda tympani, which are derived from the facial. We observe sometimes, in connection with facial paralysis, that the patient

complains of certain subjective sensations of taste, as sour or metallic, and an examination will in some cases reveal that the sense of taste is lost on the anterior two-thirds of the tongue on the side of the paralysis. The fibres which convey the sense of taste pass centripetally from the tongue in the chorda tympani nerve, join the facial just within the stylo-mastoid foramen, and continue united with it to the geniculate ganglion of the facial, at which point they leave it to pass in the great superficial petrosal to the sphenopalatine ganglion, and thence to the trunk of the fifth nerve. Loss of sensation over the face only occurs in cases where the fifth nerve has been simultaneously affected with the facial, which may occur from exposure to cold.

It is obviously of importance in cases of facial paralysis to determine if they are of central or peripheral origin. The most prominent symptoms which mark a peripheral paralysis are the implication of all the branches of the nerve, the loss of the reflexes, the development of the degenerative reaction, and atrophy of the muscles. In facial paralysis of cerebral origin the frontal and orbital branches are not at all or but slightly affected, leaving the eye with its natural appearance, in contrast to the lagophthalmos, and the open eye which does not close even in sleep. In cerebral paralysis the reflexes are normal and the muscles retain their natural electric reaction. Accompanying brain symptoms assure the diagnosis. In facial paralysis of bulbar origin the electric reactions are diminished, and we have a complex of symptoms made up in a great measure by the implication of neighboring nerves. After the diagnosis of a peripheral facial paralysis has been made, by a careful consideration of the symptoms we may with more or less accuracy determine at which point of the nerve the lesion is situated. If there is paralysis of all the muscles of the face, without alteration of taste or hearing, the electric reaction of nerve and muscles normal, the nerve is affected outside of the stylo-mastoid foramen. This is usually the form of slight rheumatic paralysis. If we discover that the muscles of the external ear are paralyzed, it shows that the point of lesion is just within the stylo-mastoid foramen, where the posterior auricular branch is given off from the facial. If with paralysis of the face there is alteration of the sense of taste, with dryness of the mouth, without interference with hearing, the trunk of the nerve is affected within the Fallopian canal, involving the chorda tympani fibres below the point where the stapedius nerve is given off. If to the above symptoms there is added over-sensitiveness to sounds, hyperacusis, and there is no paralysis of the palate, we have the nerve affected still higher up, but below the geniculate ganglion. If the geniculate ganglion is involved, there is, in addition to the foregoing, symptoms of paralysis of the palate. If, now, the lesion is above the geniculate ganglion, we will have eliminated the symptom due to implication of the chorda tympani, which leaves the trunk of the facial at the geniculate ganglion, and the sense of taste is unaffected, while there remains paralysis of the face, dryness of the mouth (the secretory fibres run in the trunk of the seventh), hyperacusis, and paralysis of the palate.

It was in facial paralysis that the first observations upon the degenerative reaction in muscles were made, and it is in that affection that these electric phenomena have been best studied, and give us the clearest indi-

cations for prognosis and treatment in peripheral paralysis generally. In rheumatic facial paralysis, the most common form of peripheral facial paralysis, the electric reactions of the paralyzed muscles enable us to classify the cases into three groups, the prognosis and duration of which vary very much. In the first group are the slight forms of facial paralysis. Here the faradic or galvanic current, applied to nerve or muscles, causes an ordinary contraction; the electric reactions are normal. These cases scarcely require treatment, and recover in two or three weeks. In a second group are those cases in which within a short time after the invasion of the paralysis (two weeks) complete degenerative reaction is observed. This degenerative reaction, with the accompanying anatomical changes in nerve and muscle, has already been treated of in this article, and it is sufficient here to say that it is marked by total loss of electric excitability, both faradic and galvanic, in the nerve, loss of faradic and increased galvanic excitability in the paralyzed muscles, with a reversal of the normal reply of the muscles to the different poles of the galvanic battery. These cases constitute the severe form of rheumatic facial paralysis, and the prognosis is grave, recovery takes place only after months, and even after the lapse of years traces of the disease remain in the imperfect action of the muscles. A third group of cases are of a gravity intermediate between these two. In them is present the milder form of degenerative reaction; that is, there is a diminution, but not a total loss, of electric excitability in the nerve for both the galvanic and faradic currents; but in the muscles there is a marked increase of galvanic excitability, with qualitative change—*i. e.* greater contraction upon application to them of the positive than of the negative pole. These cases may be expected to recover in from four to eight weeks, the muscles still exhibiting the degenerative reaction after voluntary motion has returned. Among the symptoms to be particularly noticed in the progress of the severe forms of facial paralysis are spasmodic twitchings or spasms of the muscles on the affected side of the face, about the angle of the mouth, and around the eye, occurring spontaneously or when voluntary movements are made. Also a state of tonic contraction and rigidity may develop in some of the muscles, causing a permanent elevation of the angle of the mouth, a narrowing of the opening of the eye, or a rigidity of the cheek. These symptoms have been erroneously attributed to the use of electricity in the treatment, but they occur as frequently in cases in which it has not been employed. Traumatic facial paralysis, as from wounds, surgical operations, use of the forceps in delivery, or paralysis from compression of the nerve, as from tumors, syphilitic thickening of the dura mater, etc., do not require a detailed mention here, as such cases come under the head of nerve-injuries, already discussed. Paralysis of both facials (diplegia facialis), in so far as it is caused by peripheral nerve lesion, is an accidental occurrence, and need not be considered as a separate form of facial paralysis. It is often the result of central disease.

The TREATMENT of peripheral facial paralysis must begin with the effort to remove its cause. If syphilis is suspected, mercury and iodide of potassium must be freely used. If the cause is an affection of the middle ear, this must be treated. Wounds or traumatic injuries must receive the necessary surgical attention. In addition, in such cases electricity

must be employed in the manner presently to be described. In cases of rheumatic facial paralysis the treatment will vary with their gravity. In the lighter form in which the nerve is affected outside of the Fallopian canal, recovery takes place in a comparatively short time, even without treatment, but is hastened by the use of the faradic or galvanic current daily along the branches of the nerve. In the severe form we must open the treatment by an attempt to combat the condition of inflammation—of inflammatory exudation—which we suppose exists within the Fallopian canal. Local blood-letting by leeching upon the mastoid process may be appropriately used in the very first outset of the paralysis. Iodide of potassium, given persistently in large doses during the earlier period of the disease, appears to act beneficially independently of any syphilitic taint. Electricity is the remedy, however, on which most reliance is to be placed in the treatment of rheumatic facial paralysis, and the manner of its application may be taken as a model of how it should be employed in all cases of peripheral paralysis. The galvanic current, on account of its power of penetrating to the deeper parts and its catalytic action, is to be preferred for the direct electrical treatment of the nerve which should be instituted in recent cases. Its action is best obtained by placing the positive pole behind the ear on the affected side, the cathode behind the opposite ear, and passing a moderate current across the base of the skull (the affected nerve being thus in the course of the current) for one or two minutes. Occasionally the position of the poles may be reversed. Besides this direct application of galvanism to the point of lesion, it is necessary to make a peripheral application of electricity to the branches of the nerve and to the paralyzed muscles. For this we use both the faradic and galvanic currents. The galvanic current is used by applying the positive pole stationary behind the ear, while the negative pole, with an electrode of suitable size, is stroked over each branch of the nerve and applied to each muscle, a current being used sufficiently strong to produce decided contractions. This peripheral application should be made once daily, the time of application being from two to five minutes. The application of the faradic current is made by simply placing one electrode upon an indifferent spot, and moving the other over the face, with a current strong enough to cause contractions if the muscles still respond to it, or if they do not of such strength as the patient can bear without discomfort. Without doubt, one of the beneficial effects of peripheral electrization is the reflex excitement of the facial above the point of lesion through the irritation of the terminations of the fifth nerve in the skin. A certain advantage derived from it is that it maintains the tone of the paralyzed muscles, which in the case of the orbicularis palpebrarum is of great importance in preventing the eversion of the lower lid and the overflow of the tears. As it is impossible during the first days succeeding the paralysis to distinguish severe cases from those of the middle form, it is best to begin the treatment of all cases in the manner above described. The use of strychnia in rheumatic facial paralysis, both internally and by hypodermic injection, may be mentioned on account of the widespread prepossession in its favor, and to point out distinctly its utter futility.

Mechanical appliances and manipulation are used with advantage in the treatment of facial paralysis to prevent the paralyzed muscles about

the mouth and cheek from being drawn out of place and over-stretched by the action of the sound ones of the opposite side, thus having their tonicity and nutrition impaired.

Contractions and rigidity of muscles receive little benefit from the use of electricity, and must be treated by mechanical procedures, such as stretching, massage, etc.

Neuromata.

The term neuromata was applied to all tumors involving the nerve-trunks at a time when their histological differences had not been studied and they were all supposed to be composed of nerve-tissue; and even yet the name is conveniently retained, because, although differing widely histologically, tumors situated upon the nerves have a very similar clinical history.

Neuromas must be divided into true and false, the true consisting of nerve-tissue, the false, or pseudo-neuromas, being composed of many varieties, having this only in common, that they are seated upon the nerves.

The true neuromas are again subdivided into those in which the nerve-tissue composing them resembles exactly the fibres of the peripheral nerves, showing with the microscope the double-contoured white substance of Schwann surrounding an axis-cylinder, and those in which the tumor is made up of fibres which Virchow has shown to be non-medullated nerve-fibres—*i. e.* the axis-cylinder without the white substance of Schwann. These two forms have been distinguished by the names myelinic and non-myelinic. The true neuromas are non-malignant, although showing the tendency to recur after extirpation, are of slow growth, and as a rule do not increase to a very great size. The best type of the myelinic neuromas is found in the spherical or spindle-shaped enlargements at the cut ends of nerves, particularly in the stumps of amputated limbs, where they are found oftenest intimately connected with the cicatricial tissue, though sometimes lying free. They consist of true medullated fibres mixed with some fibrous tissue. The fibres composing them are derived partly from splitting up and proliferation of the fibres of the nerve itself, partly are of new formation, the appearances strongly recalling the process of regeneration in nerves. Myelinic neuromas consist of fibres and nuclei so closely resembling in microscopic appearance the fibromas that they have hitherto been confounded with them; and there is a difference among the highest authorities as to the certainty of their diagnosis, and, in consequence, of the frequency of their occurrence. The true neuromas may include in their structure all of the fibres of the nerve-trunk or only a portion of them (partial neuroma)—a fact of importance in their symptomatology. Of the false neuromas, the fibromas are by far the most frequently met with. They appear as knots, more or less hard, upon the course of the nerve-trunk, which they may involve completely or partially. They are often excessively painful to the touch or spontaneously, most of the so-called tubercula dolorosa belonging to the fibro-neuromas. Fibromas sometimes occur along the trunk and branches of a nerve, forming a plexus of knotted cords (plexiform neuroma). Fibro-sarcomas are not an infrequent form of neuroma.

Myxomas often occur upon the peripheral nerves, and are frequently multiple, their points of predilection being the larger trunks, as the sciatic, ulnar, etc. They show their characteristic soft structure, and are usually spindle-shape, assuming a rounder form as they attain a large size. The various forms of sarcoma occasionally form tumors upon the nerves, attacking generally the large trunks. Carcinomatous tumors beginning upon the nerves sometimes occur, but as a rule these growths involve the nerve by extension to it from adjacent parts.

Syphilitic gummata have been found almost exclusively upon the intracranial portion of the cranial nerves.

Gliomas appear to affect only the optic and acoustic nerves. *Lepra nervorum* (*lepra anæsthetica*) produces usually a spindle-form thickening upon the nerve-trunks, but sometimes there are more distinct knots, which may be felt beneath the skin, bead-like, along the course of the nerves of the extremities.

Like the true neuromas, the false neuromas, developing from the neurilemma and perineurium, may involve the whole or only a part of the fibres of a nerve, or the nerve-fibres may run at the side of the tumor—different conditions, which may alter materially the effects produced upon the nerve.

Neuromas, both false and true, may occur not only singly, but often in large numbers, many hundreds having been counted upon an individual. Sometimes they are numerous upon a single nerve-trunk and its branches, and again they may appear scattered over nearly all of the nerves of the body, even to the cauda equina and roots of the nerves. According to Erb,¹ isolated neuromas are more frequent in females, while multiple neuromas are found almost exclusively in men. Neuromas vary greatly in size, as we might expect from the very great difference of their nature and structure; sometimes no larger than a pea, they may attain the size of a child's head.

ETIOLOGY.—In cases of multiple neuromata it would seem as if there was a constitutional condition or diathesis as the foundation of the affection. This we may the more readily believe as there appears good evidence to show that the tendency to the formation of these nerve-tumors is sometimes hereditary, and some of them are congenital.

Idiots and cretins have been observed to suffer in undue proportion with multiple neuromas. We find a direct exciting cause of neuromas in mechanical injuries of nerves, wounds, blows, pressure, etc. Thus, as has been already seen, true neuromas occur in the divided ends of the nerves after amputations or otherwise where a nerve-trunk has been divided (*cicatricial neuroma*). As such neuromas are in some degree the result of inflammation, it is probable that they may sometimes be caused by chronic neuritis.

For a large number of neuromas no cause can be assigned, and we must at present consider them as originating spontaneously.

SYMPTOMS.—The position and connections of neuromas being so different, sometimes simply in contact with the nerve; sometimes situated in the thickness of the nerve-trunk, the fibres being pressed aside and spread out upon the surface of the tumor; sometimes involving in their tissue a part or the whole of the nerve-fibres,—we cannot but expect a

¹ *Ziemssen's Handbuch.*

very marked difference in their clinical history. Not a few cases occur in which the presence of neuromas, even in large numbers, gives rise to no symptoms during life, and their existence has been revealed only upon a post-mortem examination.

The symptom most common to neuromas, and one to be expected from their mechanical interference with the nerves, is neuralgic pain—sometimes extreme, local or shooting along the course of the nerves, stubborn, and hardly to be alleviated by remedies. It is paroxysmal, notwithstanding the unvarying character of its cause, in consonance with the tendency to periodical activity which prevails in the nervous system. Sometimes the pain is increased notably by atmospheric changes. The pain may sometimes be arrested by firm pressure upon the nerve above the seat of the tumor. In some cases pressure upon the neuroma, or even handling it, causes great pain. The intensity of the pain does not depend upon the size of the tumor, some of the smallest having earned the appropriate name of *tubercula dolorosa*. The continued irritation of a neuroma sometimes produces a condition of general nervous excitability, which shows itself in hysterical and even in true epileptic convulsions. Occasionally there are abnormal sensations (*paræsthesiæ*), formication, numbness, etc., in the distribution of the nerve affected, and when from pressure or histological changes the fibres are destroyed anæsthesia results.

The interference with the conductivity of the motor fibres, which occurs less frequently than alterations of sensation, shows itself in cramps, tumors, paresis, and paralysis, according to its degree.

Neuromas may destroy life by the continued excessive pain, which wears down the strength and depresses the vitality. Death may be caused by their peculiar situation; as, for instance, upon the cauda equina, where they produce paraplegia, paralysis of the sphincter and bladder, and trophic changes.

The DIAGNOSIS of neuromas can only be made when they are sufficiently superficial to be recognized by the touch, and along with the symptoms above detailed the tumor is situated upon the known course of a nerve, to which, moreover, its attachment allows a lateral movement.

The only TREATMENT available for neuromas is extirpation, which must be conducted with a view to sparing any fibres of the nerve not involved in the tumor. Where it is necessary to divide the nerve in the removal of the tumor, as small a portion as possible must be excised, with the hope of a regeneration and reuniting of the cut ends. The success of extirpation depends largely upon the nature of the neuroma. The true neuromas, while they often show a strong tendency to recur after removal, are benign and show no metastasis. For the false neuromas the prognosis will be in accordance with their benign or malignant character.

NEURALGIA.

BY J. J. PUTNAM, M. D.

DEFINITION.—It is customary to describe as neuralgic those pains for which no adequate cause can be assigned in any irritation of the sensory nerves from outside, which recur paroxysmally, are unattended by fever, and are distributed along the course of one or more nerves or nerve-branches.

The general use of the term neuralgia further implies the common belief that there is a disease or neurosis, not covered by any other designation, of which these pains are the characteristic symptom. Of the pathological anatomy of such a disease, however, nothing is known; and if it could be shown for any given group of cases that the symptoms which they present could be explained by referring them to pathological conditions with which we are already familiar, these cases would no longer properly be classified under the head of neuralgia.

The attempt has frequently been made, and on good grounds, in obedience to this reasoning, to cut down the list of the neuralgias, strictly so called, and to account for many of the groups of symptoms usually classified under that head by referring them to anæmia or congestion of the sensory nerves, to neuritis, etc.

One of the best and most recent statements of this view is that of Hallopeau,¹ who, although he does not wholly deny the existence of a neurosis which may manifest itself as neuralgia, goes so far as to maintain that the gradual onset and decline and more or less protracted course so common in the superficial neuralgias, such as sciatica, suggest rather the phases of an inflammatory process than the transitions of a functional neurotic outbreak, and that, in general terms, a number of distinct affections are often included under the name of neuralgia which are really of different origin, one from the other, and resemble each other only superficially. This subject will be discussed in the section on Pathology, and until then we shall, for convenience' sake, treat of the various neuralgic attacks as if they were modifications of one and the same disease.

GENERAL SYMPTOMATOLOGY.—The neuralgias may be conveniently divided into—1, external or superficial; 2, visceral; 3, migraine and the migrainoid headaches.

Superficial Neuralgia.

The most prominent symptom of a neuralgic attack of the superficial

¹ *Nouveau Dict. de Méd. et de Chir. pratiques*, art. "Névralgies."

nerves is of course the pain, and sometimes, from first to last, no other sign of disease is present. In an acute attack the pain is usually ushered in by a sense of discomfort, which the patient vainly tries to shake off, or by a feeling of weight and pressure or of numbness and prickling, or of itching. Sometimes, though far less often than in the case of migraine, there are prodromal signs of a more general character, such as a feeling of thirst¹ or of mental depression or drowsiness.

A dart of pain may then be felt, which soon disappears, but again returns, covering this time a wider area or occupying a new spot as well as the old. The intensity, extension, and frequency of the paroxysms then increase with greater or less rapidity, but, as a rule, certain spots remain as foci of pain, which radiates from them in various directions, principally up or down in the track of the nerve-trunk mainly implicated. The pain rarely or never occupies the whole course and region of distribution of a large nerve or plexus, but only certain portions, which may be nearly isolated from one another.

In an acute attack the affected parts may at first look pale and feel chilly, and later they frequently become congested and throb. Mucous surfaces or glandular organs in the neighborhood often secrete profusely, sometimes after passing through a preliminary stage of dryness.

The skin often becomes acutely sensitive to the touch, even though firm, deep pressure may relieve the suffering. Movement of the painful parts, whether active or passive, is apt to increase the pain. When the attack is at its height, the pain is apt to be felt over a larger area than at an earlier or a later period, and may involve other nerves than those first attacked. Thus, a brachial becomes a cervico-brachial neuralgia or involves also the mammary or intercostal nerves. A peculiarly close relationship exists between the neuralgias of the trigeminal and of the occipital nerves. It is said that when the attack is severe the corresponding nerves of the opposite side may become the seat of pain. This is perhaps remotely analogous to the complete transference of the pain from one side to the other which is so characteristic of periodical neuralgic headaches, especially if they last more than one day.

Some cutaneous neuralgias pass away after a few hours' or a night's rest, after the manner of a migraine or a headache, and patients in whom this takes place are, as a rule, constitutionally subject to neuralgia or other neuroses. Toward the end of such an attack there is often a copious secretion of pale, limpid urine. In a large class of cases, on the other hand, the attack is of several days' or weeks', or even months' or years', duration, with remissions or intermissions and exacerbations, which may be either periodical or irregular.

The most marked periodicity of recurrence is seen with the neuralgias of malarial origin, which may take on any one of the typical forms of that disease.

These malarial neuralgias affect pre-eminently, though not exclusively, the supraorbital branch of the fifth nerve; but it should not be forgotten that there is also a typically periodical supraorbital neuralgia of non-malarial origin, of which the writer has seen several pronounced examples, the pain usually recurring regularly every morning at eight or nine o'clock and passing away early in the afternoon. The same periodicity

¹Spoken of by Mitchell's patient with neuralgia of the stump (see below).

is seen, though less often, in other neuralgias. Thus, Trousseau¹ speaks of neuralgic attacks from cancer of the uterus in a young woman, which recurred daily at exactly the same hour. Some of the traumatic neuralgias show the same peculiarity to a marked degree.

In many neuralgias, on the other hand, the exacerbations are worse at night, like the pains of neuritis. In the intervals between the attacks the pain may be wholly absent, or may persist, usually as a dull aching.

After a neuralgia has lasted a few days—sometimes, indeed, from the outset if the attack is severe—it is usually found that definite spots of tenderness have made their appearance at certain limited points on the course of the nerve. These are the famous points *douloureux* which Valleix described with such minute accuracy, believing them to be invariably present in true neuralgias. This is certainly not strictly the case, though they are very common. They are not necessarily coincident with the foci of spontaneous pain, as Valleix supposed, but do correspond in general to the points at which the affected nerve emerges from its bony canal or from deep muscles and fascia, and to portions of its area of distribution in the skin. The spinous process corresponding to an affected spinal nerve may also become tender, but this is probably to be looked on, like the same symptom in so-called spinal irritation, not as a sign of local disease, but as due to a general reaction on the part of the nervous system, and as a fact of a different order from the tenderness along the nerve.

The termination of an acute neuralgic attack is usually gradual, like its onset, although in some cases of headache, and in other neuralgias to a less degree, there comes a moment when the patient suddenly declares that he is free from pain.

Neuralgic attacks are usually characterized, besides the pain, by a highly-interesting series of symptoms, which are in part transitory and functional, and in part due to structural changes in the tissues.²

The spasm and subsequent dilatation of blood-vessels in the affected area have already been alluded to. A disturbance of secreting organs in the neighborhood of the painful region, the lachrymal gland, the skin, the mucous membranes, the salivary glands, is of equally common occurrence, and is probably in great measure due to direct irritation of the glandular nerves, since the increased secretion is said to occur sometimes unattended by congestion.

The hair may become dry and brittle and inclined to fall out, or may lose its color rapidly, regaining it after the attack has passed.

The increased secretion of urine already alluded to attends not only renal neuralgias, but those of the fifth pair, intercostal, and other nerves. There may be unilateral furring of the tongue (Anstie).

The muscles supplied by the branches of the affected nerve or of related nerves may be the seat of spasm, or, on the other hand, may become paretic; and this is true even of the large muscles of the extremities.

Vision may be temporarily obscured or lost in the eye of the affected side in neuralgia of the fifth pair, and hearing, taste, and smell are likewise deranged, though more rarely. I am not aware that distinct hemian-

¹ *Clin. Méd.*

² See Notta, *Arch. gén. de Méd.*, 1854; Anstie, *Neuralgia and its Counterfeits*.

opsia is observed except in cases of true migraine, where it forms an important prodromal symptom.

In connection with these disorders of the special senses the occasional occurrence of typical anæsthesia of the skin of one-half of the body should be noted, which several observers have found in connection with sciatica. The writer has seen a cutaneous hyperæsthesia of one entire half of the body in a case of cervico-occipital neuralgia of long standing. These symptoms are probably analogous to the hemianæsthesia which comes on after epileptic or other acute nervous seizures, or after concussion accidents, as has lately been observed both in this country and in Europe, and it is perhaps distantly related to the hemianæsthesia of hysteria. Local disorders of the sensibility in the neuralgic area are far more common than this, and, in fact, are usually present in some degree. The skin is at first hyperæsthetic, but becomes after a time anæsthetic; and this anæsthesia offers several interesting peculiarities. When this loss of sensibility is well marked, areas within which the anæsthesia is found are apt to be sharply defined, but they may be either of large size or so small as only to be discovered by careful searching (Hubert-Valle-roux). The sensibility within these areas may be almost wanting, but in spite of this fact it can often be restored by cutaneous faradization around their margins, and the functional or neurosomal origin of the anæsthesia is thus made apparent. Where the anæsthesia is due, as sometimes happens, to the neuritis with which the neuralgia is so often complicated, it is more lasting, but usually less profound and less sharply defined.

These changes may be transient, or, if a neuralgia is long continued and severe, they may pass into a series of more lasting and deeper affections of the nutrition.

The skin and subjacent tissues, including the periosteum, from being simply swelled or œdematous may become thickened and hypertrophied. The writer has known a case of supraorbital neuralgia, at first typically intermittent, to lead to a thickening of the periosteum or bone over the orbit, which even at the end of several years had not wholly disappeared.

Neuralgias of the fifth pair, which are as remarkable in their outward results as they are in their severity and their relation to other neuroses, are said to give rise to clouding and ulceration of the cornea, to iritis, and even to glaucoma.

Herpetic eruptions on the skin sometimes occur, of which herpes zoster is the most familiar instance.

Muscular atrophy is very common, especially in sciatica, and in some cases this occurs early and goes on rapidly, while in others it may be only slight and proportioned to the disease and relaxation of the muscles, even where the neuralgia has lasted for weeks or months.

Neuritis of the affected nerve is a common result or attendant of neuralgia, and may remain behind for an indefinite period after the acute pain has gone, manifesting itself by subjective and objective disorders of sensibility, by occasional eruptions on the skin, or by muscular atrophy.

It is plain that in this list of symptoms a variety of conditions have been described which would never all be met with in the same case, and which, as will be shown in the section on Pathology, are probably due to different pathological causes.

Neuralgia of the Viscera.

These neuralgias are less definitely localized by the sensations of the patient than those of the superficial nerves, and it is not definitely known what set of nerves are at fault.

They are deep-seated and are referred to the general neighborhood of the larynx, œsophagus, heart, or one of the abdominal or genital organs, as the case may be.

The pain is usually of an intense, boring character, and does not dart like the pain of superficial neuralgia, but is either constant or comes in waves, which swell steadily to a maximum and then die away, often leaving the patient in a state of profound temporary prostration.

Deep pressure often brings relief. A patient of the writer, who is subject to attacks of this kind in the right hypochondrium, will bear with her whole weight on some hard object as each paroxysm comes on, or insist that some one shall press with his fists into the painful neighborhood with such force that the skin is often found bruised and discolored.

The functions and secretions of the visceral organs are apt to be greatly disordered during a neuralgic attack, and it is often difficult or impossible to tell with certainty which of these conditions was the parent of the other. Undoubtedly, either sequence may occur, but the pain excited by disorder of function, or even organic disease of any organ, is not necessarily felt in that immediate neighborhood. Thus I have known the inflammation around an appendix cæci, of which the patient shortly afterward died, to cause so intense a pain near the edge of the ribs that the passage of gall-stones or renal calculus was at first suspected.

There seems to be as much variation as to modes of onset and duration among the visceralgias as among the superficial neuralgias, but the tendency to short typical attacks of frequent recurrence seems to be greater with the former.

The visceral neuralgias are quite closely enough related to certain of the superficial neuralgias to show that they belong in the same general category. The two affections are often seen in the same person, and not infrequently at the same time or in immediate succession. Thus in the case of the patient just alluded to above, the attacks of deep-seated neuralgia in the neighborhood of the right flank are at times immediately preceded by severe neuralgia of the face or head. Similarly, intercostal neuralgia may occur in immediate connection with neuralgias of the cardiac or gastric nerves.

The phenomenon of tender points is not entirely wanting in the visceralgias, though less constant and definite than in the superficial neuralgias.

The liver and the uterus especially become the seat of more or less localized tenderness, and possibly the tenderness in the ovarian region which is so common, and so often unattended by real inflammation, is, in part, of this order.

The secondary results of the visceralgias are not easy to study. Besides the disorders of secretion and function above alluded to, swelling of the liver with jaundice and paresis of the muscular walls of the hollow viscera may be mentioned as having been ascribed to neuralgia.

It is not known to what degree neuritis occurs as a cause or complica-

tion of these neuralgias, and this is a question which is greatly in need of further study.

Migraine, or Sick Headache.

This is often classified as an affection of a different order from the neuralgias, but there seem to be no real grounds for this distinction.

The superficial neuralgias themselves are probably not one, but a group of affections, with the common bond of severe and paroxysmal pain.

Neither is what is called migraine always one and the same disease.

Although in its most typical form it presents very striking characteristics, such as a marked preliminary stage, with peculiar visual and sensory auras, sometimes occupying one entire half of the body, a short and regular course and periodical return, deep-seated pain without tender points, and prominent unilateral vascular disorders, yet these symptoms shade off by imperceptible degrees into those of neuralgia of the fifth pair, or more often into one or another form of unilateral neuralgic headache which stands midway between the two.

The vascular phenomena of migraine are believed by various observers, as is well known, to constitute the primary and essential pathological feature of the disease, and to be the cause of the pain. But this is a pure hypothesis, and as a matter of fact the cases are abundant in which no greater vascular changes are present than in other neuralgias of equal severity.

Migraine seems to occupy an intermediate position between the grave neuroses, especially epilepsy, and the neuralgias of neurosal origin.

The symptomatology will be described at greater length below.

GENERAL ETIOLOGY.—The causes of neuralgia may be divided into predisposing and exciting causes.

The most important of the first group are—

1. Hereditary tendencies ;
2. The influences associated with the different critical periods of life ;
3. The influences attached to sex ;
4. The action of constitutional diseases, such as phthisis, anæmia, gout, syphilis, diabetes, nephritis, malarial poisoning, metallic poisoning.

The most important of the second group of causes are—

1. Atmospheric influences and the local action of heat and cold ;
2. Injuries and irritation of nerves ;
3. Irritation of related nerves (so-called reflex and sympathetic neuralgias) ;
4. Acute febrile diseases.

In most cases more than one cause is to blame, and each should be separately sought for.

PREDISPOSING CAUSES.—1. Hereditary Tendencies.—It is generally admitted as beyond question that neuralgias are most common in families in which other signs of the neuropathic taint are prominent. Such affections as hysteria, neurasthenia, epilepsy, asthma, chorea, dipsomania, and even gout and phthisis as it would seem, are akin to the neuralgic tendency.

The neuropathic family is thought to contain, in fact, a much larger number of members than this,¹ but there is danger of exaggerating the importance of an influence of which we know as yet so little.

It should be remembered, moreover, that even where an inherited taint is present its influence may be but slight as compared with that of some special exciting cause.

Some neuralgias are more closely associated with the inherited neuropathic diathesis than others. The connection is especially close in the case of migraine;² then follow other forms of periodical headache and the visceral neuralgias. Even the superficial neuralgias³ are more or less subject to this influence. This is thought to be especially true of the facial neuralgias.

Reasons will be offered later for suspecting that many cases usually classed as neuralgia, and characterized by gradual onset and protracted course, are essentially cases of neuritis; and there is need of further inquiry as to how far hereditary influences are concerned in producing them, and whether such influences act by increasing the liability of the peripheral nerves to become inflamed, or only by increasing the excitability of the sensory nervous centres.

2. Age.—Neuralgia is oftenest seen in middle life and at the epochs marked by the development and the decline of the sexual functions. The affection, when once established, may run over into advanced age, but cases beginning at this period are relatively rare and very intractable (Anstie).

Childhood is commonly said to be almost exempt from neuralgia, but, in fact, there seems no sufficient reason for withholding this term from the so-called growing pains of young children⁴ so long as it is accorded to the almost equally irregular neuralgias of anæmia in the adult. The same remark applies to the attacks of abdominal pain in children, which often seem to be entirely disconnected from digestive disorders.

Adolescents and children also suffer from periodical headaches, both of the migrainoid and of the neuralgic type. These are obstinate and important affections.⁵ Migraine especially, coming on in early life, points to a neuropathic constitution, and will be likely to recur at intervals through life, or possibly to give place to graver neuroses.

3. Sex.—Women show a stronger predisposition than men to certain forms of neuralgia, as to the other neuroses, but it is generally conceded that whereas neuralgias of the fifth and occipital and of the intercostal nerves are met with oftenest among them, the brachial, crural, and sciatic neuralgias are commoner among men. This probably indicates that the neurosial element is of greater weight in the former group, the neuritic element in the latter.

4. Constitutional Diseases.—The blood-impooverishment of phthisis and anæmia, the poison of malaria, syphilis, and gout, and the obscurer

¹ Féré, *Arch. de Névrologie*, 1884, Nos. 19 and 20, "La famille névropathique."

² There is a witty French saying (quoted by Liveing), "La migraine est le mal des beaux esprits;" which might be rendered, "The disease of nervous temperaments."

³ For tables of illustrative cases see Anstie, *Neuralgia and its Counterfeits*, and J. G. Kerr, *Pacific Med. and Surg. Journ.*, May, 1885.

⁴ Probably due to anæmia or imperfect nutrition (see Jacobi, "Anæmia of Infancy and Childhood," *Archives of Med.*, 1881, vol. v.).

⁵ Blache, *Revue mensuelle de l'enfance*, Mar., 1883, and Keller, *Arch. de Névrologie*, 1883.

forms of disordered metamorphosis of tissue, undoubtedly predispose to neuralgia and the other neuroses, as well as to neuritis and others of the direct causes of neuralgic attacks.

Anstie regards the influence of phthisis as so important as to place it fairly among the neuroses. Gout is likewise reckoned by some observers among the neuroses,¹ but we tread here upon uncertain ground. Anstie does not regard gout as a common cause of neuralgia, but most writers rate it as more important, and gouty persons are certainly liable to exhibit and to transmit an impaired nervous constitution, of which neuralgia may be one of the symptoms. The neuralgias of gout are shifting, irregular in their course, and sometimes bilateral.

Syphilitic patients are liable to suffer, not only from osteocopic pains and pains due to the pressure of new growths, but also from attacks of truly neuralgic character. These may occur either in the early or the later stages of the disease. They may take the form of typical neuralgias, as sciatica or neuralgia of the supraorbital nerve (Fournier²), or they may be shifting, and liable to recur in frequent attacks of short duration, like the pains from which many persons suffer under changes of weather, anæmia, or fatigue.

There are other obscure disorders of the nutrition, as yet vaguely defined, in connection with which neuralgia of irregular types is often found. Some of these are classed together under the name of lithæmia, and are believed to be due to imperfect oxidation of albuminoid products.³

Diabetes seems also to be an occasional cause of neuralgia, especially sciatica, and Berger,⁴ who has recently described them, says that they are characterized by limitation of the pain to single branches of the sacral nerves, by a tendency to occur at once on both sides of the body, by the prominence of vaso-motor symptoms, and, finally, by their long duration and obstinacy. There may not, at the moment, be any of the characteristic symptoms of diabetes present.

Chronic nephritis also causes neuralgia, either directly or indirectly; and severe neuralgic attacks may accompany the condition, which is as yet but imperfectly known, characterized pathologically by a general arterio-fibrosis and by increased tension of the arterial system.

True rheumatism does not appear to be a predisposing cause of neuralgia.

Anæmia, both acute and chronic, is a frequent cause of neuralgia, both through the imperfect nutrition of the nervous tissues, to which it leads, and, it is thought, because the relatively greater carbonization of the blood increases the irritability of the ganglionic centres.

Even a degree of anæmia which might otherwise be unimportant becomes of significance in the case of a patient who is otherwise predisposed to neuralgia; for such persons need to have their health kept at its fullest flood by what would ordinarily seem a surplus of nourishment and care.

Under the same general heading comes the debility from acute and

chronic diseases, and the enfeeblement of the nervous system from moral causes, such as anxiety, disappointment, fright, overwork and over-excitement, and especially sexual over-excitement, whether gratified or suppressed (Anstie), or, on the other hand, too great monotony of life; also from the abuse of tea, coffee, and tobacco.

Lead, arsenic, antimony, and mercury may seriously impair the nutrition of all the nervous tissues, and in that way prepare the way for neuralgia.

IMMEDIATE CAUSES.—1. Atmospheric and Thermic Influences.—Neuralgia is very common in cold and damp seasons of the year, in cold and damp localities, and in persons whose work entails frequent and sudden changes of temperature. Exposures of this sort may at once excite twinges of pain here and there over the body, and may eventually provoke severe and prolonged attacks of neuralgia.

The action of damp cold upon the body is complicated, and it exerts a depressing influence on the nervous centres in general which is not readily to be explained. One important factor, however, is the cooling of the superficial layers of the blood, which occurs the more easily when the stimulus of the chilly air is not sufficiently sharp and sudden to cause a firm contraction of the cutaneous vessels, while the moisture rapidly absorbs the heat of the blood. From this result, indirectly, various disorders of nutrition of the deeper-lying tissues or distant organs; and, among these, congestion and neuritis of the sensitive nerves.

Neuralgia often coincides with the presence or advent of storms. A noteworthy and systematic study of this relationship was carried on through many years under the direction of S. Weir Mitchell¹ by a patient of his, an officer who suffered intensely from neuralgia of the stump after amputation of the leg. The attacks of pain were found to accompany falling of the barometer, yet were not necessarily proportionate to the rapidity or amount of the fall. Saturation of the air with moisture seemed to have a certain effect, but the attacks often occurred when the centre of the storm was so remote that there was no local rainfall. It was impossible to study the electrical disturbances of the air with accuracy, but a certain relationship was observed between the outbreak of the attacks and the appearance of aurora borealis.

This patient's neuralgic attacks were almost certainly of neuritic origin, and it is possible that the exacerbations were due to changes of blood-tension in and around the nerve-sheaths. It is also possible that they were the result of circulatory changes and disordered nutrition of the nervous centres, already in a damaged condition from the irritation to which they had been exposed.

2. Injuries and Irritation of Nerves.—Wounds and injuries of nerves² and the irritation from the pressure of scars, new growths, and aneurisms are prolific causes of neuralgic pain, partly by direct irritation, partly by way of the neuritis which they set up. Neuralgias are likewise common during the period of the healing of wounds, as Verneuil long since pointed out. The pain may be near the wound itself or in some distant part of the body.

Neuralgia due to the pressure and irritation of tumors, new growths,

¹ *Am. Journ. of Med. Sci.*, April, 1877, and *Philada. Med. News*, July 14, 1883.

² See S. Weir Mitchell, *Injuries of Nerves*.

or aneurisms requires a special word. The pain is apt to be intensely severe, but what is of especial importance is that the symptoms may not present anything which is really characteristic of their origin, except their long continuance; and this should always excite grave suspicion of organic disease.

These attacks of pain may be distinctly periodical; and this is true whether they are felt in the distribution of the affected nerve or of distant nerves.

Not only are direct injuries of nerves a cause of neuralgia, but sudden concussion or jar may have a like effect—whether by setting up neuritis or in some other way is not clear. Ollivier¹ reports a case where a blow beneath the breast caused a neuralgia which eventually involved a large portion of the cervico-brachial plexus; and the writer has seen a like result from a blow between the shoulders.

Peripheral irritations, such as caries of the teeth (see below, under Facial Neuralgia) and affections involving other important plexuses, such as those of the uterine nerves, are a frequent cause of neuralgia, and should always be sought for. They act in part by setting up neuritis, and in part evidently in some more indirect manner, since the neuralgia which they excite may be referred to more or less distant regions, forming the so-called—

3. Reflex and Sympathetic Neuralgias.—The term reflex, as here used, is ill chosen, and the term sympathetic only covers our ignorance of the real processes involved, and which we should seek for in detail. Thus, disease of the uterus or ovaries may cause facial, mammary, intercostal, or gastric neuralgia.

Hallopeau² suggests that some of these results may be brought about by the pressure of enlarged lymphatic glands attached to the affected organ.

Another important centre of nervous irritation is the eye. Slight errors of refraction, or weakness of the muscles of fixation, especially the internal recti, are a source of frontal headaches and other nervous symptoms, and even of typical migraine,³ to a degree which is not usually appreciated. It is improbable that in the latter case the irritation acts as more than an exciting cause, but it may nevertheless be a *conditio sine qua non* of the attack.

Acute and chronic inflammations of the mucous membrane of the frontal sinuses, perhaps even of the nasal membrane, are likewise important; and although it is probable that the opinions sometimes expressed as to the significance of these causes are exaggerated, it is equally true that an obstinate and, as it were, illogical persistence in their removal will sometimes be richly rewarded.

It is especially worthy of note that there need be no local sign whatever to call the attention of the patient to the presence of the peripheral irritation.

Nothnagel⁴ has described neuralgias which come on in the first week of typhoid, and are to be distinguished from the general hyperæsthesia of later stages. He describes an occipital neuralgia of this sort which finally disappeared under the use of a blister. Other acute diseases may have a like effect. The writer has seen a severe facial neuralgia in the

² *Loc. cit.*, p. 766.

³ *St. Barthol. Hosp. Repts.*, vol. xix.

⁴ *Virch. Arch.*, vol. liv., 1872, p. 123.

first week of an insidious attack of pneumonia in a person who was not of neuralgic habit, and before the fever or inflammation had become at all severe.

PATHOLOGY AND DIAGNOSIS.—In surveying the clinical history of the neuralgias and the circumstances under which they occur, we have grouped together a large number of symptoms of very different character from each other, and we have now to inquire to what extent these symptoms are really united by a pathological bond.

Two opposite opinions have been held concerning the pathology of neuralgic affections. According to one opinion, every neuralgic attack, no matter how it is excited, is the manifestation of a neurosis—that is, of a functional affection of the nervous centres—to which the term neuralgia may properly be applied. This view is based on the resemblance between the different forms of neuralgia, or the apparent absence, in many cases, of any adequate irritation from without, and the fact that the persons in whom neuralgias occur usually show other signs of a neuropathic constitution.

According to the other opinion, the various forms of neuralgia are so many different affections, agreeing only in their principal symptom, and are due sometimes to congestion or anæmia of the nerves or the nerve-centres; sometimes to neuritis, the pressure of tumors, or the irritation of distant nerves; sometimes, finally, to a functional disorder of the nervous centres. The arguments in favor of this opinion are that the difference between the symptoms of the different neuralgias as regards their mode of onset and decline, their duration, the persistence of the pain, and the degree to which the attacks are accompanied by organic changes of nutrition in the tissues and in the nerve itself, are so great as to make it appear improbable that we are dealing in every case simply with one or another modification of a single affection.

This is a valid reasoning, and it is certainly proper to exhaust the possibilities of explaining the symptoms that we find in a particular case by referring them to morbid processes which we can see or of which we can fairly infer the presence, before we invoke an influence of the nature of which we understand so little as we do that of the functional neuroses. At the same time, it must be distinctly borne in mind that the symptoms of certain neuralgias, and the relation which the neuralgias in general bear to other neuroses, can only be accounted for on the neurosal theory, and that in a given case we can never be sure that this neurosal tendency is not present and is not acting as at least a predisposing cause. It is especially important to bear this possible influence in mind in deciding upon prognosis and treatment.

We may now review briefly the signs which should lead us to diagnose or suspect the presence of the various special causes of neuralgic symptoms.

Neuritis is indicated by the presence of organic disorders of nutrition affecting the skin, hair, or nails, or of well-marked muscular wasting; by pain, not only occurring in paroxysms, but felt also in the intermissions between the paroxysms, or continuous sensations of prickling and numbness, even without pain; by tenderness along the course of the nerve; by anæsthesia, showing itself within the first few days of the outbreak of a neuralgia; by persistent paralysis or paresis of muscles.

Neuritis may be suspected, even if one or all of these signs are absent, in the prolonged neuralgias which follow wounds or strains of nerves or exposure to damp cold, or which occur in nerves which are in the immediate neighborhood of diseased organs; also where the pain is relieved by compression of the nerve above the painful part, or, on the other hand, where pressure on the nerve excites a pain which runs upward along the course of the nerve.

It may also be suspected in the large class of superficial neuralgias which follow a regular and protracted course with gradual onset and decline, and where the pain is felt not only in the region of distribution of a nerve, but also along its course—that is, in the nerve-fibres (either the recurrent nerves or the *nervi nervorum*) which are distributed in the sheath of the main trunk or the adjoining tissues.¹

It must be remembered that the study of neuritis, and especially of chronic neuritis, is still in its infancy, and that we are by no means in possession of its complete clinical history.²

The presence of congestion of the sensory nerves or nerve-centres may be inferred with some degree of probability where neuralgic attacks of relatively sudden onset and short duration occur in parts which have been exposed to heat or cold, or in connection with suppression of the menstruation, or, it is said, as a result of intermittent fever. The exacerbations of pain which take place in cases of chronic neuritis under changes of weather and after fatigue are very likely due to this cause; and the same may be true of some of the fleeting pains which occur in chlorotic and neuropathic persons who are subject to fluctuations of the circulation of vaso-motor origin.

The same vaso-motor influences which cause congestion may also cause the correlative state of anæmia, which becomes thus a cause of transient and shifting though often severe attacks, which may be irregular in their distribution. General anæmia is also a predisposing cause of severe typical seizures, as has been pointed out above.

The pressure of new growths or of aneurisms is to be suspected when neuralgic attacks are unusually severe and prolonged, recur always in the same place, and occur in persons who are not predisposed to neuralgias. The pains from this cause are apt to be relatively continuous, but they may, on the other hand, be distinctly paroxysmal, and may occupy a part of the body far removed from the irritating cause.

Bilateral pains should also excite suspicion of organic disease, though they may be due to other causes, such as gout, diabetes, and metallic poisoning.

Neuralgic attacks may be supposed to be of neurosal origin when they are of sudden onset and short duration, or when they occur in persons of neuropathic constitution, and, by exclusion, when no other cause is found. These conditions are best fulfilled in the case of migraine and the visceral neuralgias. It must, however, be borne in mind that the neuropathic predisposition is sometimes well marked even in the case of the superficial neuralgias, especially the epileptiform neuralgia of the face.

GENERAL TREATMENT.—To treat neuralgia with satisfaction it is

¹ See Cartaz, *Des Névralgies envisagées au point de vue de la sensibilité récurrente*, Paris, 1875.

² See Pitres and Vaillard, *Arch. de Neurologie*, 1883.

necessary to look beyond the relief of the particular attack and search out the causes by which it was provoked. As has already been remarked, these are usually multiple, and among them will be found, in the great majority of cases, some vice of nutrition or faulty manner of life.

It is safe to say that any dyscrasia occurring simultaneously with neuralgia, whether gout, phthisis, malaria, or diabetes, should receive its appropriate treatment, whatever theory we may hold as to the real connection between the two conditions.

In protracted neuralgias it is always proper to assume that neuritis may be present—*i. e.* to treat the nerve itself by galvanism and local applications. Local irritations, such as diseases of the eye, ear, teeth, nose, or uterus, should be sought out and removed; and attention may here be called again to the fact that a neuralgia may be due to some local condition which does not of itself attract the patient's attention.

Patients who are subject to pain at changes of weather or on exposure should be suitably protected by clothing, and should have their cutaneous regulatory apparatus strengthened by baths and friction. The best protection, however, is incapable of entirely warding off the effect of atmospheric changes upon the nervous centres. Vaso-motor changes of neurotic origin can be, in a measure, prevented by removing the patient from the influence of irregularity of life and emotional excitement and through an improved nutrition.

If the patient has been subjected to chronic fatigue or nervous strain, not only must these be avoided, but their action should be counteracted by the requisite rest and tonic treatment.

Long hours of sleep at night may often be supplemented to advantage by rest during certain hours of the daytime. If the patient cannot take active exercise, massage is indicated, and in some cases of anæmia this may advantageously be combined with the wet pack, in the manner described by Mary Putnam Jacobi.¹

Where these measures cannot be carried out, the writer has found it of much service in these, as in a large class of debilitated conditions, to let the patient rub himself toward the end of the forenoon in a warm room with a towel wet in cold or warm water, and then lie down for an hour or so or until the next meal. If acceptable, the same operation may be repeated in the afternoon.

Neuralgic patients are apt to be underfed, and even where this is not distinctly the case, a systematic course of over-feeding,² with nourishing and digestible food, such as milk, gruel, and eggs, given at short intervals, is often of great service if thoroughly carried out. The full benefit of this treatment cannot always be secured unless the patient is removed from home, and, if need be, put to bed and cared for by a competent nurse.

A change of climate, and especially the substitution of a dry and warm for a moist and cold climate, will sometimes break up the neuralgic habit, for the time at least. In making choice of climate or locality, however, the physician should keep distinctly in view the end that he desires to gain. Thus, the debility or anæmia which is the essential condition of many neuralgias may often be relieved by surroundings which

¹ *Massage and Wet Pack in the Treatment of Anæmia.*

² See S. Weir Mitchell, *Fat and Blood; and Nervous Diseases, especially of Women.*

would not be thought favorable to the neuralgic tendency as such. Oftentimes the sedative influence of quiet country life is all that is required.

Of the the tonic drugs, cod-liver oil, iron, arsenic, and quinine are by far the most important, and it is often well to give them simultaneously. Iron may be used in large doses if well borne, for a short time at least. Quinine may be given in small doses as a tonic, or in larger doses to combat the neuralgic condition of the nervous system. This remedy has long been found to be of great value in the periodical neuralgias of the supraorbital branch of the fifth pair, but its usefulness is not limited to these cases. It may be of service in periodical neuralgias of every sort, and often even in non-periodical neuralgia.

When the attacks recur at stated intervals care should be taken to anticipate them with the quinine by about four hours, even if the patient has to be waked in the early morning for the purpose. Single doses of fifteen, twenty, or even thirty grains may check the attacks where smaller doses have failed. Such doses cannot, however, be long continued, and are not to be classed as tonic.

Of other remedies which directly influence the neuralgic condition, the following are the most important: opium, aconite, gelsemium, phosphorus, belladonna, chloride of ammonium, cannabis Indica, croton-chloral, electricity, hydropathy, massage, counter-irritation, subcutaneous injections of water, chloroform, osmic acid, etc.; surgical operations.

Opium is usually employed only for the momentary relief of pain, but it has also been claimed that in small and repeated doses it may exert a really curative action. This should not, however, be too much counted on. Opium should never be used continuously for the simple relief of pain unless under exceptional circumstances, the danger of inducing the opium habit is so much to be dreaded. Moreover, both patient and physician are less likely to seek more permanent means of cure if this temporary remedy can always be appealed to. It is best given by subcutaneous injections of the various salts of morphine. The dose should always be small at first (gr. $\frac{1}{12}$ and upward), unless the idiosyncrasy of the patient is already known; and there is probably no advantage in making the injections at the seat of pain or in the immediate neighborhood of the nerve supplying the affected part, except such as might attend the injection of any fluid (see below).

Belladonna (atropia), which is so often given with morphine to diminish its unpleasant effects, seems at times, even when given alone, to have an effect on neuralgia out of proportion to its anæsthetizing action, which is very slight. It is considered to be especially useful in the visceralgias.

Aconite, given, if necessary, in doses large enough and repeated often enough to cause numbness and tingling of the lips and the extremities for some days, will sometimes break up an attack, especially of trigeminal neuralgia,¹ better than any other means; but its use is liable to depress the heart, and it is a dangerous remedy if not carefully watched. Some patients complain that it causes a marked sense of depression or faintness, and a feeling of coldness; and indeed its full therapeutic effect is sometimes not obtained until such symptoms as these are induced to some degree. The use of the crystallized alkaloid, aconitia, has the advantage of ensuring certainty of dose.

¹ See Seguin, *Arch. of Med.*, vol. i., 1879; vol. vi., 1881.

The susceptibility of different persons to this drug is so different that the dose should first be as small as $\frac{1}{400}$ gr., but this may be repeated every three hours, and gradually increased to $\frac{1}{100}$ gr., or until its physiological effects are felt. Patients must sometimes be kept under its influence for weeks together.¹ It is, however, a remarkable fact that occasionally a few full doses will secure an immunity from pain for a long period. Although most useful in facial neuralgias, the writer has known it to be effective in brachial and mammillary neuralgia. Aconitia can now be had in granules of $\frac{1}{400}$ gr., or can be given in alcoholic solution.

Gelsemium is also occasionally very useful in facial and even in intercostal neuralgia, and is said to be of special service in the neuralgia due to carious teeth. The commencing dose of the fluid extract is five minims, which may be gradually increased to twenty, or until a slight degree of muscular prostration, ptosis, or dilatation of the pupil is induced.

The use of phosphorus has been revived of late years, chiefly through the efforts of J. Ashburton Thompson, and it is at least occasionally of service. Success is said to be best obtained by full doses (about $\frac{1}{20}$ gr. every three or four hours, up to $\frac{1}{2}$ or $\frac{1}{4}$ gr. daily for some days), watch being kept for signs of gastric irritation. The best preparation is an alcoholic solution (Thompson's), such as the following:

| | |
|-----------------|---------|
| Ry. Phosphorus, | gr. j ; |
| Abs. alcohol, | fʒvi. |

Dissolve with heat.

| | |
|-------------------|----------|
| Glycerin, | fʒiiss ; |
| Alcohol, | fʒij ; |
| Spts. peppermint, | ℥v. |

One teaspoonful represents gr. $\frac{1}{20}$.

Electricity, if properly used, is capable of temporarily, and even radically, relieving the neuralgic state. The forms most often employed are faradic and galvanic electricity, though frictional electricity has also been coming into use of late, mainly as a substitute for faradism. The galvanic current is by far the most efficacious of all. This probably acts mainly by directly inducing better nutritive and better functional conditions in the nerves and nerve-centres, but the fact that it is often of use in cases of undoubted neuritis seems to indicate that it may also influence the grosser structural changes in the affected parts, if such are present. It is impossible to explain its action more exactly, and the teachings of physiological experiments do not lend us much aid.

It is probably not of much consequence which pole is used in the neighborhood of the affected nerve. It should be remembered that the peripheral nerve-trunks are so deeply buried that the electrodes cannot be directly applied to them, as they are to the exposed nerve of a frog in the laboratory, and, further, that instead of being isolated they are surrounded with tissues of good conducting power, into which the current must rapidly flow off. For these reasons the nerve near which either electrode is applied is virtually exposed to the action of both poles in almost equal degree; and although it is more customary to use the positive pole in the neighborhood of parts which are considered to be in a state of irritation, yet clinical experience has not justified the conversion of this custom into a rule. Neither is the direction of the current of material consequence.

¹ See Seguin, *Arch. of Med.*, vol. vi., 1881.

It is, however, very important in acute cases to take care that the current-strength should not be rapidly changed; and for this reason the electrode should be drawn slowly to a distance from the nerve before it is removed, or left in situ while the current is gradually diminished by a suitable rheostat. As a rule, the former method is the more practicable.

In the treatment of acute cases moderate currents and short applications, frequently repeated, are the best. On the other hand, in cases of long standing, especially cases of sciatica, strong currents are sometimes more effective, and even interruptions and reversals of the current may be in place.

The choice of a battery is not a matter of indifference. Any stationary battery of high interior resistance will answer the purpose, but most of the portable (zinc-carbon) batteries in common use are objectionable,¹ for the reason that their interior resistance is so low in proportion to that of the body that it may almost be counted out as a factor in determining the strength of the current. The latter is liable to rise, therefore, quite suddenly as the resistance of the body—*i. e.* the vascularity of the skin—becomes modified. This objection is obviated if a large, constant resistance (water or graphite rheostat) is attached to the battery and kept always in the main circuit.

Faradism probably owes its efficiency to the indirect effects of stimulation of the sensitive nerves of the skin. This may be produced either by the wire brush, which causes a sharp irritation and reddening, and is to be compared with the counter-irritants, or by the milder application of a moist or dry electrode or the hand of the operator. The latter procedure may be compared to the superficial manipulation which is sometimes so grateful, especially in nervous headaches.

The value of electricity as a general tonic should be remembered in this connection.

Hydropathy.—Douches and baths of various kinds have doubtless proved of much value in the treatment of neuralgia. The majority of them, however, are difficult of application for the general practitioner, and we confine ourselves to mentioning the tonic and soothing action of the wet pack and of the prolonged warm bath, which should be followed by sponging with cool water, and used under every possible precaution against exposure.

Long-continued local applications of gentle heat (bags of sand or salt, or hot water) are often temporarily grateful, and in the treatment of chronic cases the daily application of hot water or ice-bags to the spine is said to have a good effect. In acute and subacute neuritis, and in those forms of neuralgia in which neuritis plays a large part, such as sciatica, the persistent application of ice-bags along the course of the affected nerve, even for days together, is sometimes of great service. Even where we cannot be sure that neuritis is present, long-continued applications of ice may be of use, but alternations of cold and heat, on the other hand, are usually to be carefully avoided. This treatment is safer in chronic than in acute cases, though it may be useful in either.

Counter-irritation.—A spray of ether may be substituted for ice when only a temporary chilling is desired, for its counter-irritant effect. This

¹ *Archives of Medicine*, April, 1884.

has even been used on the face, the eye being protected by some suitable covering, and a good deal of benefit is to be hoped for both from this and from the similar use of chloride of methyl.

Debove¹ has found the chloride of methyl, used in this manner, singularly effective in the treatment of sciatica. A considerable and long-continued counter-irritation is thus made over a large surface and without great pain. The neuralgia is said to be greatly relieved and a rapid cure sometimes affected.

Counter-irritation is also practised by making applications of cutaneous irritants, such as blisters, mustard, turpentine, chloroform, or of the actual cautery carried in light superficial stripes over the skin, and repeated if necessary at short intervals. As a rule, the counter-irritation is more effective the larger the surface which is covered.

The use of the cautery and of blisters is in place in almost every form of neuralgia where the temporary disfigurement is of no consequence.

Of other cutaneous applications, aconite and chloroform liniments, menthol in substance or in alcoholic solution (3j or 3ij to f3j), aconite and veratrine ointments, are the most useful. A strong aconitine ointment, made with Duquesnet's aconitia and lard (5j to 3j), has been recommended by Webber² to be used in portions of the size of half a split pea, but, though effective, it needs to be employed with great caution.

These applications act in part as irritants, by keeping up a play of sensitive impressions in virtue of the lodgment which they effect in the skin, but also, no doubt, by reducing the sensitiveness of the cutaneous nerve-fibres, and thus removing one source of excitation of the diseased nervous centres. The remarkable temporary benefit sometimes obtained from the instillation of cocaine into the eye in cases of neuralgia of the ophthalmic division of the fifth nerve bears testimony in favor of this explanation.

Surgical operations for neuralgia are of three kinds—section (neurotomy), removal of a piece of nerve (neurectomy), and nerve-stretching. The two former operations are of course rarely practised, except upon the purely-sensitive fifth pair of nerves, the latter upon mixed nerves also.

Neurectomy is now almost always substituted for simple neurotomy, and sometimes still more effective means are taken to prevent the reunion of the nerve, such as doubling over the cut end, destroying the nerve throughout the length of the bony canal in which it lies, and even plugging the canal with cement.³

The inconvenience following nerve-section is as nothing compared to the pain of a severe and intractable neuralgia. It has rarely happened that the disease has been increased by the operation, and under proper antiseptic precautions the surgical risks are not great. There is some chance of permanent cure, and a much greater chance of securing an immunity from pain for a long period.

It is important to remember that when the neuralgia occupies the distribution of several branches of the fifth nerve, an operation on the one primarily or most severely affected may relieve the pain in all. On the

¹ *Bulletin générale de Thérap.*, cited in the *Boston Med. and Surg. Journ.*, vol. cxii. p. 210.

² *Nervous Diseases*, Boston, 1885.

³ Heustis (*Med. News*, Dec. 8, 1883) found that the infraorbital nerve could be readily drilled out with a piece of piano wire.

other hand, the converse may be true,¹ inasmuch as the same district is supplied by recurrent fibres from several different sources. Before any operation is decided on it should be remembered that even in apparently desperate cases of trigeminal neuralgia the persistent and thorough use of tonic and other remedies may in the end be crowned with success, perhaps at the moment when it is least expected.

During the past few years the operation of nerve-section has been to some degree superseded by that of nerve-stretching, as being less serious in its immediate (though not necessarily in its remote) consequences, and sometimes more efficacious. Hildebrandt, indeed, raises the question whether the traction which is apt to be exerted when a nerve is cut is not an important element in bringing about the result. On the other hand, cases are reported where neuralgia which had not been relieved by stretching was cured by resection.²

The best showing for the operation is in the treatment of sciatica, but most of the other superficial nerves, including the intercostals, have been successfully treated in the same manner.

On the other hand, this treatment is not without its dangers. Apart from the risks of the operation itself, cases have been reported in which the spinal cord has been injured, so that chronic myelitis has been set up, and a greater or less degree of paralysis—rarely permanent, it is true—may be induced by the direct injury to the nerve.

This means of treatment is therefore certainly to be thought of in serious and obstinate cases, but not lightly decided on.

A substitute operation for sciatica is the so-called bloodless stretching, in which, the patient having been etherized, the thigh is forcibly flexed on the pelvis, and then the leg extended on the thigh and the foot on the leg (dorsal flexion), and held for a short time in this position. A very material degree of stretching of the sciatic nerve is doubtless possible in this way, and a number of cures have been thus effected. But, though less dangerous than the stretching of the exposed nerve, this operation is not a trifling one.

In one case of sciatica the writer has seen a neuritis of some severity lighted up by this operation, perhaps because the disease was in too active a state, although it had lasted some months. The operation is probably most indicated in chronic cases.

The anatomical effects of nerve-stretching are manifold. Nerve-fibres are usually destroyed in greater or smaller number, and the conducting power of the nerve correspondingly impaired. Small blood-vessels are broken and the circulation and nutrition of the nerve-trunks altered, and it is probable that adhesions in and around the nerve-sheaths, where such exist, are severed. The nerve-fibres ramifying in the inflamed sheaths of the large trunks may also be ruptured, and it may be that the displacement of the fluid contents of the nerve brings about better nutritive conditions.³ It is also probable that the operation either directly or indirectly affects the nutrition of the nerve-centres,⁴ and although this is not without its dangers, the chances are in favor of a beneficial result.

³ See "Die Rückenmarks-dehnung," Hegar, *Samml. klin. Vorträge*, 239.

⁴ Hegar, *loc. cit.*

Another means of directly acting on neuralgic nerves is by subcutaneous injections of water, chloroform, ether, osmic acid, nitrate of silver, and other substances. The deep injection of water over the affected nerve is attended with but little danger, and is occasionally successful. The similar use of chloroform, in doses of 15 to 30 minims, is much more often effective, but sometimes causes great pain, and even abscess. It has been mainly used in sciatica, also in other neuralgias, even those of the fifth pair. In this case the injection is best made through the buccal mucous membrane. This treatment is not without danger of causing collapse, or even death, probably due to the wounding of a small vein. In one case of sciatica treated by the writer the chloroform probably entered the nerve itself to some extent, as the injection was followed by very severe pain lasting for several hours, and eventually by some degree of muscular wasting. The neuralgic pain, which had continued obstinately for a long period, was, however, cured, and had not returned at the end of some days, when the patient was lost sight of.

Osmic acid has been used recently in the same way, and the reports show about an equal number of successes and failures. The dose is about 8 minims of a 1 per cent. solution, and the injection may be repeated at intervals of a few days. It has been used successfully in various parts of the body, including the face and the fingers. The injection causes no great pain, but occasionally, though rarely, excites abscess.

Under the general heading of massage a number of manipulations may be grouped which are of value in the treatment of neuralgia, even of long-standing cases of sciatica and the like.¹ When, as often happens in the case of sciatica, the nerve is the seat of congestion and exudation, strong and deep kneading along its course, with vigorous stroking upward in the direction of the lymph-vessels, is the important part of the treatment. Besides this, however, the prolonged and gentle manipulation of the painful region may greatly relieve the patient for a time, apparently by acting on the sensitive nerves and exerting a sort of inhibitory action, in which it is not at all impossible that an influence upon the attention analogous to that of Braidism plays a part.

A striking instance of the effect of this treatment is seen in the case of nervous headaches, which are often very greatly relieved by a series of gentle, monotonous movements of the finger-tips, as well as by the domestic remedy of gently and persistently combing or brushing the patient's hair. A still more efficient application of a similar kind is the regular vibration communicated by a large magnet or by the instrument devised by Mortimer Granville. A thoroughly satisfactory explanation of the action of this treatment is yet to be furnished.

There is no doubt that in the treatment of neuralgia a persistent and thorough use of the remedies suggested is usually the key to success. Nevertheless, special cases are sometimes reached by special means of treatment, and the following are appended as occasionally useful: Ammonio-sulphate of copper (grs. ij.-vj, taken in divided doses in the course of the day); salicylate of soda, in full doses; caffeine; tonka (f3j of the fluid extract at repeated intervals of a few hours); oil of turpentine; muriate of ammonia.

Special Forms of Neuralgia.¹

MIGRAINE AND PERIODICAL HEADACHE.—In many of the recent treatises upon nervous disease migraine and headache are removed from the category of the neuralgias and placed in that of the functional affections of the sympathetic vaso-motor system of nerves. This classification is based upon the fact that in many of these cases marked vascular changes—congestion or anæmia, as the case may be—are observed in the external tissues of the affected parts, while the sensations of the patient often lead us to infer the presence of similar conditions within the cranium. The pain and the other symptoms of the outbreak, it is thought, are due to the changes in blood-tension in the cortex cerebri or in the region of expansion of sensitive nerves, or, in part, to the spasm of the muscular walls of the vessels themselves. This theory is seductive from its appearance of pathological simplicity and exactness, but the writer believes, with Anstie, Latham, Allbutt, and other observers, that it is not borne out by clinical experience, and that its adoption tends to cloak the wider relationship that exists between the sensory neuroses.

Migraine, nervous headache, and the superficial and the visceral neuralgias hardly differ more fundamentally from each other than individual cases of either affection differ among themselves. It is not improbable, as we have seen, that all the phenomena of some neuralgic attacks are wholly or in part the expression of irritation of the sensory nervous system from without; but in many cases, on the other hand, the signs of the neurosal tendency are clearly marked, and there is hardly one of the symptoms of a typical migraine of which the analogue may not be found, though perhaps faintly pronounced, in one or another form of superficial neuralgia, while the relation of both to the whole family of the neuroses is still more clearly evident.

Migraine is a disease of youth and middle life, characterized, in its most typical form, by attacks of severe headache of a few or many hours' duration, of gradual onset and decline, ushered in by well-marked auras involving one or more of the cerebral functions, and terminating in nausea or vomiting or profuse secretion of pale urine, or in some other critical nervous outbreak. The pain is usually, but not invariably, deep-seated. It may be confined to one side of the head, most often the left, or may involve both sides, either from the outset or in the course of the attack. The forehead or temple is usually the first part to become painful, but in severe or prolonged seizures the parietal and occipital regions are prone to be affected likewise.

The auras are manifold and important. On the day before an attack the patient may feel remarkably well, or may complain only of such sensations as thirst or giddiness. The attack itself is apt to be ushered in by visual hallucinations of dazzling and vibrating points or serrated images, sometimes with prismatic outlines, accompanied by a loss or obscuration of vision over one-half or some other portion of the field, which lasts half an hour or more, and sometimes clearing up in one part while it advances in another. Simultaneously or immediately after this there may be ting-

¹ Consult, in connection with this subject, the sections on Symptomatology and Treatment.

ling and a sense of numbness of the tongue, lips, hand, or one-half of the body, sometimes followed by partial hemiparesis, and, if the right side be affected, by more or less aphasia or mental confusion. Occasionally the other special senses are affected. Sometimes the aura may constitute the whole of the seizure.

The writer has observed a case in which migraine was represented throughout boyhood by repeated attacks of subjective numbness and tingling of the entire right side of the face, the right arm, and the right half of the body, with aphasia and hemianopsia, followed during many years by trifling headache or none at all; later in life by severe pain. Here migraine as well as neuralgia in other forms was a well-marked family disease.

These auras are especially worthy of notice, because they occasionally point to epilepsy, an affection with which migraine is allied.

The pain may begin on the same side with these prodromal symptoms or on the opposite side. Sometimes drowsiness is a marked symptom throughout the attack, and this differs in significance from the sound, refreshing sleep with which the paroxysm often comes to an end. Sometimes the arteries of the affected side seem strongly contracted, as shown by pallor and coldness of the face and dilatation of the pupil (angio-tonic form); sometimes, on the other hand, they are dilated and pulsate strongly, or the latter condition may follow the former (angio-paralytic form). The radial pulse may show corresponding modifications. These vascular phenomena are often, however, entirely wanting.

Migraine appears to be slightly more common in women than in men. The liability to the attacks often shows itself in extreme youth, usually increases at puberty, and generally ceases at the age of forty or fifty. The attacks sometimes recur at regular intervals of a week, a month, etc., but, on the other hand, they may remain absent for years unless brought on by some exciting cause.

ETIOLOGY AND CLINICAL RELATIONS.—Migraine is a directly inheritable disease, and one which stands in a close relationship to the other grave neuroses, as well as to the neuropathic temperament. Cases are occasionally seen in which the migraine of youth gives place to epilepsy in later years. It is often met with also in families and individuals of neuralgic tendency, and in fact it shades off into neuralgia of the fifth and occipital nerves on the one hand and into periodic nervous headaches on the other. It frequently occurs in gouty persons, and is thought to be related to the brow ache of malaria. The attacks may be brought on by any of the causes which depress the vitality of the nervous system, and by various special irritations, among which errors of refraction are prominent.

The **PROGNOSIS** is unfavorable in well-marked cases, in which the habit of regular recurrence is established, and where the neuropathic predisposition is pronounced and no special exciting cause can be found. On the other hand, there are many cases where the tendency is less deeply rooted, and where with the removal of the exciting cause or causes the outbreaks cease.

Finally, there is great probability that the disease will cease of itself with advancing years, not always, however, without having left its mark on the patient's mental and bodily vitality.

The TREATMENT should be directed first to the detection and removal of special sources of irritation, whether in the eye, stomach, uterus, or elsewhere. Causes of anxiety and mental strain should be as far as possible avoided, and great caution enjoined in the use of stimulants and narcotics. The nutrition should be maintained at its highest level by tonics, and, if need be, by electricity, massage, and hydropathy. Sometimes, besides this a special diet is advisable, for it seems beyond question that some patients have fewer headaches if they abandon all animal food, while others—whether because of a gouty tendency is not clear—do best on a nitrogenous diet with exclusion of sugar and starch.

Of the drugs used to control the liability to the attacks, the most important is cannabis Indica, given in doses of about half a grain of a good preparation of the extract several times daily for weeks or months together. Valerianate of zinc and the iodide and bromide of potassium in full doses are also recommended, but are less efficacious.

In the treatment of the attack itself, besides absolute rest and quiet, large and repeated doses of guarana or caffeine, either alone or combined with drachm doses of bromide of potassium, are sometimes of use if given at the very outset.

It is thought by some observers that ergot or ergotin is of value if the vessels are dilated, and conversely nitrite of amyl or glonoine if they are contracted. It must not be forgotten, however, in case of doubt, that the throbbing due to the latter drugs may increase the pain.

The writer has known a strong faradic current applied with the moistened hand to the back of the neck to relieve an attack, and prolonged but gentle manipulation of the painful area with the finger-tips may have a like effect if the pain is not too severe; as, for example, toward the end of a paroxysm.

Neuralgias of the Fifth Nerve.

Three varieties of these neuralgias may conveniently be distinguished:

1. Ordinary facial neuralgia, analogous to the neuralgias of the other superficial nerves;
2. Intermittent supraorbital neuralgia, sometimes called brow ague, though by no means always of malarial origin;
3. Epileptiform neuralgia (*tic douloureux*).

These varieties are of course closely allied, and have many features and causes in common.

THE ORDINARY FACIAL NEURALGIA is a painful and obstinate malady, although not so serious as the typical *tic douloureux*. The pain may remain fixed in one position or it may shift from one part of the face to another; and the latter is especially common in those forms which occur in anemic or ill-nourished persons. It associates itself readily with occipital neuralgia, and sometimes also with neuralgia of the pharynx and other parts. It occurs most often in persons of neurotic tendencies or impaired nutrition, and may be provoked by disorders of the ears, teeth, and even distant organs. The possibility of aneurisms of the internal carotid or of cerebral tumor should also be borne in mind, and signs of herpes zoster and locomotor ataxia carefully sought for.

The relation of caries of the teeth to neuralgia of the fifth pair forms a very important chapter, which is admirably treated by J. Ferrier.¹ Opinions on this subject are conflicting and unsatisfactory, and the fact that many patients have had nearly all their teeth drawn in the vain attempt to get cured of one of the severe forms of facial neuralgia often creates an impatience of further investigation in the matter. Ferrier points out that as a rule it is not the severest cases of epileptiform tic douloureux that arise in this way, but, on the other hand, that it is a mistake to conclude, because a neuralgia is benefited by medical treatment and made worse by fatigue, exposure, etc., and because it occurs in a person of neurotic temperament, that it is not likely to be due to this form of irritation. The teeth need not themselves be the seat of pain, and the disease in them may be detected only after diligent search.

The most important lesions are said to be caries, exostosis, and other affections involving the pulp-cavity, exposure of the sensitive dentine, ulcerations of the gums, injuries caused in extraction, and other diseases of the alveolar process. The wisdom tooth, by its pressure on other roots and on the gums, is not infrequently the one at fault.

Chronic inflammation of the mucous membrane of the nose or pharynx is said to be an occasional cause of neuralgia of the face, as well as of the upper portions of the body.

THE INTERMITTENT NEURALGIA OF THE SUPRAORBITAL is an interesting affection to which too little attention has been paid. One variety seems to bear a certain relationship to migraine, inasmuch as it occurs under similar circumstances—*i. e.* in distinctly neuropathic individuals and families, and in attacks of about the same duration and periodicity of recurrence.

Another variety approaches the other neuralgias in the longer duration of the attacks, but is characterized by a daily seizure which recurs with absolute regularity, coming on usually at about nine in the morning and increasing in severity for an hour or so, then persisting unchanged until midday or later, when it gradually diminishes, finally disappearing in the course of the afternoon. As a rule, it is brought on by catarrh of the frontal sinuses, often following an acute attack of coryza. A certain amount of neural predisposition is often found in this form, and the first attacks may show themselves in early youth, rarely in the decline of life. The writer has seen one family in which a number of members in at least two generations have been attacked in this way, the seizures having been brought on by exhaustion or coryza, or both combined.

This form of neuralgia is often greatly controlled by quinine if given in sufficiently large doses (15 to 20 or 25, or even 30, grains) and as long as four hours before the attack.

Lange² thinks the action of galvanism is remarkably successful, but the writer's experience does not fully bear this out.

Seeligmüller³ speaks very highly of the effect of the nasal douche, used for the sake of curing the catarrh of the frontal sinuses, and potassic iodide may be useful by rendering the secretions more fluid.

THE EPILEPTIFORM FACIAL NEURALGIA, OR TIC DOULOUREUX,

¹ *Les Névralgies réflexes d'Origine dentaires*, Paris, 1884.

² Cited in the *Centralbl. für Nervenheilkunde*, etc., 1881, p. 10.

³ *Centralbl. für Nervenheilkunde*, etc., June 1, 1880.

is a chronic affliction, characterized by the suddenness of onset and the severity of its paroxysms of pain, which may recur every few minutes with lightning-like rapidity, either spontaneously or brought on by motion of the jaw or the taking of food, and disappear again as quickly. After a group of such paroxysms as this there may be an intermission of some hours or days. During the attack the patient is apt to rub the seat of pain with great violence. The path pursued by the darts of pain may be either in the direction of the nerve-trunks or in an irregularly inverse direction.

In spite of their sufferings, these patients may present an appearance of health. In its worst forms, and especially in advanced life, this variety of neuralgia may be incurable, and at the best it is sure to tax the care and skill of the physician. Anstie thinks that it is apt to be associated with a taint of insanity.

The best TREATMENT consists in the most painstaking attention to hygiene, in the persistent use of galvanism, arsenic, cod-liver oil, quinine, aconite (see under General Treatment), and phosphorus. Croton chloral is occasionally of service.

As a last resort, surgical measures (see above) may be appealed to, but it should be borne in mind that even when the prospect seems most hopeless the relief under medicinal and hygienic treatment may really be near at hand. Where section of nerves is without result, the operation of tying the larger vessels, the carotid or vertebral, on the affected side may be tried, and offers some chance of success.

OCCIPITAL AND CERVICO-OCCIPITAL NEURALGIAS are second only to trigeminal neuralgia in severity, though, fortunately, less common, and either is liable by extension to give rise to the other.

Neuralgic pains in the occipital region may attend Potts's disease of the cervical vertebrae; and this is especially important to bear in mind because the osseous deformity is often wanting for a long time.

The writer has known a persistent pain in this region to be due to intracranial syphilitic disease, and to cease suddenly with the advent of more serious cerebral symptoms.

CERVICO-BRACHIAL AND BRACHIAL NEURALGIAS are less often indicative of the neuropathic taint than the facial neuralgias; and, on the other hand, they are, like sciatica, relatively often due to neuritis set up by injury, amputation, strains, enlarged cervical glands, periarthritides of the shoulder,¹ etc., or associated with herpes zoster. When not due to an unremovable cause the prognosis is favorable. The treatment needs no special description.

INTERCOSTAL NEURALGIA is a very important form, both on account of its frequency and obstinacy, and because it is often associated both with anæmia and chlorosis and with affections of the visceral organs, especially the uterus. The distressing cardiac palpitation of neurasthenic patients often associates itself with pain in the left side, and there is an intimate connection between neuralgia of the cardiac plexus (angina pectoris; see below) and neuralgia of the intercostal and brachial nerves.

Pain in this region, often due to neuritis, may accompany acute and chronic thoracic disorders, and may be the precursor of herpes zoster.

¹ See J. J. Putnam, "A Form of Painful Periarthritis of the Shoulder," *Boston Med. and Surg. Journ.*, 1882.

Caries of the vertebræ and meningitis should be thought of, and cancer if the neuralgia is very persistent, even if it is paroxysmal in character.

TREATMENT.—Besides the general indications for treatment referred to above, it is worthy of special note that nerve-stretching has been successfully tried for intercostal neuralgia. In one interesting case seven nerves were stretched at one operation.¹ The reporter discusses the surgical aspects of the operation, and points out that the nerves should be sought for, not directly beneath the rib, but behind and beneath it, and thinks that the failure to bear this fact in mind might lead to puncturing the pleura.

MAMMILLARY NEURALGIA (irritable breast of Astley Cooper), though often met with in company with intercostal neuralgia, may occur entirely independently. It is sometimes bilateral, and is apt to be associated with irregularity of the uterine functions. Cutaneous hyperæsthesia is often present to a distressing degree, and small tumors of either temporary or permanent duration may make their appearance (A. Cooper), which, however, do not affect the prognosis.

There is no especially effective **TREATMENT** beyond what has been spoken of. Surgical interference is not especially to be recommended, though it has occasionally been useful.

LUMBO-ABDOMINAL NEURALGIA, or neuralgia of that part of the lumbar plexus which supplies the flank and abdomen and the external genital region. These neuralgias are apt to accompany those of the intercostal nerves and share in their significance.

The most important facts with regard to them are that they are intimately associated, in relation both of cause and of effect, with affections of the abdominal and the pelvic organs and of the testis. Neuralgiæ of the terminal branches of the lumbar plexus, the obturator and anterior crural nerves, though well recognized, are comparatively rare.

One of the chief respects in which they are important is in calling attention to the possible presence of disease of the hip-joint or of peri-arthritis of the hip, as well as of tumors or inflammation within the pelvis.

NEURALGIA OF THE SCIATIC NERVE is one of the most severe and common forms. While sharing in the common etiology and history of the other neuralgias, it is peculiarly prone to be due to peripheral causes, which give rise to thickening of interstitial and investing connective tissue of the nerve. The distribution of the pain may be coextensive with the whole distribution of the great and little sciatic nerve, but far oftener the patient indicates certain regions as the seat of his severest suffering; and these are especially the sacral region of one side, the neighborhood of the sciatic notch, the popliteal space, the calf, and the outer side of the foot and ankle. Not infrequently the whole course of the sciatic nerve is traced out by the darts of pain; and in this case it is the nerves which supply the sheath of the sciatic itself which are supposed to be the seat of the neuralgic process.

Sciatica is usually unilateral, but exceptionally bilateral, or attacks the two sides alternately. The tender points most often met with are at the sacro-iliac synchondrosis, the posterior border of the great trochanter, just beneath the head of the peroneal bone, below and behind the exter-

¹ Lesser, *Deutsch. Med. Wochenschr.*, Sto. 20, 1884.

nal malleolus, but numerous others are likewise noted by Valleix. Sometimes no tender points can be found. Sometimes, also, it is one or more of the collateral branches of the sciatic plexus that are the seat of the neuralgia, and the distribution of the pain and of the tender points varies accordingly.

It is in sciatica pre-eminently—in part, no doubt, because of the frequency of neuritis—that disorders of sensibility of the skin are noticed, as well as muscular paresis or spasm. This anæsthesia has been studied with great care by Hubert-Valleroux and others, and it has been shown that it is often confined to limited spots, a centimeter or so in diameter, within which the loss of sensibility may be nearly absolute. Nevertheless, their functional origin is proved by the fact that under faradization they may rapidly disappear.

The duration of an attack of sciatica varies from a week or two to months or even years, and it shows a marked liability to recur, especially with changes of weather. First attacks occur pre-eminently, though not exclusively, in middle life, and oftener in men than in women, evidently because they are oftener exposed to mechanical injury and, through their occupations, to sudden changes of temperature and the like.

The occasional causes are numerous, and include sudden wrenches and jars, even if not very severe, interpelvic pressure from tumors or impacted feces, etc. Gout, syphilis, and diabetes may act as predisposing and even exciting causes, and, it is said, gonorrhœa likewise. Periarthritic inflammations of the hip-joint and varicose veins frequently excite pains in the various sciatic nerve-branches which simulate true sciatica.

As has been indicated, although sciatica may be a pure neuralgia (see under Pathology), running its course without leading to any appreciable change in the nerve, yet subacute and chronic neuritis is very common, either as a primary condition or a complication, and its presence puts a graver aspect upon the case. The pain of neuritis, when severe, is relatively constant, remittent instead of intermittent, dull rather than lancinating, increased by motion and pressure; whereas the purely neuralgic pains are sometimes relieved by movement. It is, however, doubtful whether an accurate differential diagnosis is possible (see above). It is to this neuritis that the muscular atrophy is due which is often so marked, and it may likewise give rise to various cutaneous lesions of herpetic character. The severe pain that accompanies typical herpes zoster of this region is well known.

The TREATMENT of sciatica must vary with the probable cause of the disease and its stage of progress. Diathetic taints are to be met if present, and the greatest measure of physical health secured that the circumstances possibly admit. It is a good precaution in all cases to secure free evacuation of the bowels and to guard against hemorrhoidal congestions.

As against the neuralgia itself, the proper means vary with the acuteness of the attack and the presence or absence of neuritis. For the acute stage absolute rest is almost always desirable as a prime condition. Quinine, belladonna, aconite, and turpentine in full doses should be thoroughly tried, and special reference had to the periodicity of the seizures.

Frequent and extensive but superficial counter-irritation (actual cau-

tery, blistering, ether, or chloride of methyl) is in place in this stage, and galvanism (constant current) is often of great service. It is probable that for the acute stage the prolonged use of mild currents is the best, whereas in more chronic cases the stronger, even very strong, currents, brought to bear as accurately as possible upon the nerve itself, are sometimes more useful.

Hydropathic treatment is in great repute both for acute and chronic cases, but as success in this way demands care and knowledge, the reader is referred to the special treatises.

In cases of long standing the continued application of ice-bags along the length of the limb for days together is often of excellent service, but this method of treatment is not without its dangers and needs to be carefully watched.

In chronic cases deep injections are of service, and nerve-stretching (see above) is in place.

THE VISCERAL NEURALGIAS have not received the attention which is due them both on account of their intrinsic importance and their constitutional significance. Not only are they found in common with the superficial neuralgias in the overtired and the underfed, but they point more strongly than the latter to the neuropathic diathesis, alternating with such symptoms as migraine, asthma, nervous dyspepsia, and insomnia. They occur also in the gouty and among the neuropathic descendants of the gouty, and as a result of functional and organic disorders of the viscera.

The pain of these neuralgias, though usually described as vague, ill-defined, dull, etc., yet often stirs the nervous system to its depths, causing nausea, faintness, sweating, prostration, reflex disorders of the secretions, and like symptoms.

ANGINA PECTORIS is a neuralgia probably of the pneumogastric and sympathetic nervous apparatus of the heart. The pain, which is usually of a heavy, dull, oppressive, or tearing character, and capable of rising to intense agony, is usually deep-seated, and felt to the left of the sternum and beneath the breast, often involving the left arm and side, and occasionally the left side of the face and neck, and even the leg of the same side or the right arm. It may also, as the writer has seen, be confined to the sternal region. In the case referred to this pain recurred every afternoon and evening with great regularity. Sometimes instead of pain the arm may be the seat of a tingling numb sensation only.

During the attacks the action of the heart may continue unchanged, or it may become slow and feeble or intermittent, yet without necessarily being the seat of organic disease. The onset of anginic attacks is usually, but by no means always, sudden, and their duration is commonly short. All the features of the attack, however, are subject to considerable variation, and nervous symptoms of a variety of kinds, which it is not necessary to detail, may precede or attend the seizure. In severe attacks the patient's anguish and prostration are extreme; the face and extremities become pale and cold, and a cold sweat breaks out.

In a large proportion of cases, especially the severest ones, these neuralgic attacks are associated with organic disease of the heart or blood-vessels.

A variety of causes have been suggested to account for the seizures,

prominent among which is a widespread contraction of the arterioles, bringing a sudden strain upon the left ventricle of the heart. This theory is especially noteworthy because of the success which has attended the treatment by nitrite of amyl, which brings on a rapid vascular relaxation. In other cases spasm of this kind is manifestly absent. Fraenkel¹ has recently defended the view that a momentary paralysis and over-distension of the left ventricle is the exciting cause. In other cases all sign of arterial or cardiac disease is and remains absent.

In this latter group the tendency to the attacks may cease under appropriate hygienic treatment. Thus, in an instance known to the writer a lady of usually good health suffered for several months from slight attacks of præcordial pain, with pain or a sense of numbness in the left arm, and often a feeling of breathlessness on very slight exertion. This condition had manifestly been brought about by prolonged physical and mental strain, and disappeared completely after a period of rest. Other such cases are described by Anstie, Allbutt,² and others.

In judging of the significance of anginic attacks in a given case the signs of circulatory disease should first be studiously sought, and especially, as more likely to escape notice, indications of cardiac enlargement or weakness, or of increased vascular tension, or of chronic nephritis.

Dull pains in the intervals of the attacks are also regarded as important, as indicating the presence of neuritis of the cardiac nerves, which without doubt often exists. On the other hand, as pointing rather to a neurotic origin of the symptoms, a tendency, individual or inherited, to neuralgias of other forms, to asthma, migraine, and the other neuroses, is to be looked for.

Heredity plays a certain part in the etiology, and among the special causes of the non-organic form abuse of tobacco is said to be important.

The TREATMENT would be likely, of course, to be widely different according to the nature of the case, being on the one hand addressed to the circulatory apparatus, on the other to the health of the nervous system, in both cases following well-known lines.

In the treatment of the individual attacks the diffusible stimulants and the narcotics are of value when there is time to employ them. With regard to nitrite of amyl and the longer-acting nitro-glycerin, which have given so much relief in some cases, it would be premature to confine their use to the cases of demonstrable vascular spasm or even organic disease, and they are fair agents for trial in the apparently non-organic cases as well.

A patient of Romberg's used to get great relief from swallowing pieces of ice.

When the attacks are long continued or frequent, electricity, either as galvanism or by the wire brush, is applicable, and also counter-irritation over the chest, even by vesication.

GASTRALGIA (syns. gastrodynia, cardialgia, gastric colic, cramp of the stomach, etc.) may be associated with organic disease of the stomach or may occur as an independent neurosis. It is met with in individuals and families in which asthma, migraine, gout, etc. are found. In general it is common in persons of nervous, mobile temperament, and is moreover apt to point to temporary exhaustion from some cause, though this is by no

¹ *Zeitschr. für klin. Med.*, 1882.

² *London Lancet*, 1884, i.

means always true. The writer has seen several sensory disorders of this class at the period of life of which the menopause is the chief feature. The pains of apparently hypochondriacal patients doubtless belong sometimes in this group.

The pain of gastralgia is felt primarily at the epigastrium, whence it may radiate upward and backward along the œsophagus and through into the back, as well as laterally in various directions. Allbutt says that it is sometimes associated with anginiform attacks.

Other associated symptoms are dyspœnea, prostration, faintness, coldness of the extremities, or reflex changes in the action of the heart, which may beat feebly, rapidly, and irregularly, or more slowly than normal.

À propos of the relation of gastralgia to organic disease, it is important to recall the fact that some of the organic diseases of the stomach, notably chronic ulcer and cancer, may fail to reveal their presence by any physical sign. In a case seen by the writer a cancerous growth had invaded the entire stomach, causing an enormous thickening of its walls, yet no tumor was to be felt, and the most marked symptoms were gastralgia and exhaustion.

The relations of gastralgia to the other purely functional disorders of the stomach are interesting and peculiar. It is beyond a question that every variety of digestive disorder, from simply delayed and painful digestion to pyrosis, the formation of gas, and constant vomiting, is much more often of purely neurotic origin than has been supposed.

The DIAGNOSIS of catarrhal gastritis as distinguished from nervous dyspepsia is indeed often difficult or even impossible. Leube has recently recorded a case where the matter vomited during life contained fungoid growths, such as are usually considered pathognomonic of gastritis, and yet at the autopsy the mucous membrane appeared perfectly healthy.

With these nervous disorders of digestion, which are by no means confined to hysterical patients, gastralgia may be variously associated, or it may occur independently of them all, or vice versâ. On the other hand, digestion may be attended with a sense of discomfort, often amounting to severe pain, yet without regular outbreaks.¹ This symptom is classified by Allbutt as a hyperæsthesia of the stomach rather than as a neuralgia, but from this to true gastralgia there is only a sliding scale of difference. Sometimes a persistent neuralgic habit is set up by a local disorder which itself passes away entirely.

TREATMENT.—In acute attacks the aim is simply to relieve pain by whichever of the well-known methods promises the best. The real field for thought and care is in the treatment of the underlying states—first, those which, like gout, anæmia, syphilis, or nervous debility, predispose to the attacks; second, the local or special conditions which act as exciting causes. Sometimes it will be found that such patients have special idiosyncrasies with regard to the nature of food or time of meals.

In that condition of the system which is indicated by frequent or paroxysmal excess of uric acid in the urine a long-continued use of Vichy water or lithia is sometimes of service. If it be finally concluded that the stomach is in an hyperæsthetic, not in an inflamed, condition, it may not be advisable to diminish the amount of food, but, on the contrary, by one means or another, to increase it.

¹ Allbutt, *loc. cit.*

NEURALGIA OF THE UTERUS AND OVARIES.—Attention has repeatedly been called to the fact that affections of these organs may excite neuralgias in distant parts of the body or in the lumbo-abdominal nerves; but besides these the uterine and ovarian nerves themselves sometimes are the seat of neuralgia, and it is claimed that menorrhagia and metrorrhagia may occur as a consequence.

The other abdominal organs and the testis are occasionally the seat of neuralgic pains, and attacks which involve the liver may be followed by swelling of the liver and by jaundice.

It is not always easy to assert with confidence whether an attack of abdominal neuralgia affects the external or the visceral nerves.

NEURALGIA OF THE ANUS AND RECTUM is a well-marked and painful affection, and the tendency to it may be hereditary. The seizures themselves may come on spontaneously, especially after fatigue, or may be excited by slight irritations, such as the passage of hardened feces, or may follow seminal emissions. The pain may be accompanied by quick, clonic spasm of the perineal muscles.

The rapid injection of hot water into the rectum often at once relieves the attack.

We have not space to discuss at length the neuralgiform affections of the joints and muscles and those due to the metallic poisons and other causes which do not follow the course and distribution of special nerves.

In accordance with the belief which we have expressed, that neuralgic attacks are not always of the same nature, but are the manifestations of many different conditions, we should be inclined to include many of these irregular affections under the neuralgias instead of classifying them apart, as Anstie and most writers have done. Thus, a patient of the writer, a gentleman of middle life, who has had migraine since childhood and belongs to a neuropathic family, suffers on the slightest exertion from violent pain in both thighs, which comes on very gradually, beginning at the knees and spreading upward, eventually passing away after a night's rest. One might diagnosticate this as myalgia if he confined himself to topographical considerations, but the history of the patient and the regular march of the attacks point to a different conclusion.

VASO-MOTOR AND TROPHIC NEUROSES.

BY M. ALLEN STARR, M. D., PH. D.

DEFINITION.—In the term vaso-motor and trophic neuroses it is intended to include a number of forms of disturbance of circulation and nutrition which are caused by disorders of the nervous system. Such disturbances may occur in any part of the body. They are not to be regarded as distinct diseases, but rather as symptoms of lesions in the peripheral or central nervous system. They may present themselves in various forms, as hyperæmia or anæmia or instability of vascular tone, as atrophy or hypertrophy or disintegration of normal tissue. Their consideration cannot, however, be assigned to any previous department of this volume nor relegated to various divisions of it; partly because in some cases they are to be traced to lesions of the sympathetic system, not elsewhere considered; partly because of our ignorance as to the exact location in many cases of the lesion of which they are manifestations.

It is probable that at a future time this chapter will disappear from a system of medicine, as the chapter on ascites has disappeared, and that the symptoms under consideration will be distributed among various departments as symptoms of ascertained lesions in various organs. For the present, however, they demand a separate discussion.

It is not possible to distinguish accurately in all cases between the vaso-motor and the trophic neuroses, for while in many features they are distinct, in a large proportion of cases they occur together. But it is not possible to ascribe all trophic changes to vascular disturbance, nor all vaso-motor changes to a defect or excess of trophic action. Hence a separate consideration of these allied subjects must be given. It is always to be remembered, however, that each may give rise to the other, and that in their pathology they are closely connected. Vaso-motor disturbances manifest themselves (1) by a dilatation of the vessels, producing redness, heat, and rapid metabolism in the part affected; or (2) by a contraction of the vessels, causing pallor, coldness, and malnutrition; or (3) by an alternation of these conditions and consequent temporary disturbance of function. Trophic disturbances may occur in consequence of such increase or decrease of blood-supply, or independently of any vascular change, causing (1) an abnormal production of tissue in an organ, or (2) a decrease in the size and number of its constituent cells, or (3) an actual degeneration of the elements which make it up, after which their place may be taken by another kind of tissue. Under all these circumstances the function of the part affected will be disturbed, and symptoms will be produced which will vary with the tissue or organ involved. Hence a gen-

eral consideration of these symptoms must be given. Before proceeding to a detailed consideration of these neuroses it is necessary to review the physiology of the vaso-motor and trophic systems, in order to make clear the manner in which they perform their functions. And inasmuch as the pathology of these affections is best understood by comparison with experimental lesions made by physiologists in investigating their function, it will be treated together with their physiology.

Vaso-motor Neuroses.

PHYSIOLOGY.—**Local Vascular Tone.**—Since changes in the force and frequency of the heart's action, and variations in the total amount of blood in the body, affect the body as a whole, the state of circulation in any one organ or part must be dependent upon the degree of contraction or dilatation of its own vessels. This is known as the local vascular tone. It is under the control of a system of nerve-ganglia with their subservient fibres which are found in the middle coat of all arterioles (Fig. 56). The

FIG. 56.

Vaso-motor Nerves and Ganglia accompanying the Arterioles in a Frog (Gimbert): *C*, arterioles; *N*, vaso-motor nerve; *G*, ganglion, from which nerves issue, situated at the point of anastomosis of several capillaries; *R*, fibre of Remak.

energy expended by these ganglia is manifested by a constant moderate contraction of the circular muscular coat of the artery—a contraction which is as constantly opposed by the dilating force of the blood-pressure within the vessel. An exact equipoise between these two forces never occurs, since each varies constantly, but in a state of health one never becomes permanently excessive. Considerable variations, however, in the local vas-

cular tone are frequently observed. Thus each organ is influenced to a certain degree by every other, since an increase of blood in one part must involve a decrease in all other parts, the total amount of blood in the vessels being constant. Alteration in the heart's action is felt more quickly in some organs than in others, and thus the general blood-pressure by its variations may cause secondarily a disturbance of local vascular tone. The variations now under consideration, however, are not of this kind. They are such as are produced by influences acting directly upon the ganglia in the vessel-walls.

Local irritation is such an influence, and it may excite the ganglia to increased activity, so producing a contraction of the vessel and consequent pallor; or it may suspend the action of the ganglia, so producing a dilatation of the vessel and consequent flushing.

Another influence is irritation acting from a distance and conveyed to the local ganglia by nerve-fibres. These nerve-fibres can be distinguished from all others by their structure, being non-medullated, and by the fact that they have an indirect course, passing from the central nervous system to the sympathetic ganglia, and from these to the local ganglia in the vessels. The impulses sent along these nerves may affect the local ganglia in one of two ways, and either cause contraction by exciting the ganglia, or dilatation by inhibiting the action of the ganglia. The result produced has determined the names given to the impulse, to the fibre transmitting it, and to the centre whence the impulse proceeds, and hence vaso-constrictors and vaso-dilators are distinguished from one another.

The history of the development of the sympathetic nervous system,¹ as well as its gross anatomy, affords distinct proof that it is not an independent system, as Bichat supposed, but is closely connected in its physiological action with the spinal cord and brain. Impulses which reach the sympathetic ganglia from a distance along the vaso-constrictor or vaso-dilator fibres originate in the central nervous system. The nervous mechanism which controls the local vascular tone is therefore a complex one, consisting not only of the set of local ganglia connected with larger sympathetic ganglia, but also of centres in the spinal cord connected with higher centres in the brain. The brain-centres in turn are complex, consisting of an automatic mechanism in the medulla regulating the action of all the subordinate parts below it, and of a series of cortical centres whose function it is to stimulate or inhibit the medullary mechanism. It therefore becomes evident that local vascular tone may be modified by local causes acting on the ganglia in the vessels—*e. g.* cold or heat; by changes in the sympathetic ganglia—*e. g.* the hyperæmia of the face in lesions of the cervical ganglia; by reflex action through the spinal cord—*e. g.* pallor produced by pain; by reflex action through the medulla oblongata—*e. g.* glycosuria following sciatica; or by conscious or unconscious impulses coming from the cortex—*e. g.* the blush of shame, the vaso-motor paralysis of hemiplegia.

Vaso-constrictors.—Such a mechanism, however complex in structure, would be easily comprehended if the constant manifestation of energy in the maintenance of arterial tone had its only source in the action of the local ganglia in the vessels, and was affected only occasionally by impulses

¹ W. R. Birdsall, "Embryogeny of the Sympathetic System," *Arch. of Med.*, vol. i., where a bibliography of the subject is to be found.

from a distance, as has been thus far supposed. This, however, is not the case, as has been demonstrated by a series of experiments beginning with the brilliant researches of Claude Bernard. The classical experiments of the French physiologist were made upon the sympathetic cord in the neck of a rabbit. Division of this was found to produce a dilatation of the vessels of the ear. Irritation of the peripheral end of the divided cord produced a contraction of the vessels. Division of the spinal nerves connected with the cervical sympathetic and of their anterior roots, or irritation of the cut ends, produced effects similar in character to those caused by division or irritation of the cervical sympathetic. Destruction of the spinal cord in the lower cervical region, or division of the cord at any higher level up to the medulla, was followed by dilatation of the vessels. If the segment of the divided cord just below the section was irritated the vessels contracted. Destruction of the medulla at the calamus scriptorius and above it for three centimeters produced a general dilatation of all the vessels in the body, but division above this level had no effect. The initial congestion produced by these various experiments was accompanied by a rise of temperature in the part. It was followed after a time by a partial recovery of vascular tone, which was more complete the farther the division from the local ganglia. These facts warranted the conclusion that the energy expended by the local ganglia in holding the vessels in a state of constant moderate contraction is derived from the central nervous system, primarily from the automatic centre in the medulla, which in turn is reinforced by each of the secondary centres in the spinal cord and sympathetic ganglia; and also that while the medullary centres control the entire body, the cord and sympathetic centres control only those parts with which they are especially related. In order, therefore, to the maintenance of normal vascular tone the local ganglia must be intact, and they must be in connection with the sympathetic ganglia; these must be active, and must be connected with the spinal cord; the cord must be normal, and its tracts from the medulla must be capable of conduction; the medullary centre must be active, and not hindered or spurred by cortical impulses of a conscious or unconscious nature. Any injury to one or more of these parts will produce a vascular dilatation by interfering with the transmission of vaso-constrictor impulses from within outward, and any irritation of one or more of these parts may cause a contraction of the vessels by increasing the normal stimulus sent to the local ganglia by the vaso-constrictors.

Vaso-dilators.—The action thus far considered has been wholly of a vaso-constrictor kind, and the dilatation which has been mentioned has been due to cessation of the constrictor energy normally passing outward. This may be termed a passive dilatation. It is the kind produced by division of any one of the sympathetic ganglia or cords. But further experiments have shown that another kind of dilatation may be produced, traceable not to a mere cessation of constrictor impulses, but to an impulse of a positive kind sent to the local ganglia and resulting in a sudden suspension of their activity. Such an impulse is really an inhibitory impulse arresting the action of the ganglia in spite of the continued stimulus sent to them from the central nervous system. Its result is a dilatation of the arteries, produced by the blood-pressure within them, which may be termed an active dilatation. Thus, Bernard

found that irritation of the chorda tympani caused an immediate flow of blood to the submaxillary gland because of the dilatation of its vessels. And Dastre and Morat¹ have demonstrated a similar effect in the head and extremities after irritation of portions of the cervical sympathetic and of the peripheral nerves.

Much confusion has arisen from the use of the term active dilatation, and many explanations of its mechanism have been offered. At first it was supposed that a system of longitudinal fibres in the vessel-wall acted as opponents to the circular constrictor fibres. This theory, originating with Stilling and Duchenne,² has been lately revived by Anrep and Cybulski.³ They hold that since a vessel elongates as well as dilates with every heart-beat, its total distension is the result of two factors—viz. transverse and horizontal distension. If one of these is neutralized, they claim that the other will be increased. Longitudinal fibres in the wall by preventing elongation may thus allow the entire force of the heart to be expended in dilating the vessel. This theory has not, however, been accepted, and with that of Schiff, that contractile elements of the connective tissue surrounding the vessel-walls could pull outward the walls and thus dilate the vessel, has lapsed, because of lack of demonstration of the necessary anatomical structure in all arterioles. Another theoretical explanation, that dilatation of the arteries is caused by contraction of the veins damming back the blood, is disproved by the fact proven by Dastre and Morat, that blood-pressure increases instead of diminishing in the veins during vaso-dilator action. Legros⁴ and Onimus,⁵ noticing the normal occurrence of a peristaltic motion of centrifugal direction in the arteries of the retina, which if increased produced a certain degree of hyperemia, attempted to explain the phenomena of dilatation by supposing a sudden increase of peristalsis. But Vulpian has proved that the peristalsis is both too slight and too slow in its effects to account for the rapid action of the vaso-dilators, and Dastre and Morat have shown that the peristalsis, not being synchronous with the heart-beat, really impedes the flow of blood. The last theory to be mentioned has a chemical basis, and is known as the theory of attraction (Brown-Séquard, Severini.) According to this, the organs, when active, manifest increased metabolism, to maintain which the blood is drawn toward them by the chemical changes in progress. This theory was based on the fact that irritation of the chorda tympani causes an increased secretion of saliva as well as a congestion of the submaxillary gland. It is now known, however, that these two acts are independent of each other, as either can be suspended while the other continues. Hence this theory too has lapsed.

The view already stated, that vaso-dilators act by inhibiting local ganglia which cause contraction, is now accepted, especially since it is found that such inhibitory activity is constantly displayed by other parts of the nervous system, and is competent to explain the facts. The active dilatation produced by the inhibition of the action of the local ganglia is

¹ See *Archives de Physiologie*, "Vaso-dilateurs," 1879, 1880, 1882; *Comptes rendus de l'Académie des Sciences*, 1880, pp. 393 and 441.

⁵ *Des Congestions actives*, Paris, 1874.

therefore to be clearly distinguished from the passive dilatation caused by the cessation of normal tonic impulses sent to them from higher centres. The former is a positive active vaso-dilator phenomenon. The latter is a negative paralytic vaso-constrictor phenomenon. The former is more effective, the dilatation being greater in degree and more permanent than the latter, and resembles exactly the dilatation produced experimentally by exhaustion of the activity of the local ganglia by over-stimulation of the constrictors.¹

An important point of contrast which has been established between vaso-constrictor and vaso-dilator impulses is that while the former are constant the latter are intermittent. Hence they cannot be regarded as opponents of one another. In a normal quiescent state vaso-constrictor energy is always being supplied to counteract the continued intravascular pressure ever renewed with the cardiac systole. The vaso-dilators are inactive. In an organ thrown into functional activity an increased flow of blood at once takes place, proportionate to the work being done by the organ. Such a functional hyperæmia might be produced either by a cessation of constrictor impulses or by an inhibition of their effects. It is by the latter means and through the vaso-dilators that it is produced, and it is probably the chief function of the vaso-dilator nerves to regulate the blood-supply in accordance with the need of a part. For this reason these nerves have been supposed to pass with the motor nerves to the muscles. As few organs exist without a possible use, it is probable that vaso-dilators pass to all parts of the body, as Vulpian asserts, though they have not been demonstrated in every organ or every part.

Like the vaso-constrictors, the vaso-dilators can be traced to the spinal cord, and their centres there are governed by a general centre in the medulla, which in turn may be affected by impulses from the cortex. A destructive lesion in any part of the vaso-dilator system does not produce as marked effects as one involving the vaso-constrictor system, since the symptoms of such a lesion will only appear when the vaso-dilators are called into play. When the vaso-dilator nerve to the submaxillary gland is cut, no change is observed until by some sapid substance put in the mouth its function should be excited, when the gland is no longer found to flush with blood as in the normal state. It is by means of the vaso-dilators that erectile organs become engorged with blood. Eckhard has shown the *nervi erigentes* of the penis to be vaso-dilator nerves. If they are destroyed, the organs will not respond to the wonted stimulus—a symptom which, however, would only be noticed at intervals. An irritative lesion of the vaso-dilator system may produce permanent congestion of an organ or part, but this seems to be rather more rare than a congestion from paralysis of the constrictors. It is seen in injuries of the peripheral nerves.

Origin of the Vaso-motor Nerves.—The exact course of the vaso-constrictor and vaso-dilator nerves has been traced from various parts into the central nervous system by the careful experiments of Dastre and Morat,² and more recently by Gaskell.³ It is now established that they

¹ Goltz, *Arch. f. d. gesamt. Physiol.*, xi. 92.

² See *Comptes rendus Soc. de Biologie*, and *Arch. de Physiol.*, 1879–84.

³ W. H. Gaskell, "On the Structure and Function of the Nerves which Innervate the Vascular System," *Journ. of Physiol.*, Jan., 1886.

exist as separate nerves, although they often run together, and that they usually enter the spinal cord at different levels.

If the various spinal nerves be cut singly from above downward, and the effects noted, and if the peripheral ends be irritated and the effects noted, and if with proper care the results be analyzed and compared, it will be found that the anatomical connections of the segments of the spinal cord with the sympathetic ganglia, which are so evident at each level, are not the ones by which physiological impulses pass out at that level. The vaso-constrictors of the head, which can be traced to the superior cervical ganglion, do not come from the upper cervical region of the cord, as might be supposed from the connections of that ganglion, but from the first three dorsal nerves. They reach the ganglion through the sympathetic cord in the neck, having traversed the inferior cervical ganglion on the way. There are vaso-constrictors in the cranial cavity which accompany the third, fifth, seventh, and twelfth nerves to the eye, face, and mouth. It is still undecided whether they originate in the cord and medulla, issue in the spinal accessory nerve, and with it enter the cranium (Gaskell), or reach those nerves by way of the carotid and vertebral plexus from the inferior cervical ganglion (Dastre and Morat). The vaso-constrictors of the arm, which can be traced to the inferior cervical and upper thoracic ganglia and to the thoracic sympathetic cord, are derived from the seven upper dorsal nerves. It is true that division of the roots of the brachial plexus causes a slight dilatation of the vessels of the arm, but this is so much increased when the dorsal nerve-roots are divided that it is evident that it is through them that the constrictor fibres chiefly pass. The vaso-constrictors of the leg, which can be traced into the second and third lumbar ganglia and lumbar sympathetic cord, are derived from the five lower dorsal and first lumbar nerves, and only join the crural and sciatic nerves after passing through the abdominal sympathetic. The thoracic viscera are probably supplied partly through the branches of the inferior cervical and thoracic ganglia, and partly through the pneumogastric, the latter statement being disputed by Gaskell. The abdominal viscera are supplied partly through the splanchnic nerves, which are made up of fibres issuing from the cord in the fifth to the twelfth dorsal nerves inclusive, and partly through the pneumogastric. Thus the dorsal region of the cord is the origin of the majority of vaso-constrictor fibres in the body.

The origin of the vaso-dilators is also to be traced to the dorsal cord. The vaso-dilators of the bucco-facial region come from the second to the fifth dorsal nerves, whence they pass to the first thoracic ganglion, and thence by the annulus of Vieussens into the cervical sympathetic cord. Those of the eye, head, and ear come from the same ganglion, but have their spinal origin in the eighth cervical and first dorsal nerves. Those of the arm are traced into the upper thoracic sympathetic cord, which they reach from the five upper dorsal and last cervical nerves. Those of the leg are traced to the first and second lumbar ganglia and the lumbar sympathetic cord, which they reach from all the dorsal nerves from the sixth downward. Gaskell holds, however, that the vaso-dilators of the extremities pass out of the cord in the cervical and lumbar plexuses and accompany the cerebro-spinal nerves. The vaso-dilators of the thorax and abdo-

men are supposed to pass in the pulmonary plexus and splanchnic nerves, but this is not yet fully determined.

Gaskell¹ believes that vaso-motor nerves can be distinguished from motor and sensory nerves in the spinal nerve-roots by the smallness of their calibre. He finds such fine fibres only in the spinal nerve-roots between the second dorsal and second lumbar segments of the cord (in the dog), and in the three upper roots of the spinal accessory nerve. According to his account, the vaso-constrictors issue from the spinal cord in both anterior and posterior nerve-roots as medullated fibres, and pass to the sympathetic ganglia lying on the vertebræ (proximal or lateral ganglia); there they lose their medullary sheath, and either end in cells whence new fibres issue, or more probably pass directly onward as non-medullated fibres, having a connection with the unipolar cells of the ganglia only for purposes of nutrition. The number of fibres issuing from any one ganglion is much greater than the number entering it from the cord; hence it is supposed that each medullated fibre splits up into a group of non-medullated fibres; which is possible, as the researches of Ranvier have shown that each axis-cylinder is made up of numerous fibrils. Leaving these ganglia, the nerves pass either to the second series of ganglia (distal or collateral ganglia), whence they issue in plexuses to enter the vessels, or to the vessels directly, where they divide in plexuses. It is in the meshes of the plexus that the local ganglia of the vessel-walls are found. The vaso-dilators are thought to differ from the vaso-constrictors in passing directly to the distal ganglia as medullated fibres, not being connected in any way with the proximal ganglia. Gaskell makes no statement regarding their limits of origin from the cord, except to state that the *nervi erigentes* issue with the sacral nerves. He agrees with the view that the vaso-dilators act as inhibitory nerves upon the local ganglia.

Vaso-motor Reflexes.—Thus far, reference has been made only to fibres whose direction of transmission is centrifugal, and whose exit from the spinal cord is by the anterior nerve-roots. There are other fibres, however, through which centripetal impulses pass, and these enter the spinal cord with the posterior nerve-roots. The function of these fibres is to transmit sensory impulses inward to reflex centres, and thus set in action motor mechanisms of a vaso-constrictor or dilator kind whose effects are produced at the periphery. There are, therefore, vaso-motor reflexes, as well as skin and tendon reflexes, whose centres are in the spinal cord. These reflex acts may be excited by impulses reaching the centre not only through the vaso-motor centripetal nerves, but also through the sensory nerves of the cerebro-spinal system. The effect of changes of temperature on the circulation in the skin (if the right hand be plunged in cold water there is a fall of temperature in the left hand), the effect of pain upon the color of the face and the size of the pupil, the red cheek on the affected side in pneumonia, the occurrence of glycosuria during sciatica,—are all instances of such reflex acts. Many vaso-motor affections are produced by irritation causing reflex effects at a distance from the seat of irritation—a fact always to be kept in mind. The utility of counter-irritation to the surface in diseases of the internal organs is explained by supposing that vascular changes are produced in those

¹ *Journal of Physiology*, Jan., 1886.

organs through reflex mechanisms set in action by the local irritation. While some of these reflexes may have their central mechanism in the local ganglia, it is probable that the majority are to be traced to the spinal cord. It is believed that the sympathetic ganglia are not the seat of reflex centres.

FIG. 57.

Diagram to represent the Mode of Action of Counter-irritants applied to the Chest (Lauder Brunton). The irritation of the afferent nerves by the blister on the chest wall gives rise to a vaso-constrictor reflex in the vessels of the lung.

Since the vaso-motor nerves are connected almost exclusively with the dorsal portion of the spinal cord, it is very natural to conclude that the vaso-motor reflex centres are situated in this region; and the hypothesis has been advanced by Jacobovitch, and strongly urged by Gaskell,¹ that the cells of the vesicular columns of Clarke, which are peculiar to this region, are the seat of these reflex mechanisms. This hypothesis gains some support from the pathology of syringo-myelia. In this disease the gray matter surrounding the central canal and the vesicular columns are destroyed. The characteristic symptoms are vaso-motor and trophic disturbances, consisting of changes in the vascular tone, changes of local temperature, and various eruptions, in some cases going on to ulceration in the skin and mucous membranes. It is, however, undecided whether the vaso-motor centres of the cord are limited to the columns of Clarke, or are situated in the gray matter surrounding the central canal, since both these parts are destroyed in this disease.² That they are not located in the anterior or posterior gray cornua is determined by the fact that diseases limited exclusively to these areas do not cause vaso-motor disturbances. The situation of the various reflex centres for the various parts of the body is at different levels of the cord, as has been determined by the experiments already cited to establish the level of origin of the vaso-motor nerves. The exact location of the vaso-constrictor and vaso-dilator reflex centres for definite parts is yet to be ascertained.

Vaso-motor Tracts.—These reflex centres are connected with the medulla by tracts which lie in the lateral columns of the spinal cord,³ although it is not determined in which part of these columns. It is not possible as yet to separate the constrictors from the dilators in this tract, nor to determine whether it transmits impulses in both directions or only from above downward. Nor is the course of associating fibres between reflex centres at different levels known. In cases of transverse myelitis the control of the medulla is removed from the vascular centres below the lesion, and the lack of vascular tone seen in the paralyzed limbs, together with the susceptibility to local irritation, is the result of this division of the vaso-motor tracts.

Medullary Centres.—It has been stated already that a general vaso-motor centre with both constrictor and dilator powers is situated in the medulla. This lies in two divisions on each side of the middle line, in or just beneath the floor of the fourth ventricle, from the calamus scriptorius up to the level of the sixth nerve-nucleus. Each division governs the vascular tone of its own side of the body,¹ and lesions in its region in man produce unilateral vaso-motor symptoms.² This centre can be excited to reflex action by strong irritation locally or through the blood, in which case a general constriction or dilatation of the vessels of the entire body will ensue. It seems probable, however, that the general centre in the medulla is made up of a number of special centres, each of which governs a definite set of organs. The vascular tone of the thoracic and abdominal viscera is certainly regulated by a series of such centres. Brown-Séquard and Schiff have produced hemorrhages in the lungs, pleura, stomach, intestines, and kidneys at different times by destructive lesions of the medulla, and the well-known experiments of Bernard, in which by puncture of the medulla local hyperæmia of the liver or kidneys was caused, producing glycosuria or polyuria, confirm this view. Lesions of these parts in man produce similar effects. Charcot has shown that in cerebral hemorrhage ecchymoses may be found in the stomach, pleura, and endocardium, and that pneumonia is especially frequent upon the paralyzed side. De Jonge³ has been able to collect thirteen cases of diabetes mellitus in which a lesion of the medulla (hemorrhage or tumor) was found after death; and Flatten⁴ has proven the existence of similar lesions in diabetes insipidus. The connection of these centres with the liver and kidneys has been traced elsewhere.⁵ The medulla contains a special centre for the vaso-motor nerves of the abdomen, which are in the domain of the splanchnic nerves. This centre is excited reflexly by impulses reaching it through the depressor nerve of Cyon from the heart; so that when that organ is overburdened it may be relieved by a fall of arterial pressure produced by dilatation of the abdominal vessels. Whether the connection of the medulla with the centres in the semilunar ganglion which preside directly over these vessels is made by way of the spinal cord or by way of the pneumogastric nerve is still undetermined, though the researches of Gaskell favor the former view. Gastric and intestinal disturbances are certainly produced by nervous lesions in the medulla, but whether they are due to vascular changes is uncertain. The vomiting of mucus and blood, and the large watery evacuations which accompany mental shock or anxiety, as well as the polyuria associated with mental effort, have been ascribed to irritation of local centres in the medulla governing the gastro-intestinal and urinary organs by impulses received from the cortex above. The spleen is under the control of vaso-motor centres, since section of the splenic branches of the semilunar ganglia will produce a great enlargement of the organ, and irritation of the cut end of these branches will produce con-

⁴ *Ibid.*

traction.¹ The medulla also contains a vaso-dilator centre for the erectile tissues of the genital organs, irritation of which by mental action or local disease causes impulses to pass to the nervi erigentes by way of the spinal cord, resulting in a flow of blood to the parts. Although a centre has been thought to exist controlling the circulation in the lungs, whose paralysis has been supposed to explain the occurrence of sudden pulmonary oedema without other known cause, no definite facts regarding it are known. That the action of the heart is under the control of the medulla is a fact too well known to require more than a mention. The physiology of the nervous control of the heart cannot be discussed here.

While these medullary centres are certainly influenced by impulses reaching them from the cerebral hemispheres, as is evident from the vaso-motor symptoms produced by mental action—*c. g.* pallor from fright, blushing, etc.—it is impossible to state in what portion of the hemispheres in man the higher vaso-motor centres lie. Eulenburg and Landois locate them in the motor area in animals.² They are certainly beyond control of the will, and are wholly reflex in their action, a purely mental act in this case being the excitant of a purely physical result.³

PATHOGENESIS.—From this review of the physiology of the vaso-motor system it becomes evident that disturbances of vascular tone may be produced by many different causes acting upon many various parts. They may be due to local affections of the part in which the symptoms are present, as in the case of erythema⁴ after burns or frost-bite, or congestion of any organ after injury. They may be due to affections of the vaso-motor nerves passing to the part affected, as in the case of vascular changes due to peripheral nerve lesions.⁵ They may be due to affections of the sympathetic ganglia connected with the part affected, as in the case of migraine,⁶ sudden flushing of one ear, certain cases of polyuria,⁷ and Basedow's disease.⁸ They may be due to lesions in the spinal cord affecting the vaso-motor centres⁹ or compressing the nerve-roots on their way to and from the sympathetic ganglia,¹⁰ as is the case in the various forms of myelitis and in Raynaud's disease or symmetrical gangrene, and in meningitis, tumors of the cord, or Pott's disease. They may also be caused by such conditions in the cord as cut off the vaso-motor centres from the medullary centres, such as transverse myelitis from compression or traumatism.¹¹ They may be due to lesions of the medulla oblongata,¹² as is seen in some cases of polyuria and glycosuria,¹³ and in cases of universal erythema¹⁴ following acute fevers. They may be due to diseases of the cerebral hemispheres, as is evident from the vaso-motor symptoms occurring in hemiplegia and hysteria. Finally, they may be of a reflex

origin, dependent upon some obscure source of irritation in a part quite distant from the region in which the symptoms appear.¹

The DIAGNOSIS of the seat of the lesion in many cases of vaso-motor neurosis may be made if the organ or the exact limitation of the area affected be ascertained, and the history of the case, together with the concurrent symptoms of other kinds, be considered. In some cases no organic cause can be found, and in these a reflex cause should be diligently searched for.

SYMPTOMS.—A vaso-motor affection may manifest itself either by a spasm or a paralysis of the vessels. In angiospasm the part affected becomes pale, and irritation no longer causes a vaso-motor reflex. It looks shrunk, and if the skin over it is loose it may be thrown into folds or shrivelled, presenting the appearance seen in the hands after long immersion in hot water. The lack of blood in the part arrests the processes of metabolism which are normally constant, and if the condition continues this may result in such a disturbance of nutrition that ulceration, or even gangrene, may ensue. The local anæmia, combined with the cessation of metabolism, produces a fall of temperature in the affected part, which is then more easily affected by the temperature of the air than in a normal state, so that exposure to cold is very liable to cause freezing. These conditions necessarily produce an impairment of function, so that if the affection is located in the extremities, as the fingers, they are soon rendered useless. The term *digiti mortui* has been applied to this state. In the surface of the body angiospasm causes *cutis anserina*, pallor, numbness, tingling, slight anæsthesia, and analgesia. If it occurs in a limb, the finer motions are imperfectly performed, and in time the nutrition of the muscles may be so impaired as to produce atrophy and paresis. It may even lead to gangrene. Nothnagel has recorded² five cases of sciatica in which the pain produced a reflex spasm of the vessels of the leg, which, persisting, resulted in partial paralysis, atrophy, lowering of temperature, pallor, and sensory disturbances. Ross mentions³ the sudden appearance of circumscribed patches on the hands and forearms of washerwomen, in which there is a pallor, coldness, and partial anæsthesia. These may be limited to the distribution of a single nerve, and may be accompanied by trophic affections.

Spasm of the veins may occur as well as of the arteries,⁴ or independently of them. In the latter case the blood will not pass out of the capillaries. The part will then be blue, swollen, œdematous, and painful; the temperature will be lowered by increased radiation of heat, and all the sensations and functions be impaired in greater or less degree. If this continues, nutrition may suffer, and in the end gangrene develop, which will take its course and lead to the throwing off of the part. Grainger Stewart has described such a condition occurring in both hands and feet.⁵ It may be likened to a severe form of Raynaud's disease.

Angio-paralysis is more frequent than angiospasm, and may be due either to paralysis of the vaso-constrictors or to excitement of the vasodilators. It shows itself by a bright-red or mottled appearance of the skin, and increase of local temperature, and more rapid processes of

⁵ Grainger Stewart, *An Introduction to the Study of Nervous Diseases*, p. 138.

nutrition, together with an increase of secretion if the part is a gland or a mucous membrane, and an increase of sweat if it is the skin. In the latter case an increased sensitiveness to changes of temperature, a subjective sensation of heat, and hyperæsthesia and hyperalgesia may occur. The hyperæsthesia on the paralyzed side which is present in hemiparaplegia spinalis is ascribed to the vaso-motor paralysis. But these symptoms soon give place to others. The dilatation of the vessels, which at first caused an increased flow of blood to the part, produces a slowing of the blood-current in the part, just as a river runs less rapidly where it becomes wider. The slowing of the current in the skin allows of a more complete cooling of the part as the radiation of heat and the evaporation of moisture are increased, and the slowness of the renewal of blood impairs the processes of nutrition, so that to the first stage of redness, heat, and increased metabolism there ensues a stage of blueness, cold, and defective nutrition, and the function of the part may be impaired. In this stage it usually presents a mottled appearance, and may be slightly swollen and œdematous, and the continued increase of perspiration gives it a clammy coldness to the touch. In all of these conditions severe pain, sometimes of a burning character, is a very distressing symptom (causalgia). These conditions are seen in peripheral nerve-lesions, and give rise to the appearances which have been so admirably described by Weir Mitchell.¹

A peculiar combination of symptoms may be mentioned here, to which Weir Mitchell has given the name of erythromelalgia.² This disease begins with tenderness and pain in the soles of the feet, which are soon followed by a marked distension of the capillary vessels. The congestion is attended by a sensation of burning pain similar to that produced by a blister. The surface is at first of a dull dusky-red color; later it appears purple. The redness is not uniformly distributed over the sole, but occurs in patches of irregular shape, being especially frequent over prominent parts exposed to pressure and friction, and the attacks seem to be brought on by long standing or walking. At first there is a rise of temperature in the affected surface, the arteries pulsate visibly, the veins are swollen, and there may be some œdema. Later, the foot is cold and pale. Sensations of touch and temperature are normal, but the part is so extremely tender that walking is impossible. There is no paralysis. One or both feet may be affected, but the patches of redness are rarely symmetrical. The hands are occasionally affected. The condition may occur in paroxysms or may remain for some time. It resists all known methods of treatment, although applications of cold relieve the burning pain to some extent and the tenderness enforces rest.

With angio-paralysis may be classed the taches cérébrales of Trousseau, no longer considered diagnostic of meningitis, but denoting a weakened condition of vaso-constrictor action in the local ganglia of the vessel-wall, which may occur upon local irritation of the skin in any severe disease affecting the nutrition of the general nervous system.

Actual rupture of the capillaries in the course of vaso-motor diseases is rarely observed, although the stigmata appearing in hysterical and cataleptic patients may be ascribed to this cause. In this connection tabetic ecchymoses may be mentioned, which appear suddenly without local injury,

¹ *Injuries of Nerves.*

² *Amer. Journ. of the Med. Sci., July, 1878.*

and resemble an ordinary bruise, running a similar course. They occur only in the course of locomotor ataxia.¹

In addition to these forms of vaso-motor affections there is a condition of instability of vascular tone which manifests itself by sudden transient changes in the circulation of various organs. This is a functional affection, usually due to malnutrition. It is seen in many cases of neurasthenia and hysteria, and manifests itself by sudden flushes or pallor, alternations of heat and cold, local sweating, attacks of mental confusion, and inability to use any organ continuously from disturbance of the power of the vaso-dilators to maintain a condition of functional hyperæmia.² Little is actually known about the causes of this state of the vascular system, although much has been written about it. (For a fuller description the article on Neurasthenia may be consulted.)

Many functional derangements of the internal viscera have been ascribed to such vaso-motor instability with more or less probability,³ but hypothesis of this kind, however plausible, is evidently beyond confirmation. It is especially in affections of this kind that causes of reflex irritation are to be carefully sought. Cutaneous angio-neuroses, such as have just been described, may affect any part of the body. They usually appear suddenly, producing much discomfort and an impairment of function in the part if it is an extremity. They disappear as rapidly as they come. The duration of such attacks varies from a few minutes to several days. They are very liable to recur. If it is the vessels under the control of the cervical sympathetic which are affected, the symptoms will be those of migraine or of lesion of the ganglia.⁴ If it is the vessels in the extremities which are involved, the condition of *digiti mortui* or erythromelalgia or symmetrical gangrene⁵ may be produced.

A singular epidemic occurred in France in 1828 and 1830 which was termed *acrodynia*. Many persons were suddenly seized with vomiting and purging, and soon after the onset the extremities became red or mottled in blotches, swollen and œdematous, and hot, painful, and tender. The attacks lasted from a few days to two months, and during this time the skin became thick and hard, the muscles weak and subject to spasms, and the general health was impaired. Relapses occurred in many cases, but all finally recovered, and hence the exact nature of the disease was not ascertained.

COURSE.—In any case of vaso-motor neurosis the course of the disease and its termination will depend chiefly upon its cause. If the cause is some permanent lesion of the nervous system, the condition will remain, and in this case the termination will depend upon the severity of the symptoms. Angiospasm may be so severe as to lead to gangrene and the separation of the part affected, or may be so slight as to cause only subjective discomfort and a little pallor. Angio-paralysis may lead to an extreme degree of congestion, which is attended by heat and pain at first, later by paresthesia and coolness, with increased liability of the part to be affected by changes in the surrounding air. This stage is succeeded by one of less marked dilatation of the vessels and a spontaneous partial

⁴ See p. 1263.

⁵ See p. 1257.

recovery, although the more moderate symptoms may continue indefinitely and seriously impair the function of the part. If the cause is a temporary derangement of function in the vascular mechanism, is reflex irritation which can be removed, or is a curable organic disease, the symptoms will subside rapidly or gradually and perfect recovery may follow. If the condition is one of irritability in the vaso-motor centres, producing alternations of flashing or pallor, such as is observed in nervous exhaustion, it may recur irregularly for a considerable length of time until the causative condition can be removed.

PROGNOSIS.—The prognosis must be determined in each case by a consideration of the cause of the affection, of the nature of the symptoms, of the severity of the disease, and of the possibility of success in both symptomatic and causative treatment. In the angio-paralytic cases an eventual spontaneous relief from much of the discomfort may be promised, although the duration of the symptoms cannot be predicted.

TREATMENT.—Treatment must be directed primarily to removing or diminishing the severity of the cause. A review of the section on Pathogenesis will indicate how wide a field this may include, and the reader must be referred to the special articles which are alluded to in that place for therapeutic measures. Special diligence is to be shown in searching for a source of reflex irritation. When the cause cannot be reached, and when the symptoms are of such severity as to demand immediate attention, treatment may be directed to them.

In all conditions of vaso-motor disease it is important to shield the part from external injury; for if the vessels are dilated they are liable to rupture, and any abrasion of the surface may produce serious inflammation and ulceration; and if the vessels are contracted any injury will be repaired slowly and imperfectly on account of the anæmia, and may even hasten the approach of gangrene.

Perfect rest, bandaging with cotton, and even the application of a light splint to the extremities will be advisable in cases of angiospasm. It is desirable to retain the animal heat, inasmuch as its supply is deficient. In angio-paralysis rest in a somewhat elevated position and applications of mild evaporating lotions are indicated in the early stage; later, the limb may be bandaged. It is not advisable to attempt by tight bandaging to counteract the effect of the vascular paralysis, for the nutrition of the limb is liable to suffer and gangrene may be induced.

Massage of a part affected with vaso-motor symptoms is of great service, since the circulation can be increased in the veins, and thus indirectly in the capillaries, and the nutrition of the part can thus be favored. It is more efficacious in angio-paralysis than in angiospasm. Too rough rubbing is of course to be avoided, lest the skin be injured. All counter-irritation is to be strictly forbidden.

Electricity has been used with varying results. According to Erb,¹ moderate faradic applications contract the vessels; strong faradic applications, especially with the brush, dilate the vessels. The galvanic current at first contracts the vessels, but this is followed by a secondary dilatation, which will be greater and occur more rapidly the stronger the current used.² Cathodal closures contract the vessels; the anodal con-

¹ *Electrothérapie*, 562.

² To this statement Lauder Brunton assents—*Pharmacology*, p. 250.

tinuous current dilates them widely. Stable continuous currents through a nerve dilate the vessels which the nerve supplies. Inasmuch as vaso-constrictors and vaso-dilators pass together in many nerves, and are found together in all parts, it is impossible to apply electricity to either alone. In those cases, therefore, in which it has been ascertained which set of vaso-motors is affected, it is not always possible to produce a direct effect upon that set by electrical treatment. Erb recommends in conditions of vaso-motor spasm a trial of the galvanic current, the cathode on an indifferent point, the anode being applied over the vaso-motor centres governing the part, and also over the area of the body which is affected, and held there while a moderate continuous current is passing, interruptions being avoided; or, the cathode being placed on the neck, the anode may be applied to the nerves passing to the affected part; or a strong continuous current may be sent through the nerve, its direction being changed several times during a moderately long application. Finally, the faradic brush applied to the part or a strong faradic current sent through its nerve may relax the spasm. In any case, all these methods should be tried before electrical treatment is abandoned.

In vaso-motor paralysis other methods are used. The cathode is placed on the part congested, and a weak galvanic current is employed with frequent interruptions or even with changes of the pole; or the cathode may be moved about upon the reddened skin while a mild continuous current is passing. A very weak faradic current with wet electrodes, or even a weak faradic current applied with a brush, may be of service. Here, again, various methods may be tried.

If the extremities are affected, it may be well to immerse them in a basin of water which is connected with one pole of the battery, and the current directed in the manner just described, according to the case. It must be confessed that no definite results can be predicted from the use of electricity in these cases, and much more experience is needed before definite rules can be laid down. The records show that in apparently similar cases opposite methods of application have produced favorable effects, while in other cases all methods have failed. Too much reliance should not be placed in electrical treatment. Erythromelalgia is an obstinate affection, and symptomatic treatment, directed chiefly to quieting the pain by opium and allaying the sensation of burning by cool baths, must be resorted to.

Internal remedies may be tried appropriate to the condition present. In angiospasm nitrite of amyl inhaled, or nitro-glycerin $\frac{1}{100}$ gr. t. i. d., may give considerable relief, although both of these drugs are to be used with caution. Chloral hydrate is also of some service, and where the patient is in pain and suffers from insomnia this may fulfil several indications. In angio-paralysis ergot has been used with advantage. Oxygen inhalations are of service. Chloride of potassium may also be tried. It is evident, however, that such remedies, acting as they do upon the general arterial system, are not to be depended upon in the treatment of local conditions, since they have no selective action upon the affected part. The majority of the drugs known as sedatives and antispasmodics have been used in these conditions, but the records of individual cases show that they are not of much avail. Theoretical therapeutic measures based upon experi-

mentation on animals have been fully discussed by Lauder Brunton,¹ but practical experience has not yet been sufficiently extensive to warrant any further statements.

Symmetrical Gangrene.

SYNONYMS.—Local asphyxia, Asphyxie locale, Raynaud's disease; Symmetrische Gangrän.

DEFINITION.—Symmetrical gangrene is an affection of the nervous system characterized by arterial or venous spasm appearing in symmetrical parts of the body, especially in the phalanges of all the extremities, which may result in trophic changes or in gangrene. There are various stages in the disease, which have given rise to the various names by which it is known. The stage of local syncope, in which there occurs a moderate contraction of the arterioles and consequent pallor of the part, may be followed by a stage of local asphyxia, in which the complete contraction of the arterioles cuts off entirely the supply of arterial blood, and the regurgitation of venous blood produces cyanosis of the part; and this, if continued, may result in the gangrene of the part, which is then thrown off. Instead of a condition of local asphyxia, there may be a spasm of the smaller veins, resulting in a local erythema, which may go on to capillary stasis and then to gangrene. The spasm of the vessels may cease at any stage as suddenly as it began; and if this occurs in the first or second stage, no gangrene results.

HISTORY.—While isolated cases of this affection had been recorded as curiosities during the past two centuries,² the disease was first studied with care by Raynaud in his *Thèse de Paris* in 1862. He collected twenty-eight cases which had been described with accuracy or had been personally observed in the hospitals of Paris, and after a thorough analysis of the symptoms defined the disease as "a neurosis characterized by an exaggeration of the excito-motor power of the cord presiding over the vaso-motor nerves." He called particular attention to the condition of spasm in the vessels, and proposed the name asphyxie locale to designate the peculiar appearance of the parts affected. He also noticed the resulting gangrene as a new variety of gangrene, not dependent upon embolism or upon changes of an atheromatous nature in the coats of the vessels.

The condition was at once recognized by others, and several cases had been reported prior to 1873, when Raynaud published a more complete article on the subject in the *Dictionnaire de Médecine et de Chirurgie* under the title gangrene symétrique; in 1874 he recorded five new cases in the *Archives générales de Médecine*, vol. i. pp. 5 and 189.

The disease, having been thus established as a definite nervous affection, began to be noticed in other countries than France; and Billroth in Vienna,³ Weir Mitchell,⁴ Mills,⁵ A. McL. Hamilton,⁶ and J. C. Warren⁷

in this country, and many other careful observers, published cases, together with more or less complete articles upon the disease. In 1882, Weiss produced a monograph¹ upon the subject containing references to all the cases which had appeared; and this is still the most complete article to be found, although the essay of R. Lauer² and the discussion of the disease by the Berlin Medical Society,³ as well as the short articles of Schulz⁴ and Lutz,⁵ deserve mention, for they contain additional observations of cases and numerous facts not to be found elsewhere.

SYMPTOMS.—The disease begins suddenly in all cases, and the constitutional symptoms are less prominent than the local ones. In some cases there are noticed a certain degree of mental disturbance, a condition of depression with a tendency to sigh and cry without cause, disturbed sleep with unpleasant dreams, irritability, and headache. A loss of appetite and disorders of digestion may follow, and then the local symptoms appear. In other cases, which seem to be the majority, the local condition develops without any such premonitory disturbances of the nervous and digestive systems, although these may ensue. The local symptoms first noticed may be paræsthesiæ or pain in all the extremities, usually limited to the tips of the fingers and the toes. These are continuous and severe, and are immediately followed (and occasionally preceded) by an appearance of ischæmia or of cyanosis or of erythema, in the order of frequency named.

(1) The fingers may look pale and dead, presenting the appearance of the so-called *digiti mortui*, and may be cold, painful, and anæsthetic. If this condition is moderate in degree, a certain amount of blood will continue to flow through the contracted arterioles, and then it corresponds to the description given by Raynaud of *syncope locale*. If it is extreme, the part may be wholly deprived of arterial blood, and then a true local asphyxia is present. In this stage the patients usually suffer considerably, although some do not complain of pain until the next stage. The ischæmia is attended with an impairment of sensation to touch, temperature, and pain, and finer motions become clumsy on account of the subjective numbness and actual anæsthesia. At the same time, the fingers look shrunken, the skin being thrown into folds, as if the hand had been soaked in hot water, or they may appear as if frozen, the skin being hard and immovable.⁶ The secretion of perspiration may be increased, and the fingers feel damp as well as cold, or it may be suspended. The local temperature is lowered. If the part is cut, little or no blood will flow. At this stage the arterial spasm may suddenly relax and the part return gradually to its normal condition, the cessation of the constriction of the arteries and the return of blood being usually accompanied by burning pain, which may last for some hours. The duration of such an attack may vary from a few moments to several days. If it continues longer, this stage is usually succeeded by the second stage, of cyanosis.

(2) The stage of cyanosis results from one of two conditions: either the arterial spasm is so complete that no blood passes into the part, in

¹ Weiss, *Wiener Klinik*, 1882, "Symmetrische Gangrän;" also *Zeitschrift für Prac. Heilkunde*, 1882.

⁶ Finlayson, *Medical Chronicle*, 1885, No. 4.

which case venous blood from lack of *vis a tergo* or in response to gravitation regurgitates into the capillaries, distending them and producing a state of blueness; or a venous spasm occurs, preventing the exit of blood from the part, which then becomes actively congested, and the blood in the capillaries, from want of renewal, soon becomes venous and produces the cyanotic appearance. The stage of ischæmia may be so short that it is hardly noticed, so that the patient's attention is first attracted by the swollen, blue, and extremely painful condition. The skin may be stretched, the tissue infiltrated with products of exudation, which can be pressed out, as can also the venous blood, and the surface may itch as well as be painful. Anæsthesia is rarely present in this stage, and there may even be hyperæsthesia. The part is cool from the increased radiation of heat and cessation of the processes of metabolism, the local temperature being lowered. The small vessels on the surface will be visibly injected, and capillary ecchymoses may rarely be seen. There is less liability to difficulty in movement in this stage than in the former one, as the sensations of the part are not benumbed, but if present it is due to the swelling. This condition, like that in the former stage, may cease suddenly, the recovery of the normal appearance being, as a rule, slower than after a simple ischæmia. The duration of this stage has varied from a few seconds to several days. It is usually followed by gangrene.

(3) The condition of local erythema is described here because it may lead to gangrene, and has therefore been considered by Weiss as one of the early stages of the disease. As a rule, however, it is not followed by the death of the part, and the affection in these cases is probably one of erythromelalgia rather than of symmetrical gangrene. Like the stage of ischæmia, the stage of erythema may appear suddenly. The part presents a bright-red or a mottled appearance—is hot and swollen, and painful. The vessels are visibly injected, the local temperature is raised, the secretion of sweat may or may not be increased, and the patient feels a burning sensation rather than pain. Hyperæsthesia to touch and temperature and pain is usually present, or the sensations are normal. The blood can be pressed out, but returns immediately. In this condition of hyperæmia slight injuries lead frequently to an inflammatory process, ulcers may form in the pulps of the fingers or around the nails, and the eschars may appear dark and even gangrenous; or an actual condition of gangrene may appear in the tips of the fingers, the exact method of its occurrence being a matter of dispute. The erythematous condition is much more likely to be permanent than are the other stages of the disease—another fact which has led to some hesitation in considering it a true stage. This condition of erythema may be due to a paralysis of the vaso-constrictors, the converse of the spasm occurring in ischæmia. It has also been ascribed to an irritation of the vaso-dilators; and this appears to be the more probable hypothesis.

(4) The stage of gangrene is always preceded by that of cyanosis, and the death of the tissue is due to the arrest of nutrition consequent upon a stasis of the blood. It is not necessary to invoke the injury of trophic nerves to explain its appearance. In the tips of the cyanotic fingers, on their palmar surface, beneath the epidermis, a small blister appears, filled with a dark serous fluid or with pus or blood. This soon ruptures, and a dark dry scab forms, beneath which an ulceration may go on destroying

the corium, but not penetrating deeper. In the majority of cases the gangrene is limited to a small area of the pulps of the fingers, and only involves the superficial layers of the corium. The gangrenous spot is surrounded by a purple margin. When the sphacelus has separated a scar remains which is frequently insensitive. In other cases when the sphacelus is thrown off it leaves a deep ulcer, which may look as if the lost tissue had been cut out with a punch, and this gradually granulates and heals. In still other cases the entire skin of the terminal phalanx may become black and dry, presenting a true gangrenous appearance. Then a line of demarcation is formed, usually at the junction of the terminal with the middle phalanx; separation of the gangrenous part occurs, and a stump is left covered with thin, glossy skin. This extensive gangrene, involving an entire phalanx, is the exception rather than the rule.

While the gangrenous process is in progress in the tip of the finger the nails cease to grow, and may become bulbous and rigid; the epidermis elsewhere may become dry and desquamate, and ulceration around the root of the nail may take place. With the completion of the stage of gangrene, which may last from one to five weeks according to its extent, the local symptoms terminate.

It is the symmetrical distribution of the local symptoms just enumerated which is the peculiar characteristic of the disease. The fingers of both hands, the toes of both feet, symmetrically situated spots upon the back, trunk, thighs, legs, forearms, and arms (in the order of frequency named), are affected either singly or in combination. In the majority of cases fingers and toes are affected together, and a few spots are seen on the trunk. In many cases the toes escape. In a large number of cases the face has been affected, spots of cyanosis appearing on the nose or ears or lips. As a rule, the stage of gangrene only ensues in the tips of the extremities, but a few cases are recorded in which little areas of skin elsewhere have passed through all the stages of the disease. Pigmentation occurs in spots upon the body when the process does not go on to gangrene.

Among the rare symptoms which have occurred in some cases are great impairment of temperature, pain, and electric sensations in the affected extremities; swelling, pain, redness about, and effusion into, the joints; considerable loss of motion in the muscles of the hands and feet, with diminution of electric excitability, but no qualitative change; and oculo-pupillary changes ascribed to an irritation of the cervical sympathetic fibres at their origin in the spinal cord.

In addition to the constitutional symptoms mentioned, which may usher in the disease and may continue during its course, there have been observed temporary albuminuria, glycosuria, and hæmaturia. Fever never occurs as a symptom of the disease, and if present must be ascribed to some other condition. The special senses have been affected in a few cases. In one case a spastic contraction of the retinal arteries alternated with attacks of ischæmia in the extremities.¹ The intellect is usually unaffected, but Weiss observed a case in which transient aphasia occurred, which he attributes to local spasm in the arteries of the cortex. The patient could find words only after long thought, and spoke slowly and with difficulty.

¹ Raynaud, *Arch. gén. de méd.*, 1874, p. 11; Galezowski examined the discs.

COURSE AND DURATION.—The onset of the disease is sudden. The symptoms in the first two stages may last only for a few minutes and pass off, or the disease may pass through all the stages and terminate in gangrene. It is usual for the first stage of ischæmia to last several days, varying in severity; for the second stage to last several days; and for the stage of gangrene to occupy about three weeks. The shortest duration of a single attack has been ten days, the longest five months. If the gangrene begins simultaneously in all the fingers, the duration will be shorter than if it proceeds to one after another. In one-third of the cases a recurrence of the disease within a year of the first attack has been observed, and it is probable that the proportion would have been larger had all the patients been kept under observation. In some cases three and four attacks have succeeded each other with some rapidity, some of the attacks being much less severe and shorter than others. In some cases the condition of gangrene has developed only in one out of three attacks. When the condition is one of local erythema the duration may be indefinite, the state becoming chronic and lasting for several years.

NATURE.—The nature of the disease is a matter of deduction from the study of the symptoms, no autopsies having as yet been made. As already stated, the symptoms are explained on the theory of a vaso-constrictor irritation in the stages of ischæmia and cyanosis—of a vaso-dilator irritation in the stage of erythema. Whether this irritation is the direct result of abnormal processes going on in the vaso-motor centres in the spinal cord, or is the reflex result of irritation arising elsewhere, is undetermined. Raynaud held that it must be of central origin, since in his cases galvanization of the spinal cord modified the arterial spasm. The latter observation has not been confirmed by other observers. Weiss believes that the condition may occur in response to irritation arising in the skin, in the viscera, or in the brain, and thus prefers the theory of reflex origin. This theory is adopted by several observers, who find a source for such irritation in the female genital organs in their cases.

ETIOLOGY.—The disease occurs in adult life, only two cases having been observed in persons fifty years old. It is most frequent between the ages of fifteen and thirty, although children and adults beyond the age of thirty are about equally liable. Females are more liable to it than males, four-fifths of the recorded cases having been in women. It occurs more frequently in the winter months, exposure to cold being a common exciting cause. Other exciting causes are nervous exhaustion, especially occurring in those who are predisposed to nervous diseases by heredity; general weakness from anæmia, malnutrition, or the occurrence of acute fever or exhausting disease; and mental agitation, a fright having preceded the attack in several cases. In women menstrual disorders and uterine disease have been considered as etiological factors. Occupation has something to do with its occurrence, since washerwomen, waitresses, and chambermaids are the class most often affected. In many cases, however, no cause of local irritation can be found.

DIAGNOSIS.—The diagnosis rests upon the development of vaso-motor symptoms in the extremities, situated symmetrically, going on to gangrene, in a person not afflicted with cardiac disease or with endarteritis of any kind, and not having been exposed to frost-bite or ergot-poisoning. The age of the patient, the symmetrical position of the symptoms, the

persistence of the pulse in the main arteries, and the limitation of the gangrene to the tips of the extremities distinguish it readily from senile gangrene. The history of the case, the absence of itching, and the presence of pain during the arterial spasm which passes off when the spasm ceases, serve to separate it clearly from chilblains. Congenital cyanosis is produced by cardiac anomalies, and the entire body is affected. Ergot-poisoning can be ascertained by the history.

PROGNOSIS.—Life is not endangered by this disease, no fatal cases having been recorded. Recovery from an attack is certain, but the duration cannot be stated, as it will depend in any case on the character, the extent, and the severity of the symptoms. The possibility of a recurrence of the attack should be stated to the patient.

TREATMENT.—The methods of treatment have varied, and none are wholly satisfactory. If the causes can be met—*e. g.* anæmia, nervous exhaustion—they should be treated. If not, the disease itself may be attacked by means of electricity. Or the symptoms may be treated as they demand it. Electricity has been used by almost all observers. The faradic current produces an aggravation of all the symptoms except in the stage of erythema, and has been discarded. The galvanic current may be employed in several ways. Two methods are in use. In the first the positive pole is applied over the cervical region, and the negative pole over the lumbar region, a descending current being thus sent through the spinal cord. The current should be of moderate strength, not above twenty-five milliamperes, few patients being able to endure the strength implied in Raynaud's statement that he used sixty-four cells of a Daniel battery. The duration of the application should be ten minutes, and the electricity may be applied once daily. In the second method the anode is applied over the brachial or lumbar plexus, as the case may be, and the cathode passed over the affected extremity, the current being constant and care being taken not to break it suddenly. The strength, duration, and frequency should be the same as in the first method. From these two methods, separately or combined, Raynaud claimed to have seen favorable results. His assertions have not been confirmed by other observers who have followed his directions closely, and hence considerable doubt at present prevails as to the efficacy of the electric current. The so-called electrical application to the cervical sympathetic is certainly useless. In the stage of erythema a very weak faradic current applied to the hands in a bath may be of service.

Many observers have found that the progress of the case to recovery was quite rapid if the limb were put at rest in an elevated position, were kept warm by cotton batting or similar bandaging, and were kept clean with antiseptic lotions when the stage of gangrene set in. Massage is to be used in all cases, the limbs or affected parts being gently rubbed with the dry hand or with aromatic liniments or oils. All local injury, however, and especially counter-irritation, are to be carefully avoided. General tonic treatment, especially iron and cod-liver oil, is to be used in all cases.

The pain occurring in the early stages is often so severe as to require the use of opium or other narcotics. And when the nervous symptoms are especially aggravated, and irritability and insomnia give the patient discomfort, bromide and chloral may be employed.

Diseases of the Cervical Sympathetic.

ETIOLOGY.—Diseases of the cervical sympathetic ganglia or cord may be of two kinds—either irritative or destructive.¹ They are produced by pressure upon the cervical ganglia or upon the sympathetic cord between these ganglia, by tumors, especially aneurisms, and enlarged glands; by abscesses; and by cicatrices of old wounds in the neck. They are also due to extension of inflammation from a thickened pleura in phthisis and chronic pleuritis of the apex. They may be caused by injuries, such as stab-wounds, gunshot wounds, etc. Any disease which produces marked irritation of peripheral branches of the sympathetic in the neck, or of the cerebro-spinal cervical nerves, may cause reflex phenomena resembling the symptoms of actual disease. From such phenomena it is not justifiable to conclude that the sympathetic cord and ganglia are the seat of lesions, and the only cases which will be considered here are those in which actual disease was proven to be present by an autopsy.

Inasmuch as the cervical sympathetic is in close anatomical connection with the spinal cord, especially with the eighth cervical to the second dorsal segments (the so-called cilio-spinal centre of Budge), and as the functions of the sympathetic are dependent upon the integrity of the spinal cord, it is evident that any lesion of the nerves uniting it with the cord, or any lesion in the cord itself at the levels mentioned, may produce symptoms which resemble closely those of disease of the sympathetic. Thus, cervical pachymeningitis, myelitis (especially from injury of the cord, or hæmato-myelia), and diseases of the cervical vertebræ which produce either or both conditions, may cause a train of symptoms somewhat similar to those to be described.² A careful distinction must be made between primary and secondary disease of the sympathetic, between reflex and direct symptoms, between lesions in its substance and lesions in its governing centres in the spinal cord. The symptoms produced by affections of a reflex or central nature are rarely as numerous as those of disease of the sympathetic itself. An example of such a secondary affection is the combination of sympathetic symptoms occurring in progressive muscular atrophy. And, finally, since mental action of an emotional nature may cause flushing or pallor of the face, with profuse sweating and variations in the size of the pupil and prominence of the eyeballs, as well as palpitation or arrest of the heart, there is reason to believe that symptoms of sympathetic disease may be produced by cerebral lesions.

PATHOLOGY.—The pathological anatomy of the cervical sympathetic is obscure. This is probably owing to the fact that the ganglia are rarely examined, and pathologists have not been familiar with their histology. Lesions of the cervical sympathetic have been described in almost every imaginable form of disease, and at one time, when many obscure conditions were blindly termed sympathetic, the records were filled with descriptions of fatty degeneration or interstitial inflammation or pigment deposit in the ganglia. As no actual symptoms of disease of the cervical

² Ross, *Diseases of the Nervous System*, 2d ed., i. 686-688.

sympathetic, as now understood, were present in such cases, it is impossible to believe that the lesion was other than hypothetical.

The conditions which have been observed in a few carefully-studied cases of primary disease have been—(1) A parenchymatous inflammation of the cells of the ganglia, attended by swelling, loss of nuclei, granular and fatty degeneration, and by atrophy, together with a degeneration of the fibres issuing from the cells. (2) A sclerotic process in the connective tissue in and about the ganglia and in the nerves, resulting in such an increase in the interstitial tissue as to compress and injure the cells and axis-cylinders. These may be observed together in the later stages of the disease. (3) In a number of cases the capillaries within and about the ganglia have been found dilated, tortuous, and varicose, and hemorrhages from them are not rare.

SYMPTOMS.—The symptoms of irritation of the cervical sympathetic are dilatation of the pupil, widening of the palpebral fissure, protrusion of the eyeball, pallor of the entire side of the face and head, with slight fall of local temperature and possibly an increased secretion of perspiration, and an increased frequency of the heart. It is rarely that these are all observed in any case, dilatation of the pupil with slight pallor and rapid pulse being the only signs of irritation as a rule. Such irritation is a less common occurrence than might be supposed, many lesions which produce pressure even of a slight degree on the sympathetic having caused symptoms of a suspension of its function rather than of an increased activity. This is doubtless due to the non-medullated structure of the fibres, which thus lack protection from injury.

The symptoms of destructive disease of the cervical sympathetic are the converse of those just mentioned, and they are all present when the part is seriously involved. The patient will then have a marked contraction of the pupil, which no longer responds to light or to irritation of the skin of the neck, but may change slightly in the act of accommodation. It resists the action of mydriatics. The vessels of the choroid and retina may be dilated, as well as those of the iris, in which case the patient will feel a sense of weariness on any long-continued attempt to use the eyes. There is no actual disturbance of vision, and the cornea is not usually flattened, as was formerly supposed. There is a noticeable narrowing of the palpebral fissure, the upper lid falling slightly as in a mild state of ptosis, and the lower lid being slightly elevated. This is due to the paralysis of the muscles of Müller in the eyelids, which are controlled by the sympathetic. It is present in 90 per cent. of the recorded cases, and in many the apparent size of the eye is reduced a half. Retraction of the eyeball is a less constant symptom, and one which develops only after the disease has existed some time. It is due partly to the paralysis of the orbital muscle of Müller, and partly to the decrease in the amount of fat in the orbit behind the eye. A marked symptom, and one which is constant, is a dilatation of the vessels of the face, conjunctiva, nasal mucous membrane, ear, and scalp. This is attended by redness, a subjective sense of heat, and an actual rise of local temperature, which may exceed that of the other side by 1.5° F., measured in the auditory meatus or nose. This vascular congestion has persisted in some cases for three years. In others it has been followed much earlier (in nine months) by a partial or complete return to the normal condition, and

even when the local temperature remains higher on the affected side, the visible congestion and the sensation of heat may have disappeared. The dilatation, succeeded by the contraction (normal tone), of the vessels has led to a division of the disease into two stages, and in a few cases the affected side has become paler than the other in the second stage. In both stages the part affected is less sensitive to changes in the external temperature.

An increased secretion of tears and of perspiration has been supposed to accompany dilatation of the vessels of the skin of the head inevitably. This is not a constant symptom, as the recent cases have demonstrated. And no definite statement of the effect of disease of the cervical sympathetic on the occurrence of dryness or dampness of the face can be made, both conditions having been observed. A difference between the degree of moisture on the two sides of the face on exposure to heat is usually present. Palpitation of the heart has been an annoying symptom to the patient in many cases, and is usually associated with a marked slowing of the pulse. This was reduced from 74 to 66 in Möbius' case,¹ and remained slow for some weeks. The frequency of the heart may, however, be increased after the first period of slowing, but never reaches a very high rate (88 in the case cited). A slight atrophy of the affected side of the face has been observed in several cases, appearing after the disease has existed for some time. The muscles of the cheek feel flabby and are slightly sunken; but the condition does not approach in severity true facial hemiatrophy, nor is it sufficiently rapid to be considered due to a trophic disturbance. Changes in the secretion of saliva, dryness of the nasal mucous membrane, and symptoms referable to paralysis of the intracranial vessels, such as might be expected from the result of physiological division of the sympathetic, have only been occasionally observed. Glycosuria has been noted in a few cases.²

COURSE.—The course of the disease has been divided into two stages, as already mentioned, the majority of the symptoms remaining permanently from the onset. The second stage is characterized by the cessation of the dilatation of the vessels, by the appearance of retraction of the eyeball, and by the development of slight facial atrophy. In the cases where the sympathetic is extensively destroyed by the lesion no recovery is possible. When it is simply divided by a wound there has been a considerable degree of recovery, probably due to a spontaneous union of the divided ends and re-establishment of the function. From these facts the prognosis can be deduced.

DIAGNOSIS.—The symptoms are so characteristic that there is no difficulty in reaching a diagnosis. The most important point in any case is to determine the cause, care being taken to consider all the possibilities already mentioned in discussing the causation. The symptoms of lesion are always unilateral.

TREATMENT.—If the cause can be removed, an indication for treatment is afforded. Sources of reflex irritation are to be eliminated. If the sympathetic has been divided by a wound, it may be well to unite the cut ends, as in suture of other nerves, although this has not yet been attempted; otherwise there is little hope from any method of treatment.

Electricity has been applied in vain, and galvanization of the sympathetic in the neck is now regarded by all good authorities as useless.

Diseases of the thoracic and abdominal sympathetic ganglia and cords have been suspected, but nothing definite is known of their symptoms or pathology; the statements which have recently been made regarding visceral neurosis not being based upon any cases in which post-mortem lesions were found.

Trophic Neuroses.

TROPHIC NERVES AND NERVOUS CENTRES.—The nutrition of the body depends upon the nutrition of the individual cells of which it is made up. Each cell has the power of appropriating from the blood such substances as will preserve its existence, enable it to perform its functions, and produce a successor. Whether this power is inherent in the cell or is controlled by the nervous system is a question upon which authorities are divided. Those who hold the first position deny the existence of trophic nervous centres and of trophic nerves from those centres to the organs and elements of the body, claiming that this hypothetical trophic system has not been demonstrated anatomically, and that the facts urged in its support are capable of another interpretation. Those who believe in the existence of a trophic system have been able to demonstrate the existence of fine peripheral nerve-fibres passing to and ending in individual cells of the skin, glands, and other organs,¹ and have brought forward a large collection of facts which merit a careful examination.² They are as follows:

ATROPHY.—When a nerve is cut certain changes occur in it which are known as Wallerian degeneration.³ This affects the peripheral end of a severed nerve, the peripheral end of a severed anterior nerve-root, and the central end of a posterior nerve-root. To maintain its integrity a motor nerve must be in direct continuity with a normal cell of the anterior cornu of the spinal cord; a sensory nerve must be in connection with the intervertebral spinal ganglion on the posterior nerve-root. Nerves which pass between two such ganglia do not degenerate when cut. The degeneration consists⁴ in a coagulation of the myelin in the medullary sheath, a fatty degeneration of the coagulum, and a gradual absorption of the débris. The axis-cylinder is compressed, and finally disintegrated, by a mass of protoplasm which develops about the nuclei of the interannular segments, and after undergoing fatty degeneration its débris becomes mingled with that of the myelin, and is also absorbed. The sheath of Schwann, whose nuclei have in the mean time increased by a process of subdivision, is partly filled by the protoplasm (from which the new axis-cylinder develops if regeneration occurs), remaining as a fine

thread of connective tissue when all other traces of the nerve-fibre have disappeared. There may be a proliferation of cells of the endo- and perineurium at the same time which aids in the transformation of the nerve into a connective-tissue strand. This process of degeneration involves the terminal plates by which the nerves join the muscles, but the terminations of the sensory nerves—*i. e.* tactile corpuscles—do not appear to be affected. The central end of the cut nerve may display a similar change for a distance not greater than one centimeter; it usually develops a bulbous swelling of connective tissue, and retains its conducting power indefinitely.

Degeneration in the tracts of the spinal cord occurs after various forms of lesion,¹ and is similar in its processes to degeneration in the peripheral nerves. The increase in the connective-tissue elements is more noticeable in contrast with the parts unaffected, and from the density of the tract involved the result has been called sclerosis. The recent researches of Homen² have shown that the process of degeneration begins in the entire length of the affected tract, and does not proceed from the point of lesion onward, as was formerly supposed.

When a muscle is separated from its connection with the central nervous system, either by a division of the nerve passing to it or by a destruction of the cells in the anterior cornu of the spinal cord from which that nerve arises, it undergoes an atrophy which is peculiar in being immediate and rapidly progressive, thus contrasting strongly with the gradual and slighter atrophy from disuse in cases of cerebral paralysis where the cells mentioned and the nerve-fibres are intact. There is at first a simple diminution in the number of the fibrillæ of which the muscular fibre is made up, together with an increase in the interstitial connective tissue nuclei. Then an albuminoid and fatty degeneration of the muscular elements occurs, with a proliferation of muscle-corpuscles or nuclei, and a gradual absorption of the debris. The interstitial connective tissue then increases rapidly, forming fibrous bands through the degenerated muscle which compress the few muscular fibres remaining, until as a result the muscle is transformed into a mere ribbon of connective tissue without any power of contractility.³ As these changes go on the electrical reactions change, the three degrees of reaction of degeneration corresponding to the three stages of atrophy described.⁴ These phenomena of nerve- and muscle-degeneration are observed in traumatic or idiopathic neuritis, in acute and chronic poliomyelitis anterior, in general myelitis involving the anterior cornua, and in bulbar paralysis.

The influence of the nervous system on the nutrition of the bones has also been ascertained. When a bone is developing, a lesion of the nerve to it, or of the deeper portion of the anterior cornua of the spinal cord from which these nerves arise, will modify and partly arrest its growth. This is often seen in anterior poliomyelitis and in hemiatrophy of the face occurring in children. In the adult a no less marked effect is produced, although the results are less noticeable. A condition known as osteo-

porosis is caused, consisting of an enlargement of the Haversian canals and an infiltration of fatty matter into them and an actual decrease in all the inorganic constituents of the bone, which loses in weight, becomes thinner and more fragile, so that spontaneous fractures may occur.¹ This condition has been noticed more frequently in diseases of the spinal cord than in neuritis; it is said to occur in locomotor ataxia. It has been found in a few cases of long-standing hemiplegia and also in dementia paralytica, no explanation of its pathogeny in these instances, however, being offered. In a case of ataxia with a lesion in the medulla which involved the nuclei of the fifth, ninth, tenth, and eleventh nerves on one side, all the teeth of the upper jaw on that side fell out within a few weeks, those in the lower jaw remaining.² Changes in the nutrition of the bones have also been recorded in cases of progressive muscular atrophy in the paralyzed limbs.³

The condition of the skin and its appendages is influenced decidedly by changes in the nervous system, either in the nerves, in the spinal ganglia, or in the central gray matter. Here it is the sensory nerves which convey the trophic influence, not the motor nerves, as in the cases hitherto considered; and when the lesion producing trophic changes in the skin is central, it is situated in the posterior cornua of the spinal cord or in the gray matter near the central canal. The glossy skin seen on the fingers after injuries to the nerves is a type of such atrophy from disturbance of trophic impulses. Glossy fingers present a smooth, shining appearance, are dry from the diminution in the secretion of sweat, feel soft and satin-like to the touch from the marked thinning of the skin, and frequently show a defective or irregular growth of the nails, which may be ridged, curved, or deformed.⁴ They are red and mottled from accompanying vaso-motor paralysis, and are usually hot and painful. Changes in the pigmentation of the skin and hair are recorded as a not infrequent accompaniment of severe neuralgia and as a result of great mental anxiety. Thus in several cases of supraorbital neuralgia the eyebrow on the affected side has turned white; in infraorbital neuralgia the beard has become gray; and in both the hair has been observed to fall out.⁵ The sudden turning white of the hair is ascribed to a swelling of the hair by air within it.⁶ In one case, frequently cited, the hair and nails fell out after a stroke of lightning.

When a gland is cut off from its nervous connection with the cord or cerebral axis by section of its nerves, its function is impaired and its nutrition suffers, so that after a time it loses weight and undergoes a progressive total atrophy. This has been proven experimentally in animals in the submaxillary gland. It has been observed in the testicle in man after division of the spermatic nerve (Nélaton) and after destruction of the spinal cord by traumatic and idiopathic myelitis (Klebs, Förster).⁷ The sweat-glands are known to be under the control of a central

nervous mechanism, as cases of hyperidrosis, anidrosis, and chromiodrosis prove;¹ and an atrophy of them and of the sebaceous glands has been observed² after nervous lesions.

Progressive hemiatrophy of the face is treated elsewhere. The following case of progressive hemiatrophy of the entire body may be mentioned here: A boy, aged fourteen, dislocated his ankle, which in a few days became swollen, red, hot, and painful. The inflammation extended up the leg, but did not involve the knee, and soon subsided. After a short time the foot began to atrophy. The atrophy extended up the leg, and involved the thigh; it then progressed to the trunk and the arm, and lastly to the face on the affected side, until in the course of two years there had developed a unilateral atrophy of the entire body. Muscles, fat, and bones were all affected, but no difference in the skin or hair of the two sides was noticed. Fibrillary tremors were present in the muscles. The electric reactions were not altered, but were gradually lost. There was a hypersensitiveness to touch and to cold, but no other sensory disturbance. The boy was alive and fairly well when the case was reported.³ It is unique.

These various instances of atrophy cannot be ascribed to simple disease, since they differ markedly in their pathological changes and in the rapidity of their progress from such atrophy. Nor are they to be referred to vaso-motor disturbances, since in many cases no vascular changes are evident. Their distribution in the body often corresponds exactly with that of peripheral nerves, and they accompany nerve lesions too frequently to be explained on any theory of coincidence. There are many authorities, however, who refuse to ascribe them to a lesion of trophic nerves.⁴ In regard to the degeneration of nerves it is said that each nerve axis-cylinder is a part of the nerve-cell from which it arises, and hence destruction of the cell or division of the cylinder, by disturbing the unity of existence, results in the death of the part. The fibre shares all the changes of nutrition which the nerve-cell undergoes, and if separated from it necessarily perishes. To this it is replied that trophic paths and motor paths are distinct at some points in their course, at least in the central nervous system, since each can be affected alone. Erb, who has studied this subject carefully,⁵ believes that trophic are distinct from motor centres in the spinal cord, but that both impulses may be conveyed by the same axis-cylinder in the peripheral nerves—a middle ground which is widely accepted. It is now known that each axis-cylinder is made up of several fibrils, so that this theory gains probability. This would also explain the occurrence of atrophy in the muscles, the trophic centres being affected when the muscle atrophies, and unaffected when it is paralyzed without atrophy. Mayer, however, denies this explanation of the muscular atrophy, holding that the motor system, cell, nerve, and muscle-fibre, forms a nutritive as well as functional unit, and that the simple suspension of function, by interfering with the special

conditions of nutrition attendant upon physiological excitement, is competent to cause a pathological change. To this it is replied that the parts of the motor system are not interdependent, since disease of the muscle does not produce degeneration of the nerve and of the cell, and the fact

FIG. 58.

Diagram of the Arrangement and Connection of Motor and Trophic Centres and Fibres in the Spinal Cord and Motor Nerve (after Erb): *a*, motor fibre of spinal cord from the brain to *d*, the motor cell, which is joined to the muscle *m* by the motor nerve; *b*, trophic cell in the spinal cord for the muscle, to which it is joined by the trophic fibre *b'*; *c*, trophic cell in the spinal cord for the motor nerve, to which it is joined by the trophic fibre *c'*; *s*, a fibre bringing sensory (reflex) impulses to the cell. If *d* is destroyed, the fibres from *b* and *c* perish with it, and the result is paralysis and atrophy of the muscle and degeneration in the motor nerve—*e. g.* poliomyelitis anterior. If *b* is destroyed, the muscle atrophies, and paralysis is a secondary result—*e. g.* progressive muscular atrophy. If *c* is destroyed, the nerve degenerates, and paralysis and atrophy of the muscle are secondary results—*e. g.* neuritis with reaction of degeneration. If *a* is destroyed, voluntary power is lost, but reflex power remains, and no trophic changes occur—*e. g.* lateral sclerosis. If the motor nerve is cut between *d* and *m*, the result is the same beyond the division as when the motor cell is destroyed.

of a degeneration in a peripheral direction alone is evidence of central trophic influence. The attempt to ascribe trophic changes in the skin, nails, and hair to vaso-motor disturbance has been equally unsuccessful in covering all the observed cases.

HYPERTROPHY.—Trophic changes are not limited to the process of atrophy. There are conditions of hypertrophy of supposed nervous origin. Samuel considers the hypertrophy of one testicle which attends atrophy of the other from section of its nerve as an example of this. It has been ascertained that one kidney hypertrophies when the other is atrophied or extirpated. When the spleen is removed the lymphatic glands increase in size. But these facts are capable of another explanation—viz. that increased demand upon the organ leads to its increased growth. Hypertrophy of the skin and of the tongue is seen in cretins in contrast with the deformity of the body and atrophy of the limbs. A hemihypertrophy of the face has been noticed in several cases, the counterpart of hemiatrophy; and in one case a unilateral hypertrophy of the entire body was observed.¹ The local thickening of the skin known as ichthyosis hystrix, and other hypertrophies of the skin, certain deposits of pigment, and vitiligo, have been ascribed to nervous causes. Mitchell has recorded cases of abnormal growth of the nails and hair after injuries to the nerves, and similar phenomena have followed central lesions. He has also described a thickening of the skin of the first three fingers and of the back of the hand following a wound of the brachial plexus. These conditions of the skin and its appendages indicate an abnormal activity in the cells of the affected part, a rapid metabolism and reproduction, resulting in an undue production of tissue, apparently dependent on nervous impulses reaching the cells from a distance. The insane ear may be mentioned in this connection as a trophic disturbance due to central lesion.

MYXŒDEMA (cachexie pachydermique) is a disturbance of nutritive processes characterized by a production of mucin, which is deposited in all the tissues of the body, but especially in the subdermal connective tissue.² It is considered by the majority of authors a trophic neurosis, and is therefore considered here.

PATHOLOGY.—In the few autopsies which have been made an increase in the connective tissue of all the organs has been found, in the meshes of which a thick, transparent, slimy substance (called animal gum), consisting of mucin, is present. This may compress and destroy the parenchyma of the organs involved. There is also found a thickening of the coats (adventitia and media) of the vessels. An atrophy of the thyroid gland has occurred in every case, and experimental extirpation of the thyroid in animals produces symptoms so nearly identical with those of myxœdema that this is considered the chief pathological feature of the disease. Whether this atrophy is due to a compression by the mucin deposited, or is due to a disease of the trophic centres of the thyroid in the medulla, or is a primary affection of the gland, remains to be determined.

ETIOLOGY.—The actual causation is unknown. Cold and mental shock have been considered exciting causes in some cases. Women are much more liable to the disease than men, and it develops after the age of forty in the majority of cases. It may occur in childhood and result in a cre-

tinoid state. Syphilis and tuberculosis do not appear to be etiological factors.

SYMPTOMS.—The disease begins gradually, and the nervous symptoms or the local œdema may appear together or in succession. The patient notices a thickening of the skin, which becomes dry, rough, and scaly. The thickening is uniform and involves the entire body. It is most marked where the subdermal connective tissue is loose, as in the cheeks, lips, eyelids, and in all parts where the skin is thrown into folds. The hands and feet do not escape. The thickened skin is hard, and does not pit on pressure, thus differing from ordinary œdematous swelling. It appears of a waxy color, and is free from perspiration, the sweat-glands becoming atrophied from pressure. The hair may fall out or become woolly and brittle, and may change its color. In a few cases spots of pigment have appeared on various regions.¹ The nails are brittle. The teeth are carious. The mucous membranes show similar changes, and the mouth and tongue, rectum and vagina, may be so swollen as to impair their respective functions. Digestive disturbances, constipation alternating with diarrhœa, and uterine hemorrhages, which occur, are ascribed to this cause. Albumen is occasionally found in the urine, but is not a constant symptom. The nervous symptoms are constant. The patients complain of paræsthesiæ and anæsthesia of the extremities or over the entire body, and the special senses may be impaired, as well as the tactile sense. They are very liable to severe attacks of neuralgia. They suffer from subjective sensations of cold, and are easily affected by changes of temperature. Motion is interfered with; tremors occur early; movements become slow and awkward; the gait is unsteady; the voice is rough and nasal; but no true paralysis or muscular atrophy has been observed. The patella-tendon reflex is occasionally lost, but not in all cases.

These symptoms have been ascribed to the pressure of the mucin upon the terminal filaments of the nerves, and also to changes in the central nervous system. That the latter theory is probably correct is shown by the occurrence of mental symptoms in the majority of cases. The patients become apathetic and all mental action is slowly performed. Indifference to surroundings, loss of memory, and inability to concentrate the attention may be succeeded by transient delirium, hallucinations, and occasionally by delusions of persecution, and the patient finally lapses into a state of imbecility. If the disease develops in early life, education is impossible, and the patient remains in an infantile condition.

Whether the changes in the nervous system are due to pressure by deposit of mucin (Hadden), or are due to an altered nutrition of the most delicate tissues of the body consequent upon the general metabolic derangement (Horseley), is undetermined. In experimental myxœdema the degenerative processes have been found in the nerve-cells.

There are no symptoms referable to the heart or lungs, and if cirrhosis of the kidney and liver develop, their symptoms supervene upon and are secondary to those of myxœdema. High arterial tension has been noticed in the majority of the cases.

The **COURSE** of the disease is a chronic one, and is progressive. There are, however, intermissions in the severity of the symptoms in some cases. Recovery does not occur.

¹ Allan McLane Hamilton, *Journ. Nerv. and Ment. Dis.*, 1885, April, p. 180.

DIAGNOSIS.—The diagnosis from the accumulation of fat is made by observing the thickening of the nose, lips, fingers, and tongue, and the changes in the skin and its appendages. Scleroderma is not universal like myxœdema. In scleroderma the skin is harder and more adherent to subjacent parts, is not transparent and waxy, and the nervous symptoms are wanting. Cretinism seems to be closely allied to myxœdema, but is only observed before the age of seven, and is accompanied by hypertrophy of the thyroid gland.

TREATMENT.—The treatment is only palliative. Simple nutritious diet, especially milk diet, with the use of such tonics as iron and quinine, has been found useful. The progress of the disease is hastened by exposure to cold, and in a very warm climate the symptoms may remain stationary for several years. Jaborandi or pilocarpine has been used in some cases with a moderate degree of success. Nitro-glycerin, gr. $\frac{1}{10}$, has also been of benefit. For the paræsthesiæ and anæsthesia of the early stage the faradic brush has been applied, and for the motor weakness the faradic current, with the effect of relieving but not curing these symptoms. During the attacks of neuralgia morphine may be employed.

Inflammation.—The most important trophic disturbances are those which consist of an actual disintegration of tissue. These are very numerous. Herpes zoster, certain forms of eczema and pemphigus, lepra anæsthetica, scleroderma, acute ulceration of the fingers, perforating ulcer of the foot, acute bed-sores, keratitis with anæsthesia of the cornea, sympathetic ophthalmia, and various forms of joint disease, are examples of such trophic diseases.¹ For the discussion of the skin and eye diseases mentioned the reader is referred to special articles on those subjects. In regard to lepra anæsthetica, it may be mentioned that in this disease lesions have been found both in the sensory nerves and in the posterior cornua of the spinal cord.²

I have reported³ a case of acute ulceration of the ends of the fingers and toes occurring in an anæmic girl aged twelve, and persisting for more than a year, associated with cyanosis of the hands and feet, and with a tendency to rapid ulceration of any part of the body which happened to be exposed to pressure. The hair of the eyebrows, eyelids, and to a less extent that of the scalp, fell out during the disease. There was no local asphyxia and no appearance of gangrene; hence the case was not one of Raynaud's disease. Its symmetrical distribution, the lack of any constitutional organic disease or of any local cause for the production of the ulceration, and the anæmic and nervous condition present, all pointed to a disturbance of the central nervous system. It did not yield to treatment, either local or general or electrical. Mills has seen a similar case.⁴

Perforating ulcer of the foot begins on the sole, beneath any of the metatarso-phalangeal articulations, preferably the first or the fifth, or under the heel, as a small pustule under the epidermis. This ruptures, and the ulcer which results begins to extend in a direction vertical to the surface, involving the deeper tissues or even opening into the joint and destroying the bone. It appears rather like a sinus than an ulcer, and is

⁴ Mills, *Amer. Journ. Med. Sci.*, Oct., 1878.

remarkable from the fact that it is not painful and is insensitive to touch, although it may prevent the patient from walking on account of extreme tenderness. The epidermis around the sinus is thickened and insensitive, and there may be anæsthesia of the entire sole of the foot, and even of the leg, although this is due to the neuritis present, which is also the cause of the ulcer, rather than to the ulceration. The circulation is sluggish in the affected extremity; it becomes cyanotic on exposure to cold, and seems peculiarly liable to become œdematous. The œdema may go on to suppuration, and involve the articulations, and ankylosis of the smaller joints may follow. This, too, is to be traced to the neuritis. The skin of the foot becomes pigmented, and may be dry or covered with offensive sweat. As the patient cannot walk while the ulcer remains, the condition demands treatment. Rest, moist warm applications, antiseptic lotions, scraping out the sinus, and other surgical means appropriate to the treatment of ulcers and sinuses do not often prove of benefit, and in obstinate cases recourse has been had to amputation of the foot. Electrical treatment has been tried in vain.

Such perforating ulcers may occur symmetrically on both feet, and may be numerous. They also occur rarely on the hands. They have been observed not infrequently in locomotor ataxia, occurring either early or late in the disease,¹ and have appeared in patients suffering from dementia paralytica. The only constant lesion found is a degeneration of the peripheral nerve supplying the affected part.

Acute bed-sores (decubitus) develop in many cases of spinal and cerebral disease, but not in all. It is argued that anæsthesia of a part or simple pressure upon a part or irritation of an anæsthetic part will not explain their occurrence, and that they must be traced to a destruction of trophic centres in the cord or brain. No amount of attention to the position and cleanliness of the patient is thought to be sufficient to prevent them in some cases, and their progress is often so rapid as to remove them from the category of simple ulceration. Their most frequent seat is upon the buttocks, over the sacrum, on the heels, and over the scapulæ; but it is believed that in the conditions in which they appear in these places pressure on any part may cause one. They begin within a few hours after the occurrence of the lesion as irregular mottled patches of redness, in which there soon appear small or large vesicles filled with dark serum. These rupture, leaving little areas of ulcerated surface, which soon unite to form a large ulcer with softened, infiltrated, and bloody base and ragged edges. The tissues around and within the ulcer have a tendency to slough and to become gangrenous, and the process goes on rapidly until a considerable area of the surface is completely destroyed, together with the deeper structures, fat, muscles, and fasciæ, down to the bone, which may become necrosed. Acute cystitis is so frequently associated with acute bed-sore that it is traced to the same nervous cause, though here, again, another explanation is possible. The constitutional disturbance produced by these two affections may be increased by a true septicæmia, to which the patient succumbs; or metastatic abscesses may be formed, and pyæmia cause death; or, lastly, the ulcer on the back may lay bare the vertebræ and erode their ligaments, thus opening a way for the extension of suppuration to

¹ For bibliography see Ross, *Diseases of Nervous System*, 2d ed., i. p. 256, and Blum, *Berliner klin. Wochen.*, 1875, Nos. 13-15.

the meninges of the spinal cord. The duration may be from a few days to two weeks, and the prognosis is very grave.

Chronic bed-sores develop in a similar manner, although all the processes described occur more slowly and are much less severe. They do not show the tendency to extend so widely or so deeply, nor to become gangrenous. They remain stationary after attaining a certain size, and the tissues seem to lack all tendency to reproduction and repair. When the central lesion which they follow begins to pass away they heal; sometimes local treatment is successful; but in many cases they persist for years, always threatening the life of the patient from the possibility of their sudden aggravation or from the occurrence of the complications already mentioned in connection with the acute process.

Since neither form of decubitus occurs after lesion of the anterior cornua of the spinal cord, nor in sclerosis of the posterior or lateral columns, nor in those cases of locomotor ataxia in which extensive invasion of the posterior cornua is present, while they are particularly frequent as a complication of general myelitis, hemorrhage in the cord, and syringo-myelitis, it is argued that the trophic centres whose destruction is the cause of these bed-sores lie in the central gray matter of the cord, near to the central canal. In unilateral lesion of the cord the bed-sore occurs on the anæsthetic side of the body—*i. e.* on the side opposite to the seat of the lesion—a fact which may indicate a decussation of the trophic nerve-fibres in the cord,¹ but which has also been urged in proof of the theory that the sore is always due to irritation of an insensitive surface.

The treatment of bed-sores belongs to the domain of surgery, the same methods being pursued as in the case of any large ulcer. The application of electricity to the sore has been tried, but the results are not sufficiently encouraging to warrant its recommendation.

Joint affections of neurotic origin are discussed in the articles upon Locomotor Ataxia, Hemiplegia, and Hysteria.

It is evident from this review that the nervous centres have some influence upon the activity of the cells of which the body is made up, and that they control the processes of growth, function, repair, and reproduction. The facts are too numerous, too varied, and too positive to admit of any other explanation. Trophic disturbances must therefore be considered as a set of symptoms referable to various lesions of the nervous system. It is evident from the preceding discussion that they may be produced by disease of the peripheral nerves; by disease of the ganglionic cells, which nourish those nerves; by disease of the spinal cord, especially in the region of the central gray matter; and, finally, by disease of the brain. Whether in the last condition the effect is a direct one, or is produced secondarily by an irritation of the spinal centres, cannot yet be determined. There are no trophic centres as yet localized in the cerebrum, but the pathological facts already mentioned warrant the conclusion that such centres will not long elude search. Certain facts observed in cases of infantile hemiplegia point to the motor area of the cortex as the seat of trophic centres for the motor mechanisms; since it is found that when the motor cortex is destroyed in early life the bones and muscles

¹ Recklinghausen believes that these cases of disturbance of nutrition can be explained by injury of anæsthetic parts in which vaso-motor disturbances of central origin exist (*Handbuch d. Path. d. Ernährung*, pp. 236, 237).

which it controls fail to develop properly. Trophic centres for sensory mechanisms are not yet discovered. Certain investigations of Luciani recently published¹ point to the cerebellum as the part of the brain which governs the general nutrition of the body, but these need confirmation.

CONCLUSION.—While an attempt has been made here to consider vaso-motor and trophic neuroses separately, it must be admitted that in very many conditions the two are coincident. This follows inevitably from what has been stated regarding the localization of the vaso-motor and trophic centres in the spinal cord, and regarding the course of the vaso-motor and trophic nerves from the spinal centres to the periphery. These two classes of centres and nerves lie side by side in the central and peripheral organs, and it is less surprising that they should be jointly affected than that one should ever be involved alone. In any case of lesion of the peripheral nerves or of the central nervous system they may be expected. In all cases they are to be regarded as symptoms of such lesions rather than as distinct diseases.

HYSTERO-EPILEPSY, 288
Definition and synonyms, 288
Diagnosis, 307
from true epilepsy, 308
from simulation, 310

HYSTERO-EPILEPSY—Duration and course, 307

Etiology, 291

Age, influence of, 291

Emotional, 293

Painful menstruation, 293

Sex, race, and climate, 291

History, 289

Pathology, 291

Prognosis, 310

Symptoms, 293

Anæsthesia, 298

Contracture, 297

Digestive, 297

Hallucinations, 301

Hystero-epileptogenic zones, significance of, 298

of contortions and great movements, 301

of delirium, 301

of emotional attitudes, 301

of epileptoid period, 300

of irregular types, 302

of regular types, 293

of paroxysms, 293, 304, 306

Ovarian hyperæsthesia, 298

pressure, effect of, 299

Permanent, 307

Prodromal, 297

Treatment, 310

Compression of nerve-trunks, 310

Electricity, use of, 311-313

Metallic salts, use of, 313

Metallo-therapy, 313

Nitrite of amyl and nitro-glycerin, 311

Oöphorectomy, question of, 312

Potassium bromide, use of, 313

Torsion of abdominal walls to arrest paroxysms, 311

Varieties, 290

I.

Ice, use of, in acute simple meningitis, 720

in cerebral meningeal hemorrhage, 715

in neuritis, 1194

in tubercular meningitis, 736

Idiocy, intellectual and moral, 138

Ill-health, influence on causation of insanity, 116, 117

Illusions in nervous diseases, 20

Imbecility, intellectual and moral, 138

in inflammation of the brain, 791

Imitation, influence on causation of catalepsy, 319

of hysteria, 222-229

Impotence in tumors of spinal cord, 1096

Impulsive insanity, 146

Inco-ordination in nervous diseases, 47-50

Inebriety, trance state in, 346

INFANTILE SPINAL PARALYSIS, 1113

Anatomical lesions, 1131

Atrophy of anterior spinal horns, characters, etc., 1133, 1138, 1139

nerve-roots and anterior columns of the cord, 1138, 1139

Autopsies, tables of, 1133-1136, 1139

INFANTILE SPINAL PARALYSIS—Anatomical lesions: Microscopic lesions, 1137

Theories interpreting the lesions of the cord, 1140-1144

regarding origin, premature, 1132

Complication with progressive muscular atrophy, 1149

Course of, 1148

Definitions, 1113

Deformities of atrophic paralysis, 1127

Criticism of theory of muscular antagonism, 1128

Dislocations in, 1130

Mechanism of, 1128, 1131

Muscular contraction in, 1127

Relation of weight and muscular forces, 1130

Diagnosis, 1152

from cerebral paralysis, 1152

from diphtheritic paralysis, 1153

from diseases of bony skeleton and articulations, 1154

from hæmatomyelitis, 1153

from lesions of peripheric nerves, 1153

from progressive muscular atrophy, 1153

from pseudo-paralysis of syphilitic children, 1153

of special paralysis, 1123

Atrophy in, 1124

Loss of faradic contractility, 1125

Negative symptoms, 1126

Temperature of skin, 1124

Etiology, 1151

Blood-poisons, influence of, 1151

Cold, influence of, 1152

Traumatism, influence of, 1151

History, clinical, summary of, 1114

Invasion, mode of, 1115

Pathogeny, 1144

Consequence of limitation of the myelitis to anterior horns of spinal cord, 1144

Relation between limitation of the myelitis and age, 1147

Trophic lesions of, 1145

Prodromata, 1115

Acute specific and apyretic diseases, 1116

Convulsions, 1116

Fever, duration of, 1115, 1116

Hemiplegia, 1120

Immunity of certain muscles and nerves, 1118

Paralysis, characters of, 1117

Crossed, and paralysis of trunk, 1120

Locality of permanent, 1119

of facial nerve, 1120

Significance and original extent of, 1117

Paralyzed muscles, combinations of, 1121-1123

Prognosis, 1149

Special paralyses, influence on locomotion, 1150

Symptoms in detail, 1114

Synonyms, 1113

- INFANTILE SPINAL PARALYSIS — Treatment, 1155**
 Belladonna, use, 1155
 Counter-irritation, 1155

- Lungs**, disorders of, in chronic alcoholism, 608
 in the opium habit, 658
- Lupulin**, use of, in the opium habit, 676
- M.**
- Magnesium sulphate**, use of, in chronic lead-poisoning, 691
- Main en griffe** in chronic spinal pachymeningitis, 749
- Malaria** as a cause of cerebral anæmia, 790
 influence of, on the causation of chorea, 444
- Malarial epilepsy**, 472
 neuralgias, 1212
- Male sex**, prevalence of hysteria in, 215
- Malnutrition of brain in infants**, 778
- Malt liquors**, characters of intoxication from, 591
- Mammillary neuralgia**, 1235
- Mania**, 161
 chronic, 163
 following epilepsy, 482
 in alcoholism, 631
- Maniacal excitement in general paralysis of the insane**, 192
 form of acute alcoholism, 592
 of general paralysis of the insane, 188
- Marriage**, influence on recovery from epilepsy, 498
 question of, in the insane temperament, 115, 141
- Massage**, use of, in hemiplegia, 978
 in hysteria, 280
 in infantile spinal paralysis, 1157
 in lead palsy, 691
 in melancholia, 160
 in neuralgia, 1223
 in neurasthenia, 360, 361
 in progressive unilateral facial atrophy, 702
 in symmetrical gangrene, 1261
 in vaso-motor neuroses, 1255
 in writers' cramp, 536
- Mastoid cells**, inflammation of, as a cause of thrombosis of cerebral veins and sinuses, 985
- Masturbation**, influence on causation of cerebral anæmia, 778
 of epilepsy, 474
 of insanity, 119
 in the insane, treatment of, 137
 of hysteria, treatment of, 276
- Mechanical appliances**, use of, in infantile spinal paralysis, 1159
 in writers' cramp, 540
 restraint in treatment of the insane, 135, 136
- Medulla oblongata**, degeneration of, in labio-glossolaryngeal paralysis, 1172
 localization of lesions in, 79
- Medullary centres of the vaso-motor system**, 1250
- Megalopsia in nervous diseases**, 40
- Melancholia**, 155
 agitata, 158
 cerebral nutrition in, 775
 in alcoholism, 631
 in children, 158
 in general paralysis of the insane, 188
- Membranes**, spinal, congestion of, 746
- Memory**, loss of, significance of, in nervous diseases, 28-30
- Ménière's disease**, 422
- Meningeal cerebral hemorrhage**, 710
 Diagnosis, 714
 Etiology, 711
 Pathological anatomy, 713
 Prognosis, 715
 Symptoms, 712
 Synonyms, 710
 Treatment, 715
- Meningeal spinal hemorrhage**, 754
- Meningitis**, acute, 716
 and chronic, following thermic fever, 399
 spinal, 749
 chronic spinal, 752
- MENINGITIS, TUBERCULAR**, 723
 Definition, synonyms, and history, 723
 Diagnosis, 732
 from acute simple meningitis, 733
 from eclampsia, 734
 from gastro-intestinal affections, 734
 from hydrocephaloid disease, 734
 from typhoid fever, 733
- Etiology**, 724
 Age and sex, influence of, 725
 Exciting causes, 725
 Hereditary tendency to tuberculosis and scrofulosis, 724
 Season, influence of, 725
- Pathological anatomy and duration**, 729
- Prophylaxis**, 736
- Prognosis**, 735
- Symptoms**, 725
 Abdomen, state of, 726
 Cerebral, 726-729
 Constipation, 725-727, 729
 Cry, 726, 727
 Decubitus, 727
 Eyes, state of, 726-729

MENINGITIS, TUBERCULAR — Symptoms:

- Headache, 725-727
- in the adult, 737-739
- Paralysis and convulsions, 727, 728
- Prodromal, 725
- Pulse, respiration, and temperature, 726-728
- Pupils, state of, 726-729
- Sensitiveness to light, 725-727
- Strabismus, 727
- Stupor, 726-729
- Tongue, state of, 726, 729
- Vomiting, 725, 729
- Treatment, 735
 - Bromides, chloral, and hyoscyamus, 736
 - Counter-irritation, value of, 736
 - Diet in, 736
 - Iodide of potassium, use, 736
- Menorrhagia and amenorrhœa in the insane, treatment of, 136
- Menstrual disorders, influence on causation of hysteria, 220
- in the opium habit, 656, 658
- insanity, 173
- Menstruation, influence on recovery from epilepsy, 498
- on causation of cerebral hyperæmia, 766
- of spinal hyperæmia, 802
- painful, influence on causation of hystero-epilepsy, 293
- Mental condition in acute spinal meningitis, 750
 - in atrophy of the brain, 994, 996
 - in chorea, 445
 - in chronic hydrocephalus, 742, 743
 - in delirium tremens, 628
 - in disseminated spinal sclerosis, 877
 - in hemiplegia, 956
 - in hysteria, 230
 - in tabes dorsalis, 836
 - in tumors of the brain, 1037
 - of the spine, 1096
- Defects and degeneration, states of, 138
- Deterioration, primary, 70
- MENTAL DISEASES, 99**
 - Insanity, 99*
 - Causation, 113
 - Age, influence of, 116, 117
 - Alcohol and nerve-stimulants, abuse of, 116, 119
 - Drugs, abuse of, 119
 - Emotions and mental strain, 117, 118
 - Classification of, 105, 109
 - Definition of, 99-105
 - Diagnosis of, 123-125
 - Exciting causes, 118-120
 - Heredity, 113
 - Ill health, disease, etc., 116, 117, 119
 - Intermarriage, 115, 116
 - Occupation, 118
 - Pulmonary consumption, relation to, 119
 - Sex, 118
 - Social position, 117, 118
 - Vicious early training, 116
 - History, 109

MENTAL DISEASES—*Insanity*: Morbid anat-

- omy and pathology, 121-123
- Prevalence, 110-113
- Prognosis, 125
- Mortality, 125
- Percentage of recoveries, 126
- Treatment, 127
 - Asylums, methods of commitment to, 134
 - objection to, 127, 130
 - question of removal to, 127-135
 - Galvanism, use, 137
 - Home, removal from, question of, 128, 133, 135
 - Home, 131
 - Mechanical restraint in, 135, 136
 - Medicines, value of, in, 135
 - of cerebral hyperæmia in, 136
 - of constipation in, 137
 - of insomnia in, 137
 - of intercurrent diseases in, 136
 - of masturbation in, 137
 - of menorrhagia and amenorrhœa in, 136
 - Preventive, 137, 138
 - Rest and sleep, value of, in, 137
 - Sedatives and narcotics, use in, 133, 137
- Insanity complicating, 174*
- Insanity from Specific Poisons, 175*
- Organic, 176*
 - General paralysis of the insane, 176
 - Definition, 176
 - Diagnosis, 197
 - Etiology, 177
 - Age and sex, 177
 - Excesses, influence of, 177
 - Heredity, 177
 - Mental shock, 178
 - Syphilis, 178
- History, 176
- Morbid anatomy and pathology, 196
- Prognosis, 200
- Symptoms, 178
 - Delusions, characters, 187, 188, 190-192
 - Mental, 179, 190-193
 - Moral sense, perversion of, 190
 - of demented and paralytic form, 187
 - of hypochondriacal form, 188
 - Onset, mode of, 178
 - Physical symptoms, 193
 - Ataxia, 188, 189, 193
 - Bones, state, 196
 - Gait, 194
 - Handwriting, 183, 186, 193
 - Hyperæsthesiæ, 194
 - Knee-jerk, significance, 195
 - Pupils, state, 195
 - Remissions, 194
 - Sexual functions in, 195
 - Speech, alteration in, 194
 - Urine in, 1195
 - Prodromal, 178
 - Temperature in, 179
 - with melancholia, 188
 - with mania, 188

MENTAL DISEASES—*Organic*: Synonyms, 176

Treatment, 201

Cod-liver oil, use, 201

Ergot, use, 201

Hypophosphites, use, 201

Potassium bromide and iodide, use, 201

Rest and quiet, value, 201

Insanity, chronic alcoholic, 202

from gross lesions of brain, 202

secondary delusional, 203

Terminal dementia, 203

Treatment, 203, 204

States of Mental Defect and Degeneration, 138

Circular insanity, 151

Constitutional affective mental disease, 142

Prognosis, 142

Treatment, 143

Epileptic insanity, 149

Hypochondriacal insanity, 150

Hysterical insanity, 148, 149

Idiocy, 138

Classification, 139

Impulsive insanity, or instinctive monomania, 146

Dipsomania, 147

Erotomania, 147

Homicidal insanity, 147

Nymphomania and satyriasis, 147

Pyromania and kleptomania, 147

Treatment, 148

Suicidal insanity, 146

Insane temperament, 140

Treatment, 141

Moral insanity, 143

Symptoms, 143-146

Treatment, 146

Periodic insanity, 150

Primary insanity, 151

Prognosis and treatment, 152

Psycho-neuroses, 153

Affective mental disease, 153

Prognosis and treatment, 154

Climacteric insanity, 173

Delirium, acute, 163

Dementia, primary, 164

secondary, 165

Treatment, 165

Doubting insanity, 170

Hebephrenia, 171

Treatment, 172

Hypochondriasis, 154

Prognosis and treatment, 155

Insanity of childhood, 171

Katatonía, 166

Mania, 161

acute, 161

Treatment, 161

simple, 162

Treatment, 162

Melancholia, 155

Agitata, 158

Duration and prognosis, 159

in children, 158

MENTAL DISEASES—*Psycho-neuroses*: Melancholia, simple, 155

Treatment, 159

Asylums, removal to, 159

Narcotics and sedatives, use, 160

Tonics, use, 160

with delusions, 156

with stupor, 158

Menstrual insanity, 173

Primary confusional insanity, 167

Primary delusional insanity, 167

Primary mental deterioration or brain atrophy, 170

Puerperal insanity, 173

Senile dementia, 174

insanity, 173

Transitory insanity, 164

Mental emotion, influence on causation of neurasthenia, 354

influences as a cause of cerebral anæmia, 780

shocks, influence on causation of general paralysis of the insane, 178

strain, influence on causation of insanity, 118

symptoms of external pachymeningitis, 705

of general paralysis of the insane, 190

Mercurial tremor, 429

Mercury, use of, in cerebral hyperæmia, 1016

in chronic spinal meningitis, 754

in hæmatoma of the dura mater, 710

in spinal sclerosis, 900

in tetanus, 555

in tubercular meningitis, 736

Metallic salts, use, in catalepsy, 338

in labio-glosso-laryngeal paralysis, 1175

in progressive unilateral facial atrophy, 702

Metallo-therapy, use, in hysteria, 284

in hystero-epilepsy, 313

Metastasis as a cause of cerebral abscess, 796

Microcephalism, 138

Migraine, 406, 1216, 1230

Diagnosis and prognosis, 410

Etiology, 406

Age and sex, influence of, 406

Heredity, influence of, 407

Pathology and morbid anatomy, 410-413

Symptoms, 407

Circulation, disorders of, 409

Digestive, 409

Pain, seat and character, 408

Paroxysms, characters of, 408, 409

Synonyms, 406

Treatment, 413

Bromides, use, 414, 415

Caffeine and guarana, use, 414

Cannabis indica, use, 413, 415

Climate, change of, 413

Ergot, use, 413, 414

Galvanism, use, 414, 415

in childhood, 415

- Migraine—Treatment: Indications for, 413
 Morphia, use, 415
 Muriate of ammonium and chloral, use, 415
 Nitrite of amyl and nitro-glycerin, 414
 Quinia, use, 414
 Miliary aneurisms, relation of, to cerebral form of encephalitis, 792
 hemorrhage, 921-923
 tubercles in tubercular meningitis, seat and character, 730, 732
 Mimicry in hysteria, 251, 255, 270-272
 Mind-cure in hysteria, 277
 Miryachit, the, hysterical nature of, 228
 Mitchell's rest-cure in hysteria, 279
 in neurasthenia, 358-362
 Monoplegia, hysterical, 238
 in nervous diseases, 44
 Monospasm in nervous diseases, 46
 Moral insanity, 143
 management of spinal sclerosis, 906
 sense, deterioration of, in chronic alcoholism, 624
 treatment of hysteria, 276
 Morbid anatomy of abscess of the brain, 792
 of acute simple meningitis, 719
 of acute spinal meningitis, 750
 of acute spinal myelitis, 812
 of amyotrophic lateral sclerosis, 867
 of cerebral anæmia, 781
 of cerebral hemorrhage, 919-927
 of cerebral hyperæmia, 767
 of cerebral meningeal hemorrhage, 713
 of chorea, 450
 of chronic spinal meningitis, 762
 of chronic spinal pachymeningitis, 748
 of congestion of cerebral pia mater, 716
 of congestion of spinal membranes, 747
 of delusional insanity, 169
 of diffuse sclerosis, 886
 of disseminated sclerosis, 874, 880-883
 of external pachymeningitis, 705
 of family form of tabes dorsalis, 872
 of infantile spinal paralysis, 1132
 of insanity, 121
 of internal pachymeningitis, 706
 of neuritis, 1190
 of paralysis agitans, 433
 of secondary sclerosis, 893
 of spastic spinal paralysis, 865
 of spina bifida, 759
 of spinal meningeal hemorrhage, 755
 of tabes dorsalis, 840
 of tetanus, 549
 of tubercular meningitis, 729
 Morbid anatomy and pathology of chronic lead-poisoning, 689
 of epilepsy, 488
 of writers' cramp, 526
 Morbid somnolence, 344
 Morphia, use, in acute simple meningitis, 721
 in cerebral anæmia, 788
 in hysteria, 276
 in migraine, 415
 in multiple neuritis, 1198
 Morphia, use, in neuritis, 1194
 in spinal sclerosis, 905
 in thermic fever, 398, 399
 in the treatment of the opium habit, 673, 675
 in tumors of the brain, 1068
 in vertigo, 427
 Morphœa, in progressive unilateral facial atrophy, 695
 Morphine habit, 647
 Mortality of chorea, 454
 of insanity, 125, 126
 of tetanus, 553
 Motility, disturbances of, in spinal syphilis, 1025
 Motion, disorders of, in chorea, 445, 446
 in chronic alcoholism, 620
 in diffuse spinal sclerosis, 888
 Motor paralysis in unilateral paralysis of spinal cord, 1166
 Motor symptoms of thermic fever, 391
 weakness, in spinal hyperæmia, 803
 Motory symptoms of nervous diseases, 42
 Multiple and multiple degenerative neuritis, 1195
 Diagnosis, 1197
 Etiology, 1197
 Nature and history, 1195
 Pathology, 1196
 Prognosis, 1198
 Symptoms, 1195
 Onset, 1195
 Pain, characters, 1195
 Paresis and atrophy of muscles, 1196
 Sensation, disturbances of, 1195
 Treatment, 1198
 Electricity, 1198
 Morphia, 1198
 Salicylate of sodium and iodide of potassium, 1198
 Rest, 1198
 Multiple cerebro-spinal sclerosis, 873
 Muscles, atrophy of, 1267
 changes in, in alcoholism, 614
 in injuries to peripheral nerves, 1182
 degeneration of, in labio-glosso-laryngeal paralysis, 1173
 employed in telegraphy, 508, 509
 in writing, 505, 506
 involved in infantile spinal paralysis, 1121
 rigidity of, in paralysis agitans, 435
 Muscular ataxia, in general paralysis of the insane, 188, 189, 193
 atrophy in chronic spinal pachymeningitis, 749
 in nervous diseases, 54
 in poisoning by lead, 687, 688
 in progressive unilateral facial atrophy, 696, 697
 progressive, complicated with infantile spinal paralysis, 1149
 contraction, in acute spinal meningitis, 750
 system, state of, in the chloral habit, 662
 rigidity in diffuse spinal sclerosis, 888
 Music, use of, in treatment of catalepsy, 338

Musk, use of, in hysteria, 274
 Murmurs, valvular, in chorea, 448
 Myelitis, simple acute, 810
 Ascending and descending, 816
 Clinical history, 816
 Diagnosis, 820
 Influence of poisons on cord, 815
 Limitation of inflammatory process, 816
 Myelitic cicatrices, 815
 Morbid anatomy, 812
 Prognosis and duration, 821
 Treatment, 822
 Derivation and bloodletting, 823
 Electricity, 824
 Management of bed-sores, 823
 Management of bladder troubles, 824
 Position, 822
 Rest, 823
 Strychnia, 823
 Warm baths, 823
 Myelitis, chronic, 886
 in unilateral spinal paralysis, 1168
 Myxœdema, 1271

N.

Narcolepsy, 346
 Narcotic poisoning, acute, from alcohol, 597
 Narcotics, influence on causation of catalepsy, 319
 Narcotics and sedatives, value, in melancholia, 160
 Nature of stigmata, 350
 of symmetrical gangrene, 1261
 Nausea and vomiting in lead colic, 684
 in the opium habit, 653, 657-659
 Neglect, treatment of hysteria by, 277
 Nerve-centres, syphilitic affections of, 999
 Nerve-roots, degeneration of, in infantile spinal paralysis, 1138-1140
 lesions of, in tabes dorsalis, 840-842
 Nerve-section in neuralgia, 1227
 in tetanus, 560
 Nerve-stretching in athetosis, 460
 in neuralgia, 1228
 in spinal sclerosis, 903
 in writers' cramp, 538
 Nerve-trunks, lesions, in multiple neuritis, 1196
 in neuritis, 1191
 Nerves, inflammation of, 1189
 Anatomical changes in divided nerves and muscles, 1184
 Changes in, in chronic alcoholism, 619
 Diagnosis of, 1187
 Divided, pain, seat and characters of, 1185-1187
 Electrical reactions in, 1184, 1188
 Immediate results of injuries to, 1182
 Injuries and irritation of, as a cause of neuralgia, 1220
 treatment of, 1189
 Lesions of, in neuralgia, 1221
 Peripheral diseases of, 1177
 Changes in, in chronic alcoholism, 619
 Injuries of, 1182

Nerves—Regeneration and reunion of divided nerves and muscles, 1185
 Sensation, disorders of, 1186, 1187
 Skin, state of, 1183, 1187
 Symptoms of incomplete destruction of, 1185
 Trophic disorders, 1187
 Vaso-motor, origin of, 1246
 Nervous diseases, general semeiology of, 19
 disorders of chronic hydrocephalus, 743
 of chronic lead-poisoning, 635-689
 of spina bifida, 759
 of the chloral habit, 663, 665
 symptoms of myxœdema, 1272
 system, disorders of, in alcoholism, 616
 in the opium habit, 656, 658, 659
 NERVOUS SYSTEM, LOCALIZATION OF LESIONS IN THE, 65
 Cranio-cerebral topography, 93-98
 in encephalic mass, 81-93
 in systematic lesions, 89
 in focal lesions, 89
 in base of brain, 91
 in cerebellum, 90
 in medulla oblongata, 79, 80
 in peripheral nervous system, 65-69
 in spinal cord, 69-79
 of aesthesodic system, 69
 of kinesodic system, 71
 NERVOUS SYSTEM, GENERAL SEMEIOLOGY OF DISEASES OF, 19
 Motory symptoms, 42-54
 Psychic symptoms, 19-31
 Sensory symptoms, 31-41
 Trophic symptoms, 54-59
 Principles of diagnosis in diseases of, 59
 in functional diseases of, 63
 in organic diseases of, 61
 NEURALGIA, 1211
 Definition, general, of, 1211
 Diagnosis and pathology, general, of, 1221
 Etiology, general, of, 1216
 Age and sex, 1217
 Atmospheric and thermic influences, 1219
 Constitutional diseases, 1217
 Injuries and irritation of nerves, 1219
 Reflex and sympathetic causes, 1220
 Symptomatology, general, 1211
 of migraine, 1216-1230
 of superficial neuralgias, 1211
 Muscles, spasm and atrophy of, 1213, 1214
 Pain, characters and distribution, 1212
 Periodicity of attacks, 1212
 Points douloureux, 1213
 Secreting organs, disorders of, 1213
 Sensation, altered, 1214
 Skin, disorders of, 1212-1214
 Special senses in, 1213
 Urine, condition, 1212, 1213
 Vision, disorders of, 1213
 of visceral neuralgias, 1215
 Pain, characters, 1215
 Secretion of visceral organs, disorders of, 1215

NEURALGIA—Treatment, general, 1222

- Aconite and aconitia, use, 1224, 1225, 1227
- Belladonna and atropia, use, 1224
- Change of climate, 1223
- Cocaine, use, 1227
- Counter-irritation, use, 1226
- Diet, 1223
- Electricity, use, 1225
- Hydrophathy, 1226
- Hygiene, 1223
- Injection of water, chloroform, and other substances, 1229
- Iron, arsenic, and cod-liver oil, use, 1224
- Massage, 1223, 1229
- Neurectomy, 1227
- Nerve-stretching, 1228
- Opium, use, 1224
- Phosphorus and gelsemium, use, 1225
- Turpentine, oil of, use, 1229
- Use of ammonio-sulphate of copper, salicylate of sodium, tonka, caffeine, and sal ammoniac, 1229
- Varieties, migraine and periodical headache, 1230
 - Etiology and clinical relations, 1231
 - Age and sex, 1230, 1231
 - Prognosis, 1231
 - Symptoms, 1230
 - Auras and visual hallucinations, 1230, 1231
 - Sensation, disorders of, 1230, 1231
 - Pain, 1230
 - Treatment of, 1232
 - Cannabis indica, iodide and bromide of potassium, and caffeine, 1232
 - Diet, 1232
 - Electricity, 1232
 - Nitrite of amyl, 1232
- Neuralgias of the fifth nerve, 1232
 - Anal and rectal neuralgia and uterine and ovarian neuralgia, 1240
 - Angina pectoris, 1237
 - Cervico-brachial and brachial neuralgia, 1234
 - Epileptiform, or tic douloureux, 1233
 - Facial neuralgia, ordinary, 1232
 - Treatment, 1234
 - Gastralgia, 1238
 - Intercostal neuralgia, 1234
 - Intermittent neuralgia of the supra-orbital, 1233
 - Lumbo-abdominal neuralgia, 1235
 - Mamillary neuralgia (irritable breast of Astley Cooper), 1235
 - Occipito and cervico-occipital neuralgias, 1234
 - Sciatica, 1235
 - Treatment, 1236
 - Visceral neuralgia, 1237
- Neuralgia complicating progressive unilateral facial atrophy, 699
- Neuralgias in tumors of the brain, 1041
- Neuralgic pains in hemiplegia, 956
- NEURASTHENIA, definition, 353
 - Etiology, 354

NEURASTHENIA—Symptoms, 354

- Digestive disorders, 356
- Heart disorders, 356
- Muscular strength, loss of, 356
- of brain exhaustion, 355
- Sensation and special senses, disturbances of, 356, 357
- Sexual disorders, 357
- Vaso-motor disturbances, 356
- Treatment, 357
 - Change of climate, 358
 - Rest-cure, method of carrying out, 358, 362
- Neurasthenia as a cause of vertigo, 425
- Neurasthenic headache, 404
- Neuritis, 1189
 - Etiology, 1190
 - Diagnosis, 1194
 - Morbid anatomy, 1190
 - Symptoms, 1191
 - Motor, 1192

 atrophy of, v. 993
 hypertrophy of, v. 996
 inflammation of, v. 790
 softening of, v. 989
 syphilis of, v. 1003, 1017
 and its Envelopes, Tumors of, v. 1028
 Spinal Cord, Concussion of, v. 907
 Diseases of Membranes of, v. 703
 Hyperæmia and Anæmia of, v. 763, 774
 Bright's disease, iv. 72
 Bromidrosis, iv. 584
 Bronchi, Diseases of, iii. 164

Bronchial Asthma, iii. 184
 tubes, dilatation of, iii. 227
 Bronchitis, acute and chronic, capillary,
 mechanical, pseudo-membranous, and
 rheumatic, iii. 169, 170, 171, 172, 173,
 174

C.

Caisson Disease, the, iii. 855
 Calculi, hepatic, ii. 1058
 renal, iv. 42
 Callositas, iv. 662
 Cancrum oris, ii. 338
 Canities, iv. 678
 Cannabis indica, habitual addiction to, v.
 669
 Carbuncles, iv. 606
 Cardiac murmurs and their relation to val-
 vular heart disease, iii. 651
 Cardiac Thrombosis, iii. 718
 Cardialgia, ii. 459
 Cardicentesis, iii. 798
 Caruncle, urethral, iv. 403
 Catalëpsy, v. 314
 Cerebral arteries, atheroma, v. 991
 meningeal hemorrhage, v. 710
 paralysis, v. 917
 veins and sinuses, thrombosis of, v. 982
 vessels, occlusion of, v. 917, 946
 Cervical sympathetic, diseases of, v. 1263
 Cestodes or tape-worms, ii. 931
 Chloasma, iv. 659
 Chloral habit, the, v. 660
 Chloroform, habitual addiction to, v. 667
 Chlorosis, iii. 894
 Cholera, i. 715
 infantum, ii. 741
 morbus, ii. 719
 Chorea, v. 439
 of the larynx, iii. 76
 Chromidrosis, iv. 585
 Chyluria, iv. 114
 Cimex lectularius, iv. 733
 Circulatory System, Diseases of, iii. 599
 Clavus, iv. 663
 Cocaine, habitual addiction to, v. 667
 Coeliac axis, diseases of, iii. 841
 Colic, hepatic, ii. 1058
 intestinal, ii. 658
 renal, iv. 42
 Coma, v. 26, 382
 Comedo, iv. 589
 Constipation, ii. 638, 650
 Convulsive disorders, local, v. 461
 Copodyscinesia, v. 504
 Corns, iv. 663
 Cornu cutaneum, iv. 663
 Coronary artery, diseases of, iii. 828
 Coryza, iii. 41
 Cough, nervous, iii. 71
 Cranio-cerebral topography, v. 93
 Cretinism, v. 138
 Croup, spasmodic or false, iii. 70, 92
 true, iii. 100
 Culex, iv. 733
 Cyanosis and Congenital Anomalies of

Heart and Great Vessels, iii. 687,
 712
 Cysticercus cellulosaë, iv. 732
 Cystitis, acute and chronic, iv. 126, 128
 in women, iv. 341

D.

Deaf-mutism, iv. 840
 Deafness after cerebro-spinal meningitis,
 mumps, scarlet fever, etc., iv. 839
 Death, apparent, v. 385
 Degenerations, i. 72
 Dementia, v. 164
 Demodex folliculorum, iv. 732
 Dengue, i. 879
 Dentition, morbid, ii. 371
 Dermatalgia, iv. 711
 Dermatitis, iv. 600, 604, 611, 623
 Dermatology, iv. 675
 Dermoid cyst of the ovary, iv. 299
 Diabetes insipidus, iv. 27
 Mellitus, ii. 195
 Diagnosis, general, i. 148
 Digestive System, Diseases of, ii. 319
 Diphtheria, i. 656
 Disease, causes and prevention of, i. 175
 Diseases, General, i. 229
 Distomum hepaticum, ii. 1109
 Drainage and Sewerage in their Hygienic
 Relations, i. 213
 Dreams, v. 368
 Ductus communis choledochus, occlusion of,
 ii. 1082
 Dura mater, cerebral, congestion of, v. 704
 Dysentery, ii. 777
 Dyslalia, v. 571
 Dysmenorrhœa, iv. 192
 Dyspepsia, functional and atonic, ii. 436

E.

Ear, internal, diseases of, iv. 835
 middle, diseases of, iv. 817
 Echinococcus of the liver, ii. 1101
 Eclampsia, v. 464
 Ecstasy, v. 339
 Ecthyma, iv. 653
 Eczema, iv. 625
 marginatum, iv. 718
 Effusions, i. 67
 Elephantiasis, iv. 675
 Embolism and Thrombosis, i. 56
 of the spinal cord, v. 808
 capillary, cerebral, v. 979
 Emphysema, iii. 233, 249
 Endocarditis, iii. 639, 640, 642, 643
 Endometritis, acute and chronic, iv. 460,
 462
 Enteralgia, ii. 658
 Enteritis, Pseudo-membranous, ii. 763
 Entero-colitis, ii. 726
 Epilepsy, v. 468
 Epiglottitis, inflammation and erosion of, iii.
 109
 Epithelioma, iv. 707
 Epistaxis, iii. 50

Erythema, iv. 593, 595, 596
 Erysipelas, i. 629
 Ether, habitual addiction to, v. 667
 Etiology, general, i. 125
 Eye affections, from diseases of the digestive organs, iv. 749
 diseases of the kidneys and skin, iv. 752
 general system, iv. 800
 nervous system, iv. 771, 796, 797, 799
 respiratory organs, iv. 748
 sexual organs, iv. 755
 spinal cord, iv. 792
 mental affections, iv. 791
 Eye-ground and appendages, changes in, from diseases of the circulatory apparatus, iv. 738

F.

Facial atrophy, progressive unilateral, v. 694
 nerve, peripheral paralysis of, v. 1202
 spasm, painless, v. 462
 Fallopian tubes, dropsy of, iv. 295
 Farcy, i. 909
 Favus, iv. 715
 Fibroma, iv. 686
 Filaria medinensis, iv. 732
 Fistulo in ano, ii. 897
 Flea, common, iv. 733
 Flea, sand-, iv. 732
 Fluke-worms, iii. 946
 Furunculus, iv. 604
 of external auditory canal, iv. 813
 of labia, iv. 362

G.

Gad-fly, iv. 732
 Gall-stones, ii. 1058
 Gangrene, symmetrical, v. 1257
 Gastralgia, ii. 459, v. 1238
 Gastric catarrh, acute and chronic, ii. 463, 470
 Gastritis, acute and chronic, ii. 463, 470
 Gastromalacia, ii. 618
 Gastrorrhagia, ii. 580
 Genito-urinary System, Diseases of, iv. 17
 Glanders, i. 909
 Glossanthrax, ii. 368
 Glossitis, acute, ii. 354-366
 chronic, ii. 366-368
 Glottis, œdema of, iii. 112
 spasm of, in adults, iii. 74
 Glycosuria, hepatic, ii. 973
 Gnats, iv. 733
 Goitre, iii. 974
 exophthalmic, iii. 761
 Gout, ii. 108
 Graves' disease, iii. 761
 Great Vessels and Heart, Congenital Anomalies of, iii. 687
 Guinea-worm, iv. 732

H.

Hæmatoma of the dura mater, v. 707
 Hæmaturia, iv. 104

Hæmoglobinuria or Hæmatinuria, iv. 104
 Hæmopericardium, iii. 788
 Hæmophilia, iii. 931
 Hæmoptysis, iii. 266
 Hæmothorax, iii. 582
 Hair, atrophy of, iv. 682
 blanching of, iv. 678
 Harvest mite, iv. 731
 Hay Asthma, iii. 210
 Headache, v. 402, 1216, 1230
 Heart, adventitious products of, iii. 637
 aneurism of, iii. 636
 atrophy of, iii. 618
 dilatation of, iii. 630
 diseases of substance of, iii. 601
 fibroid, iii. 607
 hypertrophy of, iii. 619
 malformations of, affecting primarily left side of, iii. 707
 malformations of, affecting primarily right side of, iii. 702
 malpositions of, iii. 601
 murmurs, iii. 651
 neuroses of, iii. 747
 spontaneous rupture of, iii. 617
 Valvular Diseases of, iii. 639
 and Great Vessels, Congenital Anomalies of, iii. 687
 clot, iii. 718
 muscle, degeneration of, iii. 609
 Heart's action, functional disorders of, iii. 747
 Heat, Acute Affections produced by, v. 387
 Hemorrhoids, ii. 882
 Hepar adiposum, ii. 1046
 Hepatic artery, aneurism of, iii. 840
 calculi, ii. 1058
 colic, ii. 1058
 glycosuria, ii. 973
 Hepatitis, interstitial, ii. 990
 suppurative, ii. 1002
 Hernia, cysto-vaginal, iv. 377
 pudendal, iv. 398
 recto-vaginal and entero-vaginal, iv. 378
 Herpes iris, iv. 609
 simplex, iv. 607
 zoster, iv. 610
 Hirsuties, iv. 669
 Hodgkin's disease, iii. 921
 Hydatid tape-worm, ii. 943
 Hydatids of liver, ii. 1101
 pulmonary, iii. 466
 Hydrocele or cyst of the canal of Nuck, iv. 397
 Hydrocephalus, chronic, v. 704
 Hydro-nephrosis, iv. 56
 Hydro-pericardium, iii. 789
 Hydrophobia and Rabies, i. 886
 Hydrothorax, iii. 570
 Hygiene, i. 173
 Hymen, atresia of, iv. 374
 Hyperidrosis, iv. 583
 Hypertrichosis, iv. 669
 Hypertrophy, v. 1271
 Hypnotism, v. 373
 Hypochondriasis, v. 154
 Hypostatic Pneumonia, iii. 258

Hysteria, v. 205
 Hystero-epilepsy, v. 288

I.

Ichthyosis, iv. 666
 Icterus, ii. 975
 Idiocy, v. 138
 Imbecility, intellectual, v. 138
 Impetigo, v. 651, 652
 Indigestion, ii. 436
 intestinal, ii. 620
 Infantile Spinal Paralysis, v. 1113
 Inflammation, i. 37; v. 1273
 Influenza, i. 851
 Insanity, v. 99
 from gross lesions of the brain, v. 202
 specific poisons, v. 175
 Insanities, complicating, v. 174
 Insomnia, v. 379
 Intercranial hemorrhage, etc., v. 917
 Intermittent fever, i. 592
 Intestinal Affections of Children in Hot
 Weather, ii. 726
 catarrh, acute, ii. 667
 chronic, ii. 699
 colic, ii. 658
 indigestion, ii. 620
 obstruction, ii. 830
 ulcer, ii. 823
 worms, ii. 930
 Intestines, Cancer of, ii. 868
 Lardaceous Degeneration of, ii. 874
 Intussusception and invagination, ii. 844
 Ixodes, iv. 733

J.

Jaundice, ii. 925

K.

Katatonia, v. 166
 Keloid, iv. 685
 Keratosis pilaris, iv. 660
 Kidneys, abnormalities of, in shape, size,
 position, etc., iv. 19
 Bright's disease of, iv. 72
 chronic congestion of, iv. 69
 cysts of, iv. 63
 diseases of parenchyma of, iv. 69
 floating, iv. 21
 malignant growths of, iv. 60
 parasites and tuberculosis of, iv. 64
 and Pelvis, Diseases of, iv. 19
 Kleptomania, v. 147

L.

Labia, furuncles of, iv. 362
 majora, phlegmonous inflammation of, iv.
 391
 Labio-glosso-laryngeal Paralysis, Progres-
 sive, v. 1169
 Laryngismus stridulus, iii. 70
 Laryngitis, Acute Catarrhal (False Croup),
 iii. 92

Laryngitis, chronic, iii. 121
 Pseudo-membranous (True Croup), iii.
 100
 Laryngoscopy and Rhinoscopy, iii. 19
 Larynx, anæsthesia of, iii. 65
 chorea of, iii. 76
 Diseases of, iii. 109
 disorders of motion of, iii. 69
 hyperæsthesia of, iii. 62
 morbid growths of, iii. 127
 neuroses of, iii. 59
 oedema of, iii. 112
 paræsthesia of, iii. 63
 paralysis and paresis of, iii. 78
 perichondritis and chondritis of, iii. 117
 spasm of, in children, iii. 70
 Lead-poisoning, Chronic, v. 678
 Lentigo, iv. 658
 Leprosy, i. 785
 Leptomeningitis, v. 716
 Leptus, iv. 731
 Lethargy, v. 384
 Leucoderma, iii. 908
 Leukæmia, iv. 697
 Lichen ruber and scrofulosus, iv. 623, 624
 Lithæmia, ii. 968
 Liver, abscess of, ii. 1002
 acute yellow atrophy of, ii. 1023
 amyloid, ii. 1040
 carcinoma of, ii. 1033
 cirrhosis of, ii. 990
 Diseases of, ii. 965
 fatty degeneration of, ii. 1046
 flukes, ii. 1109
 hyperæmia of, ii. 982
 parasites of, ii. 1101
 the, in phosphorus-poisoning, ii. 1030
 Localization of Lesions in the Nervous Sys-
 tem, v. 65
 Lung, Abscess of, iii. 296
 brown induration of, iii. 256
 cancer of, iii. 460
 cirrhosis of, iii. 440
 collapse of, iii. 251
